DECLARATION OF JOHN W. BICKHAM

I, John W. Bickham, Ph.D., declare as follows:

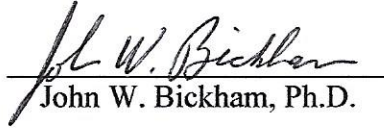

1. I am a geneticist specializing in the genetics of natural populations of fish and wildlife and a professor emeritus in the Department of Wildlife & Fisheries Sciences at Texas A&M University. I am under contract with the Tribe's legal counsel to provide expert testimony and testimony based on my personal knowledge of the International Whaling Commission's review of the Tribe's proposed hunt in this matter. My address is 31526 Lower Oxbow Trace, Fulshear, TX 77441.
2. For purposes of this hearing, I prepared and hereby incorporate the attached report and supporting exhibits as my written direct testimony.
3. The attached report includes: (1) expert opinions developed through my education, experience, research, and knowledge of genetics of natural fish and wildlife populations and of gray whales (and other marine mammals) in particular; and (2) testimony based on my personal knowledge of the proceedings of the International Whaling Commission regarding the Tribe's proposed hunt. My qualifications to testify as an expert are described in further detail at the beginning of the attached report.
4. The attached report provides factual and scientific information (and my expert opinion regarding such information) which, as qualified below, supports NMFS's proposed

waiver and regulations that would, in addition to tribal management measures, govern a ceremonial and subsistence hunt of gray whales from the Eastern North Pacific stock under the Tribe's treaty-reserved right.

5. I have reviewed NMFS's published issues for the hearing, *i.e.*, the "Issues that May be Involved in the Hearing," 84 Fed. Reg. 13639, 13641-43 (Apr. 5, 2019). As I describe in the attached report, I have concerns about some of the direct testimony NMFS has submitted in this matter and believe there is additional scientific information available that supports the proposed waiver and regulations. However, in general, as NMFS's proposed issues of fact relate to my testimony, I agree with the issues presented and support the waiver and regulations NMFS has proposed. The Makah Tribe has prepared and is submitting today a document entitled Makah Tribe's Position Regarding NMFS' Proposed Issues of Fact. The document identifies specific objections I have to certain issues presented by NMFS (or in some cases, that I have no comment), and I hereby adopt and incorporate those objections as a part of my written direct testimony.

6. The attached report provides support for additional issues of fact for the hearing. The Makah Tribe has prepared and is submitting today a document entitled Makah Tribe's Proposed Issues of Fact. The document identifies additional issues of fact for the hearing based on my attached report and I hereby adopt and incorporate those issues as part of my written direct testimony.

I declare, under penalty of perjury under the laws of the United States, that the foregoing (and the attached report) is true and correct to the best of my knowledge, information and belief.

John W. Bickham, Ph.D.

Dated: May 17, 2019

Testimony of John W. Bickham

Background, Qualifications and Experience of John W. Bickham, Ph.D: I am Professor Emeritus at Texas A&M University, in the Department of Wildlife and Fisheries Sciences, where I served on the faculty for 30 years (1976 to 2006). I also served on the Faculty at Purdue University in the Department of Forestry and Natural Resources and as Director of the Center for the Environment (2006 to 2012) and was a senior scientist at Battelle Memorial Institute from 2012 to 2016. I presently conduct research as a private contractor to Exxon and the North Slope Borough (NSB). Since 2003, I have served as a member of the U.S. delegation to the International Whaling Commission (IWC) Scientific Committee (SC), as well as a member of the NSB's bowhead whale research team. Since 2011, I have studied gray whales as part of the Joint Program for the Okhotsk-Korean Gray Whale Population Monitoring off the North-East Coast of Sakhalin Island funded by Exxon and Shell and as a consultant to the Makah Tribe on issues related to stock structure. My areas of expertise include genetics (cytogenetics, population and evolutionary genetics, genomics, genetic ecotoxicology, and evolutionary toxicology) of natural populations of fish and wildlife. I have studied a variety of marine mammals including Steller sea lions, bowhead whales and gray whales and I have published more than 240 papers in the peer reviewed literature. I recently (2010) co-edited a book *Molecular Approaches in Natural Resource Conservation and Management*. Recent publications on whales include descriptions of the bowhead whale genome and transcriptome, and the genome sequence of the gray whale. My CV is attached (Ex. M-0401).

Executive Summary: In this testimony I focus on issues of population structure of North Pacific gray whales (*Eschrichtius robustus*) as they relate to the proposed Makah Tribe hunt and its request for a waiver under the Marine Mammal Protection Act (MMPA). The eastern gray whale (EGW) population targeted by the hunt is robust, being comprised of nearly 27,000 whales, and the number of whales requested to be taken is small. Nonetheless, there are two small populations called the western gray whale (WGW) and the Pacific Coast Feeding Group (PCFG), some members of which have been observed within the area of the hunt. Inadvertent takes of WGW or PCFG whales could have significant conservation implications depending on the number of takes and the status (feeding group, breeding stock) of these populations.

My testimony does not focus on the potential number of takes of either WGW or PCFG whales in the Makah hunt. The National Marine Fisheries Service (NMFS) is proposing to regulate the Makah hunt to protect these whales. Under NMFS's proposed regulations, the likelihood that a Makah hunter would strike a WGW is extremely small; moreover, the hunt would be suspended in the event such a strike is confirmed. There is a greater likelihood that a Makah hunter would strike a PCFG whale than a WGW whale. NMFS's proposed regulations, however, carefully limit the number of PCFG whales that may be struck and require a minimum abundance of PCFG whales before the hunt can take place in any year. While these proposed regulations appear quite conservative to me, it is not the purpose of my testimony to evaluate these measures.

Instead, I provide background information on the stock definition of the WGW and PCFG, including primarily a review of the genetics data, and I attempt to explain the degree of uncertainty that exists regarding the stock structure hypotheses related to these groups. I first provide background on gray whales, including separate discussions of the WGW and the EGW, including the PCFG. In this discussion, it is important to distinguish current and historical populations because there is an important question

whether the current WGW population is a remnant of the historical WGW population. I then discuss the Rangewide Review of the Population Structure and Status of the North Pacific Gray Whale, which was recently completed by the IWC. The Rangewide Review provides the best general assessment of the stock status of gray whales based on currently available scientific information and includes 6 stock structure hypotheses that are considered plausible and are being used to model the population dynamics of gray whales. In my testimony, I explain these hypotheses and provide my opinion as to which hypothesis(es) are most plausible given the scientific data.

According to the International Union for Conservation of Nature (IUCN), the current WGW population is a small population that summers in the Sea of Okhotsk, mainly around Sakhalin Island with occasional observations on the east coast of the Kamchatka Peninsula and the northern Sea of Okhotsk, and winters somewhere in Asia. Until recently, the IUCN considered the current WGW population to be critically endangered and assumed that it is the remnant population of the historical WGW stock that was hunted to apparent extinction primarily by Japanese and Korean whalers in the early 20th Century. This assumption was supported by studies showing the current WGW population is genetically distinct by mitochondrial DNA (mtDNA) and microsatellites from samples of EGWs and occupies the feeding grounds of the historical WGW in the Sea of Okhotsk located between Sakhalin Island and the Kamchatka Peninsula (Ex. M-0444 (Lang et al., 2010b)); (Ex. M-0447 (LeDuc et al., 2002)).

In 2018 the summary and description of the WGW at the IUCN web site were updated (<https://www.iucnredlist.org/species/8099/50345475#population>) to include recent studies using satellite telemetry, genetics and photographic identification which have revealed that many or all the current WGWs migrate to Mexico and overwinter with the EGWs. Although the historical WGW wintering grounds and migratory routes are poorly known, the latter includes the east and west coasts of Japan and the coast of China. Whaling took place near Ulsan, Korea where there were two peak whaling seasons suggestive of a north bound and south bound migration. The wintering grounds were possibly near Hainan Island (Ex. M-0418 (Cooke et al., 2018)).

And, while some analyses using preliminary data based on genomics and nuclear single-nucleotide polymorphism (SNP) data support the differentiation of the current WGWs and EGWs, other analyses using these data fail to support this differentiation. Therefore, uncertainty exists regarding the true identity of these whales.

In the Rangewide Review, several different stock structure hypotheses are considered plausible. Two of these, 3a and 5a, are considered most plausible and are serving as the base models for evaluations of the status of gray whales in the Pacific Ocean, with other plausible hypotheses to be used as sensitivity tests. Considering the available information, uncertainty exists with regard to the status of the current WGW population. A spectrum of possibilities exists ranging from the current WGW population being a distinct stock comprising descendants of the historical WGW population thought previously to be extinct, to a small group of EGWs that might be defined as a feeding group, with several intermediate possibilities. Furthermore, under 5 of the 6 hypotheses considered plausible in the Rangewide Review, the portion of the current WGW population that migrates through the area of the Makah hunt is part of a western feeding group of the eastern gray whale breeding population. Under the sixth hypothesis (6b), which I do not consider the most likely to be correct, the portion of the current WGW population that migrates through the area of the Makah hunt is part of a western breeding stock which does not

resemble the conventional hypothesis of a separate western breeding population. That is, it does not show affinity to the Asian wintering ground but rather winters in both Asia and Mexico.

My opinion is that gray whales that feed in the Sea of Okhotsk and migrate to North America are not a stock descended from the historical WGW, as defined by the IUCN, but may be a population stock as that term is used under the MMPA, composed of somewhat isolated EGWs.

The population status of the PCFG is, in my opinion, much more straight-forward. The genetics data, as well as our understanding of the movements and behavior of gray whales, supports the PCFG as being a feeding group of the eastern gray whale breeding population and not a biological population or population stock as defined in the MMPA. There is no convincing evidence to suggest that the PCFG is an interbreeding population.

Introduction: The gray whale (*Eschrichtius robustus*) was once distributed in both the North Pacific and North Atlantic Oceans but was extirpated from the Atlantic by the early 1700s (Ex. M-0449 (Mead and Mitchell, 1984)). Gray whales in the North Pacific Ocean are found on both the eastern and western margins (Ex. M-0404 (Andrews, 1914); Ex. M-0460 (Rice and Wolman, 1971)). Conventional wisdom held that there were two populations or stocks. One population of gray whales wintered in the subtropical waters of Baja California, Mexico and migrated along the continental shelf of western North America to and from their summer feeding habitats in coastal waters of the Bering, Chukchi and Beaufort Seas, including waters off North America and Russia, and as far south as the eastern coast of the Kamchatka Peninsula. That population was frequently referred to as eastern gray whales (EGW) in the literature, but also as Eastern North Pacific gray whales (ENP) by NMFS (Ex. M-0473 (Weller et al., 2013)). A second population utilized summer feeding habitats in the Sea of Okhotsk, including areas off the northeastern coast of Sakhalin Island as well as the southeastern coast of the Kamchatka Peninsula (Ex. M-0404 (Andrews, 1914); Ex. M-0460 (Rice and Wolman, 1971); Ex. M-0468 (Weller et al., 2002)). This population was frequently referred to as western gray whales (WGW) in the literature (Ex. M-0418 (Cooke et al., 2018)), but also as Western North Pacific gray whales (WNP) by NMFS (Ex. M-0473 (Weller et al., 2013)). I use the terms WGW and EGW in my testimony (but, as noted above, will distinguish between current and historical populations). The migratory and wintering habits of the historical WGWs were not as well-known as those of the EGWs (Ex. M-0472 (Weller and Brownell, 2012)). Information, including historical whaling records as well as more recent observations since the 1930s showed the WGWs migrated in coastal waters off Japan and South Korea to wintering habitat somewhere in the South China Sea (Ex. M-0472 (Weller and Brownell, 2012)). Recent genetic studies suggested that current EGWs and current WGWs are discrete populations (Ex. M-0445 (Lang et al., 2011); Ex. M-0451 (Meschersky et al., 2015)). However, in this testimony, I will make it clear that there is a degree of uncertainty about this and that it is a hypothesis being tested in ongoing research projects by myself and others.

Hunting for gray whales occurred in the Atlantic Ocean and is thought to have caused or contributed to the extinction of the Atlantic gray whales (Ex. M-0449 (Mead and Mitchell, 1984); Ex. M-0472 (Weller and Brownell, 2012)). Hunting also occurred in the Pacific Ocean, where populations of both EGWs and WGWs were reduced to very low numbers. According to Alter et al. (2012) (Ex. M-0403) there were approximately 1,300 mature females at the nadir of the bottleneck for the entire North Pacific gray whale population. That contrasts with the estimated size of the pre-commercial whaling EGW

population of 15,000 to 20,000 whales based on whaling records (Ex. M-0428 (Henderson, 1984)). With regards to the WGW, Berzin and Vladimirov (1981) (Ex. M-0406) estimated the population numbered 1,000 to 1,500 individuals prior to 1910, and this number has been generally accepted. However, Alter et al. (2007, 2012) (Exs. M-0402, M-0403) estimated the historical population size of the entire North Pacific gray whale population based on genetics as approximately 100,000 individuals prior to whaling, but did not estimate the relative sizes of the historical WGW and EGW populations. Estimates of historical abundances based on genetics have been very high for some species, but for others they have been consistent with traditional methods. The very high estimate for gray whales by Alter et al. has not been generally accepted as accurate, nor has it decisively been shown to be incorrect. A key caveat to the use of genetics to estimate historical abundances is that it is difficult to accurately estimate genetic mutation rates on which the estimates of historical abundance are based. Notwithstanding the uncertainty of the pre-exploitation size of the WGW population, it is well-established that it had a considerably greater distributional range than now (Reeves et al., 2008) (Ex. M-0459) and it was reduced to a much smaller size than the EGW.

Western Gray Whales: WGWs are currently classified as endangered according to the IUCN (Ex. M-0418 (Cooke et al., 2018)). This is based on recent estimates of fewer than 50 breeding females. For example, in one recent estimate, the number of non-calves numbered about 140 in 2012 (Cooke et al., 2013) (Ex. M-0419), including only about 29 reproductive females (Burdin et al., 2012) (Ex. M-0414); Cooke et al. (2013) (Ex. M-0419) estimated 36 (± 2) mature females in 2012.¹ These estimates are similar and clearly show the small size of the population.

More recently, however, Cooke et al. (2017) (Ex. M-0420) has revised this estimate upwards by also considering animals from the southeastern Kamchatka Peninsula as part of the WGW population. Including whales that summer in Kamchatka as well as Sakhalin, Cooke et al. (2017) estimated the non-calf WGW population in 2016 to be between 320 and 410. Note that this estimate is significantly larger than the annual estimates given above. Those earlier estimates were limited to whales summering only near Sakhalin whereas the latter includes all whales that summer near southeastern Kamchatka and/or Sakhalin. The later estimate by Cooke et al. (2017) would also include animals recruited during the intervening 4 years between 2012 and 2016.

Determining what whales comprise the WGW population is becoming more complex with the new focus of Cooke et al. (2017) (Ex. M-0420) on the Kamchatka whales. Those authors differentiate between an estimated 130–170 whales that feed **predominantly off Sakhalin**, an estimated 182–222 whales that feed at least **occasionally off Sakhalin**, and the previously mentioned 320–410 whales that feed off **both southeastern Kamchatka and Sakhalin**. To clarify, the smaller estimates are comprised of whales that are included in the larger estimates. Relaxing the definition of what is a WGW results in an increased abundance estimate. It should be recognized that no matter how the populations are defined, both the Sakhalin and Kamchatka populations have increased at an estimated rate of 2–5% per year.

Despite a steadily increasing population, the estimates are still small, but they have implications for the IUCN listing of the WGW population. Specifically, with these new estimates the population was recently re-classified by IUCN as Endangered, not Critically Endangered², as the population includes more than 50

¹ This contrasts markedly with the EGW: although it was reduced to approximately 2,000 whales, the 2015/16 estimate was about 27,000 whales (Ex. M-0426 (Durban et al., 2017)).

² <https://www.iucnredlist.org/species/8099/50345475>

mature animals but less than 250. However, the modelling of Cooke et al. (2017) (Ex. M-0420) assumes that the Sakhalin feeding population includes both eastern and western breeding animals. Because the western breeding animals comprise 0 to 50 mature individuals (males and females), if such a western breeding population exists, it would be classified as Critically Endangered under IUCN's criteria. However, the eastern breeding animals (those that might migrate through the area of the Makah hunt) would be part of the large EGW population, and would not be endangered. As Cooke et al. (2017) rightly conclude (P.6): "Obtaining further information on the existence, nature and status of the relict western North Pacific breeding population is clearly a high priority."

It has been said that the loss of a single reproductive female annually could be sufficient to lead to the extinction of the current WGW population (Ex. M-0431 (IWC, 2006, pp.10, 67)). This was primarily because of the small number of reproductive females. Between 2006 and 2015 the number of WGWs has almost doubled (120 to >200; see discussion above and Cooke, 2018 (Ex. M-0421); Cooke et al., 2017(Ex. M-0420)), and the statement no longer appears to be true. Threats to WGWs include fisheries bycatch, poaching, ship strikes, and oil and gas development (Ex. M-0457 (Perrin et al., 1994); Ex. M-0468 (Weller et al., 2002)). As to the Makah hunt, as mentioned at the beginning of my testimony, it is my understanding that the likelihood that a Makah hunter would strike a WGW is extremely small (Ex. M-0452 (Moore and Weller, 2018)) and that NMFS's proposed regulations would suspend the hunt in the event such a strike is confirmed.

WGWs historically migrated along the coasts of Korea, China and Japan (Exs. M-0468, M-0473 (Weller et al., 2002, 2013)). The wintering grounds have never been known with certainty; suggestions have included the Seto Inland Sea of Japan (Ex. M-0456 (Omura, 1984)) and southern Korea (Ex. M-0404 (Andrews, 1914)). There is little evidence to support these areas as wintering grounds (Ex. M-0468 (Weller et al., 2002)), and it is more likely that WGWs wintered farther south along the mainland coast, perhaps as far south as near Hainan Island in the South China Sea (Exs. M-0468, M-0471 (Weller et al., 2002, 2012, and references therein)). In the western North Pacific, WGWs were hunted primarily in Korea and Japan in the first half of the 20th Century (Ex. M-0409 (Brownell and Chun, 1977); Ex. M-0460 (Rice and Wolman, 1971)). Gray whales were also hunted in the eastern North Pacific and the independence of these two populations was established based on the appearance that they were geographically isolated across the North Pacific Ocean basin, and because hunting pressure on one population did not seem to impact the other. According to the first report of the IWC Rangewide Review (IWC, 2014b; SC/65b/Rep08, p. 11) (Ex. M-0435), "Brownell reported that the large catches (>1,750 gray whales) by Japanese modern whalers in the East Sea of Korea from 1890-1966, but mainly in the first third of the 20th Century (Kato and Kasuya 2002) (Ex. M-0439), came at a time when the population of gray whales in the eastern Pacific was seriously depleted as a result of 19th Century whaling. This mismatch in the timing of peak catches in the eastern and western North Pacific is consistent with the hypothesis of separate populations." These observations are substantiated by the historical catch data summarized in Appendix A of Bradford (2003) (Ex. M-0408). See also Brownell et al. (2009) (Ex. M-0410).

By 1966 the WGW was considered extinct (Ex. M-0407 (Bowen 1974); (Ex. M-0468 (Weller et al., 2002)). However, in the late 1960s and the 1970s some whales were sighted in the Sea of Okhotsk, South China Sea and the Sea of Japan (Ex. M-0455 (Omura, 1974)). It was assumed that these were surviving WGWs, and the population was estimated to be 100-200 individuals by Berzin and Yablokov (1978, cited in Ilyashenko, 2011) (Ex. M-0406).

By the turn of the 21st Century, the last surviving remnant of the WGW population was thought to be the gray whales that currently summer off the northeastern coast of Sakhalin Island and some of the whales that summer off southeastern Kamchatka (Exs. M-0467, M-0468, M-0471 (Weller *et al.*, 1999, 2002, 2012)). The fact that gray whales are occasionally seen or stranded in waters off Japan, Korea and China, ostensibly during the months of the WGW migration, is an indication that some gray whales summer in the Sea of Okhotsk and migrate south to wintering sites in Asia. This is thought to be a historical migration pattern of WGWs. A gray whale photographed as a calf in the Sea of Okhotsk was subsequently killed off Japan (Ex. M-0469 (Weller *et al.*, 2008); Ex. M-0472 (Weller and Brownell, 2012)); according to the authors, this was the first confirmation of the Asian migratory corridor in recent times. There are, however, alternative explanations for the presence of gray whales observed in Asian waters during the winter. They could be whales that did not have sufficient strength to migrate to Mexico and chose to stay closer to the summer feeding grounds. If so, they likely would have been forced south by ice conditions in the Sea of Okhotsk and ended up in Japanese waters. These whales could also be vagrant individuals exhibiting extralimital movement patterns. In recent years, at least two gray whales were seen in the Atlantic and one in the Laptev Sea off the northern coast of Siberia (Ex. M-0461 (Scheinin *et al.*, 2011); Ex. M-0463 (Shpak *et al.*, 2013)). Given that there are no existing populations in those areas, these observations demonstrate that gray whales do at times travel far outside their normal migratory corridor and feeding areas.

Data are being collected and analyzed to help determine the status of the WGW population, including photo identification (Ex. M-0414 (Burdin *et al.*, 2012); Ex. M-0464 (Tyurneva *et al.*, 2012)) and biopsy data (Ex. M-0444 (Lang *et al.*, 2010b)) collected since 2002 from gray whales summering in the Sea of Okhotsk. Gray whales biopsied off Sakhalin Island are statistically significantly different from whales sampled from the EGW population based on biparentally inherited microsatellite loci and maternally inherited mtDNA (Lang *et al.*, 2010b; Ex. M-0447 (LeDuc *et al.*, 2002); Ex. M-0451 (Meschersky *et al.*, 2015)). This evidence supports the hypothesis that the gray whales summering off Sakhalin Island are the remnant of the once presumed extinct WGW. However, satellite telemetry data has called into question previously widely held hypotheses about the movements of WGWs and their relationship with EGWs. In 2010, a satellite tag was placed on a 13-year old male WGW named “Flex” by researchers off Sakhalin Island (Ex. M-0448 (Mate *et al.*, 2015)). On December 12, 2010, Flex travelled eastward to the west coast of the Kamchatka Peninsula, swam around the southern tip of Kamchatka, and proceeded north toward the Commander Islands. He swam east on January 3, 2011, crossing the Bering Sea and heading toward North America. After crossing the Gulf of Alaska and turning south, he arrived at the Washington, USA coast near Queets by February 2, 2011. Three days later the transmitter failed with Flex near the Oregon coast and heading south. The study of Mate *et al.* (2015) was a landmark in gray whale science because it immediately upended the conventional wisdom of decades of North Pacific gray whale research. The result has been an exhaustive and healthy reassessment of stock structure hypotheses related to both the WGW and the PCFG, discussed below, through the IWC Rangewide Review.

Additional efforts to follow WGWs via satellite confirmed that Flex was not an isolated observation. On August 28, 2011, a transmitter was placed on a female WGW named “Agent” which, like Flex, travelled east towards North America beginning on November 24, 2011. Agent’s transmitter ceased operating on December 31, 2011, when she was in the Gulf of Alaska. Another transmitter was placed on “Varvara”, a female gray whale at Sakhalin Island in 2011. Varvara was tracked for more than a year during which

time she moved from Sakhalin to the EGW wintering lagoons of western Baja California, Mexico, and then returned to Sakhalin Island (Ex. M-0448 (Mate et al., 2015)).

The surprising journeys of the satellite tagged whales prompted examination of other data sources to determine if additional evidence of migration between Sakhalin and North America might be found. Photographic matches of whales photographed off Sakhalin and: (a) British Columbia (n = 6, Ex. M-0470 (Weller *et al.*, 2011)) and (b) Mexico (n = 17, Ex. M-0465 (Urban et al., 2012), Ex. M-0466 (Urban *et al.*, 2013)), and genetic matches (n = 2, Ex. M-0445 (Lang et al., 2011)) of whales biopsied at Sakhalin and Southern California, have now been reported as well as whales with satellite tags. Including the three satellite-tagged whales, 28 whales are known to have migrated from the Sea of Okhotsk to North American coastal waters. This is about 14% of the Sakhalin population if we accept the midpoint N = 202 of the range 182 to 222 given by Cooke et al. (2017) (Ex. M-0420) as the size of the Sakhalin population in 2016. It is uncertain what percentage of the WGW population migrates to North America, but Cooke estimated it to be between 30% and 100% of the mature (aged 7+) Sakhalin Island gray whales (Ex. M-0436 (IWC, 2017)). It thus seems likely to be a significant portion of the population, and perhaps all of them, that migrates east to North America and the EGW wintering grounds off Mexico instead of south to wintering grounds off the Asian coast.

Questions remain about the status and population biology of WGWs. A central issue focuses on the findings of statistically significant mtDNA and nuclear gene differences between WGWs and EGWs in the face of what appears to be a high level of mixing or potential mixing (Ex. M-0443 (Lang et al., 2010a)). Below, I will clarify two biological issues that are pertinent to the question of population structure of North Pacific gray whales. These issues concern the WGWs' status as a stock and their historical identity. The first issue can be addressed through population genetics, and the second through evolutionary genetics. I will review potential stock structure scenarios that are consistent with existing data on genetics, distribution and movements of these whales, including the scenarios currently being considered as a result of IWC's 5-year Rangewide Review of the Population Structure and Status of North Pacific Gray Whales.

A Brief Explanation of the Genetics Methods and Terms Relevant to Gray Whale Population Structure:

The field of genetics is a rapidly progressing area of science in terms of both technology and theory. The basis for studying the genetics of gray whales, or any other wildlife species, is that variation exists in the DNA of individuals as a result of mutations that change the DNA sequence of a gene (or the more general term locus) by substituting a nucleotide (also referred to as a base or base pair since DNA has two strands) with an alternative one (there are 4 nucleotides, abbreviated A, T, G, and C). This is like changing a sentence by replacing one word with another. Given that the genome (i.e., all of the DNA of a cell or individual) contains the developmental blueprint as well as the operating manual of the individual, these variations can have significant implications.

We study the DNA variation using a variety of methods that are discussed in sections below. These include genetic analyses that target specific genes or regions of the DNA, and genomic analyses that include analysis of the entire genome. Genetic studies result in the assessment of hundreds or a few thousand nucleotides of DNA sequence, whereas genomics might cover the entire 35 billion bases of DNA in the gray whale genome. They use substantially different analytical approaches.

Three genetic methods are now commonly used and will be discussed below. Mitochondrial DNA (mtDNA) analysis analyzes the sequence of one or more genes on the mtDNA chromosome. This

chromosome is outside the nucleus of the cell, is part of what was once a symbiotic living bacterium that became incorporated into our ancestor's cells at the origin of higher organisms several billions of years ago. Although there are many copies of the mtDNA chromosome in any cell, the copies are typically identical, and the term "haplotype" is used to refer to mtDNA variants (in contrast to the term "allele," which is used to refer to variants of bi-parentally inherited genetic markers). Because of certain special properties mtDNA is easy to study and highly variable. It also is strictly maternally inherited; males and females both inherit it, but only females pass it to their progeny. So, it is used as a marker of female lineage diversity. Most studies focus on a few hundred base-pairs of the highly variable Control Region of the mtDNA. Due to its characteristics, this genetic marker gives us a unique window into the female contribution to population genetics.

A second frequently used kind of genetic markers is called microsatellites. These are found in the nucleus of the cell and typically they are bi-parentally inherited markers, being located on the autosomal chromosomes (which contrast with the sex chromosomes, the X and Y, which will not be discussed here). Microsatellites are short, two- or three-base repeats, such as CACACACACA, that are found throughout the genome. These repeats are highly variable in terms of the number of repeats because of a process of slippage which occurs during DNA replication. Such mutations that change the number of repeats are far more common than base substitutions, which change one nucleotide for another. Moreover, microsatellites are analyzed using a method called fragment size analysis, which estimates the number of repeats at a locus, instead of a sequence analysis like the mtDNA. Ultimately, this is a method that reveals a high degree of genetic variability because each locus will have a large number of variants, or "alleles" in the lexicon of genetics (in contrast to the term "haplotypes" used to refer to mtDNA variants). Typically, and as is the case in the gray whale studies below, the locations of the microsatellite loci are unknown, and the loci have been derived from different species which leads to potential scoring and analytical problems.

A third method that is becoming more frequently used because it does not have the analytical problems of microsatellites is called Single Nucleotide Polymorphisms (SNPs or snips). A SNP locus is any location on the DNA where alternative nucleotides are found on different chromosomes. These are almost always two-allele (bi-allelic) markers and since they are frequently derived from a whole genome sequence, their location (i.e., if they are associated with a known gene or not) is known. There are millions of these in any mammal species; in fact, DeWoody et al. (2017b) (Ex. M-0424) identified 2,057,254 SNPs in the gray whale genome from which they developed a panel of 96 SNPs located in genes of known function. As mentioned, SNPs have certain advantages of analysis compared to microsatellites including clarity or ease of scoring since they are a sequence-based analysis, not a fragment size analysis. And, because they are sequence-based the data can be archived and used from study to study as is the case for mtDNA.

Genomic analysis is the future of all genetic studies. The cost of sequencing a genome was about \$100 million in 2001, and today is only about \$1,000. Along with the rapid advance of the technology to sequence the genome, there has also been rapid advances in bioinformatics (the methods by which large scale genomics data are analyzed using supercomputers) to analyze the sequence, availability and capability of supercomputers to do this work, and analytical programs for both evolutionary and population genomic studies. DeWoody et al. (2017b) (Ex. M-0424) reported the genome sequences for two WGWs and one EGW, and Arnason et al. (2018) (Ex. M-0405) reported genome sequences for two additional gray whales. Soon we will have the ability to sequence entire genomes from large numbers

of individuals and analyze millions of genetic markers. However, at this time, the gray whale genomic data has served as a resource to identify SNPs to be used for population genetic analysis, as well as comparing a small number of EGWs and WGWs to reconstruct the population evolutionary history as described in Brüniche-Olsen et al. (2018b) (Ex. M-0412).

Genetics and genomics provide the modern methods to study population genetics and evolutionary genetics. Such studies are critical in conservation and management because they directly address two key issues in conservation biology: 1) population structure which guides the identification of management units, and 2) measuring genetic diversity in populations which is a key driver for extinction probability. These methods and issues are discussed below more fully as they pertain to gray whales.

Genetic Studies of Western Gray Whales: Comparisons of the genetics of the current WGW population to the current EGW population have been made in a series of studies primarily using biopsies from whales observed off Sakhalin Island (and a few from southeastern Kamchatka), and biopsies or tissues of stranded, harvested, or biopsied EGWs from a variety of localities including their summering and wintering habitats and migratory corridor. These studies have employed mtDNA (Ex. M-0447 (LeDuc et al., 2002); Ex. M-0438 (Kanda et al., 2010); Ex. M-0451 (Meschersky et al., 2015)), nuclear microsatellites (Ex. M-0441 (Lang, 2010); Exs. M-0443, M-0444 (Lang et al., 2010a, 2010b)), and both (Ex. M-0445 (Lang et al., 2011)). Consistent evidence of genetic divergence between the WGW and the EGW populations, expressed as statistically significant differences in mtDNA haplotype frequencies (F_{ST}) and microsatellite allele frequencies (F_{ST}), have been found. The two populations have similar levels of genetic diversity (e.g., heterozygosity) in nuclear microsatellites, and similar nucleotide diversity of mtDNA. But the EGWs have greater mtDNA haplotype diversity than the WGWs (Lang et al., 2011). These studies show significant genetic variation is present in the WGW population, despite the history of commercial whaling and current small estimate of abundance of the group. The pattern of frequency distribution of mtDNA haplotypes differs in WGWs and EGWs; there are two haplotypes in very high frequency in WGWs (Figure 1; haplotype 1, 0.51 and haplotype 2, 0.44) whereas in the EGW population the frequency of the most common haplotype (1) was 0.15. The results of these studies, which utilized appropriate methods when they were conducted, are consistent with two demographically distinct populations of drastically different sizes and numbers of breeding females as the studies cited above concluded.

Figure 1.—This is Figure 3 in Lang et al. (2011) (Ex. M-0445) and shows the mtDNA haplotype network for control regions sequences. Note that there is no evidence of population structure in the form of nested groups of related haplotypes that are found only in EGW or WGW populations. Compare this to Figure 2 which shows evidence of stock structure in Steller sea lions.

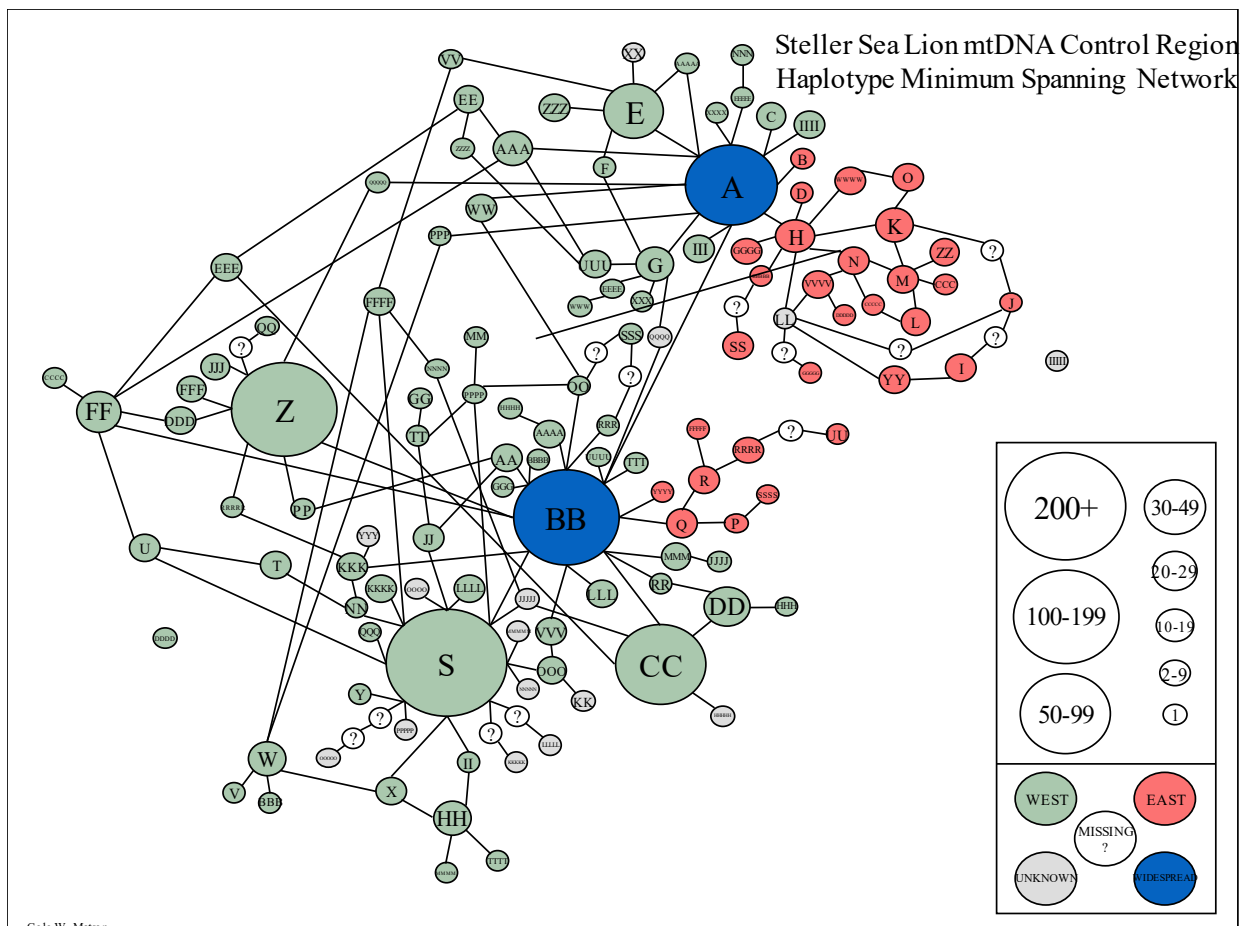

Figure 2.—Steller sea lion mtDNA haplotype network from control region sequences. Notice the groups of related (nested) haplotypes that are unique to the eastern (red) and western (green) stocks. This figure is unpublished, but the pattern of nested haplotypes in Steller sea lions has been examined by Harlin-Cognato et al. (2006) (Ex. M-0427a) and Phillips et al. (2011) (Ex. M-0458).

The observed, statistically significant, genetic distinctness between the two populations, however, is surprising given the observation of a substantial proportion of WGWs that migrate to North America rather than to wintering habitats in Asia. In fact, males and females in approximately equal numbers are known to migrate to North America (Ex. M-0466 (Urban et al., 2013)) so mating during migration among members of this population is possible. Nonetheless, Lang et al. (2010a) (Ex. M-0443) reported evidence of male mediated dispersal or gene flow from the EGW population into the WGW population. Male biased dispersal was supported by the fact that most mtDNA haplotypes found in only one or two Sea of Okhotsk gray whales are represented only by males (Ex. M-0447 (LeDuc et al., 2002); Ex. M-0445 (Lang et al., 2011)). These could be EGW males that have followed Sea of Okhotsk gray whale females back to the latter's summer feeding grounds. That is, they are not the sons of WGW females and so don't have the mtDNA haplotypes found in those females. Because they are males, they do not pass their mtDNA to offspring and so their distinctive haplotypes will not persist or increase in the WGW population. Moreover, the level of differentiation of nuclear microsatellites is quite low between EGW and WGW, with $F_{ST} = 0.010$. This low, but significant ($p=0.001$) measure of F_{ST} , was based on only 8 loci (Lang et al. 2011). Together, these observations provide an unclear picture of the population structure of North

Pacific gray whales. That is, some evidence is consistent with the WGWs comprising a distinct population, but other evidence suggests gene flow with the EGW population and low level of nuclear differentiation based on a small number of loci. Understanding the limits of gene flow among populations is key to understanding population structure and, in this case, it would be preferable to have a larger dataset, particularly in terms of the number of nuclear loci.

The pattern of differentiation between WGW and EGW in mtDNA is also meaningful in any discussion of stock structure. The significant F_{ST} for mtDNA means that haplotypes differ between the populations in their frequencies of occurrence. This frequency difference could be the result of long-term isolation such as would be expected of distinct stocks. But it could also be the result of a recent founder effect such as a small group of EGW colonizing a new habitat, or the result of genetic drift in a small, isolated population of EGWs. An examination of Figure 1 shows that the haplotypes found in WGW are also found in EGW. That is, there are no haplotypes unique to the WGW. Moreover, there are no groups of related haplotypes that would indicate that the Sakhalin population was isolated for a long period of time from the EGW population. An examination of Figure 2 shows such a pattern wherein eastern and western stocks of Steller sea lions have unique haplotypes, as well as groups of related haplotypes found only in that stock. This pattern is what we might expect of the Sakhalin whales if they are indeed the historical WGW population, that is, the descendants of the whales hunted to the verge of extinction by whalers in Japan and Korea and isolated by the North Pacific Ocean basin from the EGW. Instead, the existing pattern of significant F_{ST} but no unique haplotypes seems more likely to be due to recent divergence and a founder effect from a small group of EGWs.

The question of the relationship between the Sakhalin and Kamchatka feeding populations was addressed recently by Cooke et al. (2017). Their population model assumes two feeding populations, Sakhalin and Kamchatka, and two breeding populations, an eastern breeding population that migrates to Mexico and a western breeding population that migrates to an unknown wintering area in Asia. According to Cooke et al. (2017, P. 3) (Ex. M-0420) “The “Sakhalin” feeding population is defined to consist of the whales that feed predominantly off Sakhalin but may also be seen off Kamchatka, and possibly in other areas. The “Kamchatka” feeding population is defined as whales that feed predominantly off SE Kamchatka but may also be seen off Sakhalin or in other areas.” The model also assumes that the Sakhalin feeding area contains both eastern and western breeding whales and the Kamchatka feeding area contains only eastern breeding whales. They address the issue of stock structure by making use of genetic paternity data (Ex. M-0441 (Lang, 2010); Ex. M-0443 (Lang et al., 2010a)) to test two hypotheses of genetic closure (meaning that the population breeds within itself and is thus closed to mating with members of the other population): *(i) paternities are within each feeding population; (ii) paternities are not necessarily within each feeding population, but are within the two feeding populations combined* (Cooke et al., 2017 p. 5). The authors conclude that preferential mating occurs within the Sakhalin population, but it is not “exclusive” meaning the population is not closed. Thus, hypothesis *i* is rejected ($p < 0.05$) meaning that the Sakhalin feeding population is not genetically closed. In sum, the authors conclude (P. 6) “that the Sakhalin feeding aggregation is probably not genetically closed but that the Sakhalin and Kamchatka feeding aggregations, taken together, may be genetically closed. However, genetic data from Kamchatka would be required to confirm this.” This analysis is suggestive that the Sakhalin whales, combined with the Kamchatka whales, could be a discrete population but the results are not definitive.

Recent advances in sequencing methods (next-generation sequencing), genomic analyses, and bioinformatics have made possible new approaches to study the genetics of natural populations. These methods were not available, or were exorbitantly expensive, at the times the earlier studies of gray whale genetics were done. Studies were recently conducted using genomics methods that are relevant to measuring population differentiation of EGWs and WGWs. DeWoody et al. (2016, 2017a, 2017b) (Exs. M-0422, M-0423, M-0424) sequenced the genome of two Sakhalin whales and one EGW from Barrow, Alaska. Using the genome assembly, 92 Single Nucleotide Polymorphism (SNP) loci were identified. These included 2 SNPs useful for sex identification, 2 useful for mtDNA haplotype identification, and 88 gene-associated, bi-parentally inherited nuclear markers. The SNP panel was tested using 35 biopsies from Sakhalin WGWs and the single EGW from Barrow used in the genome sequence analysis. The data were used in preliminary assessments of relatedness and population structure, among other things. Among the 36 tissue samples there were 29 unique genotypes, indicating 7 instances where WGWs were biopsied twice. The relatedness analyses revealed apparent examples of parent-offspring, full sibling, half sibling, and other close relatives. These included two cow/calf pairs and one ostensible full-sibling pair (sisters).

A following paper (Ex. M-0411 (Brüniche-Olsen et al., 2018a)) using the SNP panel included the data in the first study as well as additional Sakhalin whales and whales from the wintering grounds in Mexico. The resulting sample sizes were 55 Sakhalin and 111 Mexican whales. These authors found a low ($F_{ST} = 0.039$; $D = 0.017$) but significant ($p = 0.001$) level of population subdivision. They analyzed the data for population structure using multiple methods including Discriminant Analysis of Principal Components (DAPC), STRUCTURE, and Lea (which is similar to STRUCTURE). The program BayesAss v3.0 was used to estimate recent migration. A genetic similarity measure was also calculated (M_{xy}).

Figure 3.—Lea analysis showing the presence of two genomes (brown and yellow) which are found at markedly different frequencies in the Mexican wintering grounds and the Sakhalin (Russian) summering grounds. Individual whales (columns) can have 100% yellow or brown genomes, or they can be admixed meaning that they are of mixed ancestry. This figure is from Brüniche-Olsen et al. (2018a) (Ex. M-0411).

There was an approximately 65-fold greater migration rate for whales migrating into the Sakhalin population, as compared to whales migrating into the eastern population. This is consistent with the large difference in estimated numbers of EGWs versus WGWs. The DAPC showed that the two

populations could be separated, but with a considerable degree of overlap. The Lea (Figure 3) and STRUCTURE analyses both showed evidence of two distinct lineages that differed considerably in their frequencies in the two populations, as well as the presence of admixed individuals. One lineage predominated in the Mexican population and the other at Sakhalin, but the Sakhalin population showed more even proportions of the two lineages, and more admixed individuals. Between-individual genetic similarity (M_{xy}) was higher in the Mexican population than at Sakhalin.

All in all, this study (Ex. M-0411 (Brüniche-Olsen et al., 2018a)) is consistent with previous work (Ex. M-0445 (Lang et al., 2011)) showing that the Sakhalin population is genetically distinct but goes further in revealing that it appears to be a mixed stock assemblage (Figure 3). Whether the two identified lineages correspond to WGWs and EGWs is not known, since individuals of both lineages migrate from Sakhalin to Mexico. But it seems clear that considerable immigration and admixture is taking place at Sakhalin. One possible interpretation is that a sub-stock of the EGW population (western feeding group) has long been present in the Sea of Okhotsk and that it is mixing with recent immigrants from the northern feeding group of the EGW population. This would be consistent with stock structure hypothesis 3a from the Rangewide Review in which the western breeding stock is extinct. It could also be consistent with hypothesis 6b in which the western breeding stock migrates to Mexico and Asia, but this seems less likely to me for three reasons. First, there is a low level of genetic divergence between putative eastern and western gray whales as measured by mtDNA, microsatellites, and SNPs. This is consistent with a small population recently derived from the larger population, but not what one would expect of a distinct stock isolated by an ocean basin. Second, there are no mtDNA lineages or even haplotypes (according to the data shown in Lang et al., 2011, see Figure 1) that are unique to the Sakhalin whales. Again, this is consistent with a small population recently derived from the larger population, but not what one would expect of a distinct stock isolated by an ocean basin. And, third, depletion of the EGW population by commercial whaling did not seem to impact the WGW population. This strongly suggests that at the time of whaling the EGW and WGW populations were distinct and isolated from one another. I discuss the stock structure hypotheses from the Rangewide Review in more detail below.

A study recently accepted for publication, Brykov et al. (2019) (Ex. M-0413), sequenced 4 mtDNA genes (control region, and the following protein-coding genes: cytochrome b, cytochrome oxidase I, and NADH dehydrogenase 2) from Sakhalin whales. Gray whales with the “eastern” SNP genotype had statistically significantly different mtDNA haplotype frequencies compared to gray whales with the “western” SNP genotype using Fisher’s exact test for both the control region ($p = 0.034$), and for the combined protein coding sequences ($p = 0.013$), analyzed separately. This gives some confidence that despite small sample sizes, the Lea analysis is identifying biologically meaningful groups. Potentially these groups are comprised of individuals representing different populations. The study goes on to analyze the evolutionary relationships of the haplotype sequences using haplotype networks for both the control region and the combined protein coding sequences. No unique clades of related haplotypes were found among the western SNP genotype animals, for either of the two networks. From these data the authors concluded the following: “This is not consistent with long-term isolation during the Pleistocene as seen in many other marine mammals with similar distributions. Rather, the “western” and “eastern” genotypes likely have diverged recently, possibly since the end of commercial whaling in the early 20th Century, but more likely post-Pleistocene.”

Although the study of Brykov et al. (2019) (Ex. M-0413) is based on small sample sizes and for this reason the authors recognize the results are preliminary, it is yet another indication that the Sakhalin population is a mixed-stock aggregation and that the “western” genotype animals are most likely not the descendants of the historical WGW population that migrated along the coast of Asia. Rather, it is more likely to be a subset of the EGW population.

Another relevant study was an analysis of the previously reported genome sequences of the two Sakhalin whales and the single EGW using population genomics methods (Ex. M-0412 (Brüniche-Olsen et al., 2018b)). Several observations are of interest here. 1) Using the genome sequence data to estimate long-term effective population size, estimates from the three individuals did not differ very much. Estimates based on the two Sakhalin whales were $N_e = 555,557$ and $582,749$; the EGW estimate was $N_e = 706,102$. These differ between the two populations but not to the expected degree since the EGW abundance was only 1.2-fold greater than the WGWs. 2) A relatedness analysis showed results that conflicted with the traditional stock structure hypothesis; although the two Sakhalin whales were more closely related to each other than expected by chance, one of the Sakhalin whales was also more closely related to the EGW than by chance. Again, this is an unexpected result. 3) The pairwise population concordance (PPC) test, which evaluates probabilities of population differentiation, indicated that the null hypothesis of all three individuals belonging to the same gene pool was not rejected. Some genomic evidence was also found that is consistent with the two Sakhalin whales belonging to a different population from the EGW individual. 4) Genome-wide genetic (nucleotide) diversity was measured for the three whales and it was found that the two Sakhalin whales had lower diversity estimates than the EGW. Various estimates of inbreeding, based on measures of Runs of Homozygosity (ROHs), consistently showed that the Sakhalin whales had higher levels of inbreeding than did the EGW.

Another very recent study of gray whale genomics was published (Ex. M-0440 (Lammers et al., 2019)) which examined the phylogenetic patterns of transposable elements (TEs) based on published genome sequences of baleen whales. In the study, they examined TEs of two WGWs (i.e., the genomes reported by DeWoody et al. (2017b) (Ex. M-0424) and the genomes of two EGWs (reported by Arnason et al., 2018 (Ex. M-0405)). There was a high degree of differentiation of TEs between the WGWs and EGWs, much greater than between any other within-species comparison and on the order of the difference between right whales and bowheads (which are in different families). This observation is at odds with all of the other studies of gray whale genomics and genetics. This, combined with the fact that TEs are not as well understood as the other genetic markers used in gray whale studies, makes me doubt the relevance of this study to gray whale stock structure. It does, however, indicate a future research direction.

While some of the genomic data can be taken as support for the concept of two distinct populations of gray whales in the North Pacific Ocean basin, the analyses of Brüniche-Olsen et al. (2018b) (Ex. M-0412) also provide evidence that population structure and status of the WGW might not be so straightforward. Notwithstanding that their analyses were based on only 3 individuals, they showed that the hypothesis of a single population of North Pacific gray whales could not be rejected. And, perhaps more interesting, is the fact that the two Sakhalin whales sampled were significantly different from each other in some analyses, such as inbreeding level, and that one individual, identified as WGW1 in the paper, was consistently intermediate between WGW2 and the EGW. Moreover, in the relatedness analysis

WGW1 and the EGW were more closely related than by chance. WGW1 is also one of the WGWs known to migrate to North America.

Taken together, the results presented in DeWoody et al. (2016, 2017a, 2017b) (Exs. M-0422, M-0423, M-0424), Brykov et al. (2019) (Ex. M-0413) and Brüniche-Olsen et al. (2018a, 2018b) (Exs. M-0411, M-0412) do not provide a definitive answer as to the nature of the WGWs because sample sizes are too small. They do indicate that further work is needed to resolve the issue of stock structure. Importantly, they employed methods of analysis that were not available to the authors of the earlier papers, *e.g.*, Lang et al. (2011) (Ex. M-0445), and provide new perspectives on the issue of population structure. That is not to say that the earlier studies did not employ the appropriate methods for their time, it is just that the rapidly progressing field of genetics has moved beyond those methods. Genomic studies of gray whales are continuing at Purdue University and NMFS.

But while these studies are not in and of themselves conclusive, the weight-of-evidence they provide indicates that the Sakhalin whales are comprised of two groups and both of the groups are likely to have been recently derived from the EGW population. These results provide greater insight into the issue of gray whale stock structure. Genetics and genomics, combined with several examples of tagged whales and other indicators of individual whale migratory behavior, demonstrate that the current populations considered as WGW and EGW are not isolated, are genetically much more closely related than expected, and experience what appears to be a considerable degree of mixture. Below, I discuss how these studies dovetail with the findings of the Rangewide Review and go into the various stock structure hypotheses in more detail.

Eastern Gray Whales (Including the Pacific Coast Feeding Group): Early in the 20th Century it was recognized that the EGW population was heavily depleted and possibly on the verge of extinction (Ex. M-0429 (Huey, 1928)). Unlike the WGW, the EGW population has made a remarkable recovery and the current abundance estimate is 26,960 (Ex. M-0426 (Durban et al., 2017)). As presently conceived, the EGW population consists of a large general population, sometimes called the Northern Feeding Group (NFG) because the bulk of the population feeds in the Beaufort, Chukchi, and Bering Seas, and a small group of whales called the Pacific Coast Feeding Group (PCFG), with a current estimated abundance of 243 (Ex. M-0416 (Calambokidis et al., 2017)). The use of the term “feeding group” in the IWC Rangewide Review as well as by NMFS in Weller et al. (2013) (Ex. M-0473) for both the NFG and PCFG is somewhat confusing because in the case of the PCFG it is referring to a group that is not thought to breed primarily with members of its own group, whereas whales of the NFG primarily do so. Thus, the term is being used for groups of animals that differ in their placement on the hierarchy of social structure. The NFG would seem to be a stock or breeding population whereas the PCFG is a group of whales with a shared learned behavior (*i.e.*, a true feeding group) that is part of the larger NFG stock. Whales that feed in the Sea of Okhotsk, including whales that migrate to North America, are sometimes referred to as the Western Feeding Group (WFG) in the IWC Rangewide Review. These terms are used by the IWC Rangewide Review in order to differentiate among different groups or aggregations of whales in the various stock structure hypotheses being modelled. I will explain this more fully below. The estimated 26,960 whales that migrate along the western coast of North America, and are counted in California, include the small numbers of PCFG whales and the WFG whales that migrate to North America, and the very large NFG.

It is well known that gray whales found off the coast of the Pacific Northwest in summer and fall appear to have different affinities to the area. Some whales return frequently and account for most of the sightings between 1 June and 30 November. On the other hand, some whales are encountered only in a single year, typically remain for a shorter period, and are not found in as many areas as the frequently observed whales. The IWC defined PCFG gray whales as: whales observed between 1 June to 30 November within the region between northern California and northern Vancouver Island (from 41°N to 52°N) and photo-identified within this area for two or more years (Ex. M-0433 (IWC 2012)). This same definition has been adopted in most studies including Calambokidis *et al.* (2017) (Ex. M-0416) and Weller *et al.* (2013) (Ex. M-0473).

Lang *et al.* (2014) (Ex. M-0446) investigated genetic differentiation between PCFG and NFG whales. They found a low, but statistically significant difference in haplotype frequencies between the two feeding groups. They conclude that “it is plausible that the PCFG represents a demographically independent group”. The acceptance of the PCFG as a management unit hinges largely on the difference in mtDNA haplotype frequencies, as no statistically significant difference in microsatellite allele frequencies (in nuclear DNA) between the PCFG and NFG has been observed (Ex. M-0425 (D’Intino *et al.*, 2013); Lang *et al.*, 2014)). A significant difference in mtDNA haplotype frequencies was also observed by Frasier *et al.* (2011) (Ex. M-0427), based on a smaller sample size of whales collected off Vancouver Island compared to samples of the greater EGW population collected from stranded gray whales along the migratory route and samples from animals hunted for subsistence in Russia. Frasier *et al.* (2011) explain the reason for the genetic difference as being due to behavioral segregation of the PCFG. They point out (P. 40) : “Subdivision with respect to summer feeding ground use is common in baleen whales, and results from maternally directed site fidelity to different feeding grounds.” They go on to discuss the well-known example of genetic divergence of feeding aggregations of humpback whales. Because mtDNA is maternally inherited, it is a useful marker to track female behavior and any resulting site fidelity in subsequent generations. Behavioral segregation begins during the first year of its life, when a calf will learn from its mother the location of good feeding habitats and is more likely to return to these localities in later years. Over the course of generations this process will increase the numbers and frequencies of the few haplotypes associated with the females that were the original founders of the feeding group. Thus, a feeding group may become statistically different in mtDNA haplotype frequency from the larger population even if the founders of the feeding group did not differ from the larger population. This is because any haplotypes present only in male founders will disappear when those animals die. Simultaneously, the haplotypes of the female breeders will increase in the population as their offspring, male and female, learn from their mothers to utilize the PCFG area. Ultimately, the genetic makeup of the feeding group will be determined by genetic drift in a small population, the number (if any) of female immigrants which will tend to homogenize the mtDNA haplotype frequencies with the larger population, and the degree of breeding within the feeding group which will lead to population differentiation. Thus the fate of a nascent feeding group can include several alternatives: remain a feeding group with different mtDNA frequencies but not biparentally inherited markers; become a discrete breeding stock if internal breeding is high enough; or become indistinguishable from the greater population if immigration into the feeding group is great enough to homogenize the mtDNA haplotype frequencies.

However, defining exactly which whales comprise a feeding group is not easy, particularly when we are dealing with groups of whales whose migratory and feeding areas overlap, offering extensive

opportunity for genetic exchange. In the case of the PCFG, some gray whales show a high degree of faithfulness to the PCFG feeding area, returning year after year. Other whales are observed with less frequency, but still more than the 2-year requirement to be counted as PCFG whales, and some whales seem to be visitors that are seen in one year and never seen again. It seems likely that whales that satisfy the IWC definition of PCFG, having learned the location of the feeding area from their mothers or immigrated to the feeding group and having been sighted in at least two or more years, return frequently to the PCFG foraging area. However, this definition is subjective. According to Report of the National Marine Fisheries Service Gray Whale Stock Identification Workshop (Ex. M0473 (Weller et al. 2013, P. 19)), "The TF [NOAA Task Force] concurred that on an annual basis, whales observed in the area used by the PCFG could be characterized as a collection of individuals whose residence patterns vary along a continuum such that some whales use the area for a single year (e.g., transients), some for a few years, and others on a consistent long-term basis." Weller et al. (2013) go on to say (P. 19) "Laake characterized the PCFG as a "leaky bucket", in that some whales are immigrating in while others are emigrating out." Nonetheless, despite the leaky bucket analogy and the IWC definition of the PCFG, there appears to be a group of whales that uses the PCFG area to a greater degree than others, and it is this group that appears to be captured mainly by the photographic and biopsy programs. These individuals are likely driving the difference observed in mtDNA haplotype frequencies.

PCFG whales associate with one another, or are in proximity, during the summer months but the available evidence demonstrates they do not necessarily mate with other PCFG whales. In gray whales, mating is thought to occur primarily during migration, and PCFG and NFG whales are known to associate then (see discussion below). Mating between PCFG and NFG whales would explain the absence of divergence of the PCFG from the NFG at the nuclear DNA loci. The difference in mtDNA is likely maintained by having sufficient recruitment into the PCFG of calves born to PCFG mothers to maintain the distinct haplotype frequency. The mtDNA of the "foreign" males mating with PCFG females is not incorporated into the PCFG because of strict maternal inheritance of mtDNA. And external recruitment of females must be small enough to not homogenize the mtDNA frequencies with the NFG whales. If this conventional wisdom is true and considering the available information, the PCFG is not a population or a stock in the usual meaning of these terms as a breeding population. Rather, it is an aggregation of whales that are associated by a shared learned behavior (feeding off the Pacific Northwest during the summer and fall) and, for at least some members of the aggregation, is descended from a small number of founding females.

There is also evidence through photographic identification studies of external recruitment into the PCFG. Immigrants into the PCFG likely would have the effect of reducing the level of mtDNA differentiation between the PCFG and the NFG. It would not affect the nuclear loci because those do not differ between the PCFG and the NFG. Modeling by Lang and Martien (2012) (Ex. M-0442) found the immigration of 1 to 8 whales a year into the PCFG is consistent with genetic differentiation observed in mtDNA with a most plausible estimate of 4 whales per year. In addition to a small number of annual immigrants, a "pulse" of whales was recruited into the PCFG following the 1999-2000 gray whale Unusual Mortality Event (UME) (Ex. M-0415 (Calambokidis *et al.* 2012)). In the Rangewide Review, annual immigration levels of 0, 2, 4, and 8 whales were being modelled, as was a one-time pulse of immigrants of 10, 20 and 30 whales (Ex. M-0436 (IWC, 2017, Table 7, P. 654)). Thus, the Rangewide Review considered annual immigration as well as pulse immigration into the PCFG as being plausible. However, recruitment of new

whales into the PCFG that were born to PCFG mothers must also be occurring at a sufficient rate to maintain observed differences in mtDNA haplotype frequencies.

A recent study by Calambokidis et al. (2017) (Ex. M-0416) investigated the composition of migratory gray whale groups to determine if PCFG whales migrate together. They found through photo identifications in Southern California that PCFG whales have been observed to migrate in groups that include other PCFG whales, and thus have an opportunity to breed with other members of the PCFG. They also found that migrating groups of whales that included multiple PCFG whales occurred in both southbound and northbound migrations. Moreover, groups with multiple PCFG whales were more frequently observed in the southbound migration when mating is thought primarily to occur. In the second paragraph of the Discussion (the manuscript is unpaginated) the authors state: "An important implication of this work is that it extends the time PCFG whales would be associated through the year and would increase the potential for breeding with other whales from the same feeding group." While this is true for at least some PCFG whales, it does not come close to providing convincing evidence that the PCFG is a breeding population. To the contrary, this paper provides evidence that is consistent with the PCFG being a feeding group because, while it does show that PCFG whales migrate together with some frequency, it also shows that they frequently migrate with ostensible NFG whales and thus there is adequate opportunity for outbreeding. Four of the seven groups observed on the southbound migration (when mating could occur) containing at least one PCFG whale (calculated from Table 1 in Calambokidis et al., 2017) included one or more individuals not identified as PCFG whales. We can assume that these are likely NFG whales given the location and that NFG comprise more than 95 percent of non-PCFG gray whales. Thus, about half the time there could be non-PCFG whales available for breeding. This does not speak to issues of mating preference, which could be in either direction, or not present at all. In light of the facts that Lang et al. (2014) (Ex. M-0446) found no evidence for nuclear gene differentiation of the PCFG and the NFG, and Calambokidis et al. (2017), based on a limited sample size, show frequent opportunity for the two feeding groups to interbreed on the southbound migratory route, the status of the PCFG as a feeding group, rather than a breeding population, seems well supported.

One could also argue this from a theoretical perspective. Typically, populations diverge as a result of geographic isolation. Clearly the PCFG and the NFG are not geographically isolated. That means that genetic differentiation of the PCFG would have to be the result of strong pre-mating isolating mechanisms; primarily this would be due to PCFG females preferentially mating with PCFG males. This is unlikely to be the case because it violates basic principles of evolutionary biology. Specifically, reproductive strategies evolve to maximize the fitness of one's offspring, which includes the avoidance of inbreeding. For any pre-mating reproductive isolating mechanism (i.e., female mate preference with other PCFG whales) strong enough to reduce gene flow to such a low level as to allow for genetic divergence of the two feeding groups, there would have to be a very high selective advantage to breeding within the group. It is hard to imagine what that would be. The other side of the coin here is, why would a female PCFG whale restrict herself to mating with a small number of PCFG males when there are literally thousands of NFG whales swimming by? In my opinion, in the absence of any genetics data to the contrary, it is implausible to consider the PCFG as a breeding population.

IWC's Rangewide Review of North Pacific gray whales: In response to the new information described above about the movements of WGWs, in 2014 (8-11 April 2014) the IWC convened the first *Workshop*

on the Rangewide Review of the Population Structure and Status of North Pacific Gray Whales in La Jolla, California (hereafter these workshops collectively will be referred to as the Rangewide Review). Rangewide Review workshops were held annually thereafter in 2015, 2016, 2017 and 2018 and included international experts in gray whale biology and population dynamics. Among the objectives of the Rangewide Review was: *(1) review available information (especially new telemetry, genetics and photo-ID data) and reappraise the population structure and movements of North Pacific gray whales with a focus on examining status* (Ex. M-0434 (IWC 2014a. P.21)). Understanding stock structure was one of the critical components to allow the completion of the other objectives which included: *(2) develop a modelling framework to better assess the status of gray whales and the potential impact of human activities and possible changes in regime or climate; and (3) provide information for updating the IUCN/IWC Conservation Management Plan for western gray whales.*

A series of plausible stock structure hypotheses were developed for potential use in the population models, from which three were **initially** selected as being of highest priority. Those hypotheses included 3a, 3e, and 5a; an additional (fourth) hypothesis, 3c, was retained as a sensitivity test in the population models. Additional stock structure hypotheses were added to this list in subsequent meetings including hypothesis 6b in 2016 and 3b in 2017. Ultimately, in 2018, the Rangewide Review (IWC, 2018b; SC/67B/REP07) (M-0437a) and the IWC SC (Ex. M-0437 (IWC, 2018a.)) decided instead to retain 3b, 6b and 3e as sensitivity tests based on information presented in Scordino and Bickham (2018) (Ex. M-0462). So, for the Rangewide Review's final modeling, hypotheses **3a** and **5a** were used as base cases in the population modelling exercises, and the remaining plausible hypotheses were modelled as sensitivity tests, including hypotheses 3b, 3c, 3e and 6b. This is discussed in Section 4.2 of the 2018 Rangewide Review final report (IWC, 2018b; SC/67B/REP07) as follows: *"The Workshop **agreed** that stock hypotheses 3a and 5a would form the references for the analyses as they appear to be most plausible, while trials would also be conducted for stock hypotheses 3b, 3c, 3e and 6b."*

The full series of stock structure hypotheses developed in the Rangewide Review is provided in Table 1, and the terminology used in the hypotheses is explained in Table 2. Notice that in Table 1 hypothesis 3b is listed as low priority. This is because the report that included this table was produced prior to that hypothesis being reconsidered and raised to high priority (Ex. M-0437 (IWC 2018)). It can be seen by perusing Table 1 that a broad spectrum of scenarios was considered, and only the ones with highest plausibility, i.e. those that are consistent with the current data, were used in the modelling. For purposes of this testimony, it is not necessary to review all of the specifics of the hypotheses being modelled or to debate their relative merits. Instead I will discuss the variable features of the hypotheses modelled in light of their relevance to the issues impinging on the proposed Makah hunt.

The two high-priority hypotheses (**3a and 5a**) considered the PCFG to be a feeding group and part of the Eastern Breeding Stock (i.e., EGWs). Judging from the fact that none of the hypotheses modelled, either as base cases or sensitivity tests, considered the PCFG to be a breeding stock, we can assume that this was thought to be implausible by the Rangewide Review participants. We can conclude from this that the best scientific evidence is that PCFG whales do not breed primarily among themselves, at least not to a sufficient degree that it has resulted in a detectable differentiation of the PCFG from the NFG according to the existing genetics (microsatellite loci) data.

Table 1.—Stock structure hypotheses taken from Table 6, P. 11 in SC/67a/Rep04.

A summary of the stock structure hypotheses initially under consideration (2015, 2016) and their status

Description	Status	Comment
(1) Panmixia with no matrilineal fidelity to feeding grounds - persistent A single breeding stock; no matrilineal fidelity to feeding grounds	No	not consistent with available data (IWC 2015)
(2) Panmixia with no matrilineal fidelity to feeding grounds - post-exploitation A single breeding stock exists, although multiple stocks may have existed in the past. No matrilineal fidelity to feeding grounds.	No	not consistent with available data (IWC 2015)
(3) Maternal feeding ground fidelity, one migratory route/wintering region used by Sakhalin whales, random mating (a) A single breeding stock (EBS) exists. The EBS includes three feeding groups: NFG, PCFG, WFG. SKNK is used by some whales that belong to the WFG and some whales that belong to the NFG.	High	
(b) The EBS is as described in 3a, except that NFG whales do not feed off SKNK. In addition, a WBS exists that overwinters in VSC and feeds in the OS (but not SI) and SKNK. Thus SKNK is used by both the WFG whales and the whales of the WBS.	Low	few or no data to assess plausibility (IWC 2015), but may be reconsidered during SC67a
(c) Same as 3a except that WFG whales migrating from SI to M occasionally travel through BSCS.	Medium	Sensitivity test
(d) Same as 3a except the EBS contains the original three feeding groups and a fourth feeding group that uses SEA.	Low	few or no data to assess plausibility (IWC 2015)
(e) Same as 3a except that a WBS exists that feeds in the OS (but not SI), EJPI, and KWJ and overwinters in VSC.	High	
(4) Maternal feeding ground fidelity, one migratory route/wintering region used by Sakhalin whales, non-random mating (a) Two breeding stocks exist and overwinter in M. One breeding stock includes NFG and PCFG, and the second breeding stock includes WFG whales. Separation between breeding stocks is maintained by WFG whales mating largely with each other while migrating to M.	Low	represented in the same way as other hypotheses in modelling (IWC 2015)
(b) Same as 3b except that a WBS exists and is made up of WFG whales that largely breed with each other while on migration to M.	Low	represented in the same way as other hypotheses in modelling (IWC 2015)
(5) Maternal feeding ground fidelity, two migratory routes/wintering grounds used by Sakhalin whales, random mating. (a) Two breeding stocks exist: EBS and WBS. The EBS includes three feeding groups: PCFG, North, and the WFG that feeds off SI. The WBS whales feed in SI, OS, and SKNK and then migrate to VSC to overwinter. SKNK is used by the WFG, the NFG, and the feeding whales that are part of the WBS.	High	
(b) Three breeding stocks exist. The EBS is as described in 5a. Two breeding stocks exist in the WNP. Both W breeding stocks feed in SI, OS, and SKNK but whales show fidelity to two different migratory routes (Pacific coast of Japan and eastern Sea of Japan) and use two separate wintering grounds.	Low	few or no data to assess plausibility (IWC 2015)
(6) Maternal feeding ground fidelity, Sakhalin whales use two migratory routes/wintering grounds without fidelity, random mating (a) A single breeding stock exists that uses wintering grounds off M as well as of VSC. Whales do not exhibit fidelity to a wintering ground. Three feeding groups exist: WFG, NFG, and PCFG. SKNK is used by both WFG and NFG.	Low	few or no data to assess plausibility (IWC 2015)
(b) Same as 6a, except the WFG whales largely breed with each other during migration, creating a second breeding stock. Whales from both breeding stocks overwinter in M and in VSC, and show no fidelity to a wintering ground.	High ¹	
(c) Same as 6a except that females' part of the WFG show fidelity to one of the two wintering areas (M and VSC), while males of the WFG do not show fidelity to a wintering ground.	Low	few or no data to assess plausibility (IWC 2015); modelling framework represented in the same way as other hypotheses (IWC 2015)
(7) Maternal feeding ground fidelity, Sakhalin whales use two migratory routes/wintering grounds with fidelity, non-random mating Three breeding stocks exist - a breeding stock comprised of WFG whales that migrate to M, a breeding stock (EBS) comprised of PCFG and NFG whales, and a WBS that includes whales that feed off SI and in the OS.	Low	modelling framework represented in the same way as other hypotheses (IWC 2015)

¹ Initially considered to be of low priority because modelling framework represented in the same way as other hypotheses (IWC 2015); when revisited, the Workshop determined that this hypothesis does differ from 5a, in that: (1) all catches off Japan are assumed to be Western stock animals; and (2) the abundance estimates off Sakhalin are assumed to relate only to the Western stock. Thus the Workshop agreed to change the status of this hypothesis to high priority (IWC 2017).

Table 2.—Terminology for stock structure hypotheses taken from Annex D, P. 19 in SC/67a/Rep04

Terminology used with respect to stock structure hypotheses

Breeding stocks. There are up to two extant breeding stocks: Western (WBS) and Eastern (EBS).

Feeding groups or aggregations.* There are up to three feeding groups or aggregations. There is dispersal between the PCFG and North Feeding Group (NFG), but the Western Feeding Group (WFG) is demographically independent of the other two feeding groups (i.e. there is no permanent movement of animals from the NFG or PCFG to the WFG).

	Feeding groups or aggregations	Abbreviation	Definition (may vary with hypothesis)
1	Western Feeding Group	WFG	Animals that feed regularly (define?) off Sakhalin Island* according to photo-identification data
2	Pacific Coast Feeding Group	PCFG	Animals that feed regularly (define?) in the PCFG area according to photo-identification data
3	North Feeding Group	NFG	Animals found in other feeding areas (and for which there is relatively little information including photo-ID)

* May need revising with regard to Southern Kamchatka animals given Justin's paper.

Sub-areas. The model includes 11 geographical sub-areas that are used to explain the movements of gray whales (breeding stocks and feeding groups) in the North Pacific and two 'latent sub-areas' used to link model predictions to observed indices of abundance.

	Sub-area	Abbreviation
1	Vietnam-South China Sea	VSC
2	Korea and western side of the Sea of Japan	KWJ
3	Eastern side of the Sea of Japan and the Pacific coast of Japan	EJPJ
4	Northeastern Sakhalin Island	SI
5	Southern Kamchatka and Northern Kuril Islands*	SKNK
6	Areas of the Okhotsk Sea not otherwise specified	OS
7	Northern Bering and Chukchi Sea	BSCS
8	Southeast Alaska	SEA
9	British Columbia to Northern California	BCNC
10	California	CA
11	Mexico	M
12	Latent sub-area	Calif-3
13	Latent sub-area	BC-BCA-3

* New at this workshop – replaces the old East Kamchatka and Kuril Islands to recognise the information from telemetry and photo-ID.

The situation with WGWs is quite different from that of the PCFG; two stock structure hypotheses were being modelled as base cases and are thus considered the most plausible ones by the IWC Scientific Committee. Under **hypothesis 3a**, there is a single breeding stock (Eastern Breeding Stock) that winters in Mexico and all the gray whales found in the Sea of Okhotsk (except for occasional strays) migrate between Mexico and the Sea of Okhotsk. These whales are considered as the WFG and part of the Eastern Breeding Stock. Under this hypothesis the historical WGW population is extinct. **Hypothesis 5a** has both Eastern and Western Breeding Stocks, and the Sakhalin whales include both Eastern Breeding Stock whales migrating to Mexico and Western Breeding Stock whales migrating to the Asian wintering ground.

It is also worth mentioning the hypotheses that were demoted to sensitivity tests. **Hypothesis 3b** is like 3a except that there is both a WFG of the Eastern Breeding Stock that migrates from the Sea of Okhotsk to Mexico, as well as a Western Breeding Stock, i.e., the descendants of the historical WGW population, that migrates between the Sea of Okhotsk and the Vietnam/South China Sea wintering ground. However, the Sakhalin whales are all WFG whales and migrate to Mexico, whereas the Western Breeding Stock whales summer elsewhere in the Sea of Okhotsk. **Hypothesis 3e** differs from 3b only in that the Western Breeding Stock whales feed not only in the Sea of Okhotsk (other than Sakhalin Island),

but also in Korea, the eastern and western sides of the Sea of Japan, and eastern Japan. **Hypothesis 6b** is succinctly described in footnote 4 on page 654 of the Report of the Third Rangewide Review (Ex. M-0436 (IWC, 2017)) as follows: “Two breeding stocks – one includes whales from the PCFG and Northern feeding sub-stocks that migrate to Mexico and largely breed with each other, and the other includes all whales that feed off Sakhalin and breed largely with each other whether on the ENP or WNP migratory routes/wintering grounds.” (Note that the term sub-stock is not one officially used by the Rangewide Review, but here the reference is to a feeding group which is one kind of sub-stock). Hypothesis 6b does not resemble the conventional or historical hypothesis of two populations, WGW and EGW, that migrate along opposite coasts of the North Pacific Ocean basin. Rather, under hypothesis 6b the Sakhalin whales represent a stock, which may or may not be the extant Western Breeding Stock, *i.e.*, the historical WGW population, that migrates along both the North American and Asian coasts with breeding occurring within the group during migration.

Notice that under four of these hypotheses (3a, 3b, 3e and 5a), including the two considered most plausible (3a and 5a), the “western gray whales” that might be encountered by Makah hunters would be WFG whales that are part of the Eastern Breeding Stock. It is only under one of these hypotheses (6b) that the “western gray whales” that might be encountered by Makah hunters would be members of a Western Breeding Stock. In my opinion, hypothesis 6b is the least plausible of these hypotheses. This is because, as explained above, hypothesis 6b assumes that the Western Breeding Stock migrates along both the North American and Asian coasts, but commercial whaling along the North American coast, which depleted the EGW, did not seem to impact the historical WGW population (Ex. M-0435 (IWC, 2014b)).

Also, Scordino and Bickham (2018) (Ex. M-0462) presented a paper at the 2018 Rangewide Review that addressed the plausibility of hypothesis 6b. They noted that in part the change to high plausibility in 2016 was due to consideration of a paper about humpback whales, which form large breeding aggregations considered to be modified leks. The paper considered the possibility that humpback whales from a “source” population moved to the breeding ground of a larger “base” population for the purpose of enhancing their breeding possibilities (Ex. M-0417 (Clapham and Zerbini, 2015)). The possibility that gray whales might also have such flexibility in selecting breeding or wintering grounds led the Rangewide Review to elevate hypothesis 6b to high priority. Scordino and Bickham pointed out that this scenario really does not fit with our knowledge of gray whale biology because gray whales do not form large breeding aggregations such as those formed by humpback whales. Nor do gray whales communicate with sound to the extent that humpback whales do, and it is therefore difficult to see how they might be attracted to such breeding aggregations from a long distance, even if such breeding aggregations existed. The Rangewide Review subsequently changed the status of hypothesis 6b to a sensitivity test.

Gray Whale Stock Structure and the Makah Hunt: With regards to the proposed Makah hunt, there are two primary stock structure issues. The first can be condensed to the question “Is the PCFG a stock or a feeding group?” In the absence of any genetics data to support the PCFG as a breeding population, *i.e.*, a stock, I concur with the Rangewide Review and consider it to be a feeding group. The existing microsatellite data are convincing that no significant difference exists between the PCFG and non-PCFG whales of the EGW population such as the NFG. It is possible that future studies with better technology might shed a different light on this, but at present I see no existing data to cause me to doubt this conclusion.

The second issue related to stock structure is “What is the stock status of the whales that summer in the Sea of Okhotsk but migrate to North America?” In part, this stems from the fact that genetic studies have shown this population differs from EGWs in both mtDNA and microsatellites. Any genetically distinct and small population will be given high conservation status by the IWC. Additionally, this group has been considered to be the remnant WGW population, the sole surviving descendants of the historical WGW stock that was hunted mainly in Korean and Japanese waters and declared extinct by the 1960s as explained above. Therefore, the ancestry of this population is a key issue in determining its evolutionary significance. This is because populations isolated by large ocean basins are likely to have had significant time and opportunity to evolve distinct adaptations that are important to conserve. Thus, how distinctive a population is, which stems from its evolutionary history, is an important consideration in conservation biology. The fact that several stock structure hypotheses are considered as plausible by the Rangewide Review points to the fact that the status of the current WGW whales is uncertain.

The identity of current WGWs is relevant to management of the Makah hunt. A key issue that has emerged is the risk to the population of accidentally killing WGWs in the hunt. Depending on the number of whales that were killed, this could be problematic because they might represent a significant proportion of the population. From an evolutionary perspective, removal of WGW whales could mean the loss of genetic diversity that could reduce the fitness of the population. As mentioned at the beginning of my testimony, it is my understanding that NMFS’s proposed regulations address this concern by minimizing the likelihood that a Makah hunter will strike a WGW to extremely low levels and by suspending the hunt in the very unlikely event of such a strike.

However, for purposes of my testimony, it is also important to note that continued use of the descriptor “critically endangered western gray whales” is misleading. It means, or at least implies, that these are the last remaining descendants of the population thought to have been made extinct by commercial whaling in Japan and Korea early in the 20th Century. Moreover, because that population was isolated by an ocean basin, it likely was very different from the EGW population genetically. We don’t know this for sure because the genetics of the pre-whaling western population has never been studied. But other marine species isolated in this way show deeper levels of genetic divergence than has been observed between the current WGW and EGW populations.

In fact, as I discuss in detail earlier in my testimony, genetics studies of the current WGW population, as described above, shows they are not very different from the EGW population. For mtDNA, there is a statistically significant haplotype frequency difference between them, but the WGW haplotypes are also found in the EGW population and there are no haplotype lineages, or groups of related haplotypes, that are unique to the WGW. For microsatellites, the level of differentiation is also statistically significant, but the magnitude of the difference is not great. And with regards to the comparisons made with genomics, some indicators suggest the WGW to be a distinct population and other analyses do not. The SNP analyses suggest that the Sakhalin population is a mixed-stock aggregation. In my opinion, the existing genetic data point towards the current WGW population as being subtly different from the EGW population, but the historical relationship of that population to those whales hunted off Japan and Korea is uncertain. It is possible that the WGWs that could be exposed to a Makah hunt are in fact part of the EGW population (i.e., the Eastern Breeding Stock); this would be the case under two hypotheses that are presently considered to have the highest plausibility and were being modelled as base cases in the Rangewide Review (3a and 5a). In that event, harm to a WGW whale would not only be unlikely but also would be of low biological concern because there would be limited to no loss of genetic diversity.

Of the other hypotheses that were retained for sensitivity trials, only hypothesis 6b suggests that WGWs that could be exposed to a Makah hunt are part of a distinct western breeding population, and that hypothesis is no longer considered to be highly plausible. Notably, even the WGWs that could be exposed to the Makah hunt under hypothesis 6b do not resemble the conventional or historical hypothesis of a geographically distinct WGW population, since WGWs under this hypothesis migrate to wintering grounds in Mexico (as well as Asia). So, the worst-case scenario, that some survivors of the historic WGW population could be exposed to the Makah hunt (where the likelihood that one might be struck would be extremely small) is only one of a spectrum of possibilities. In my opinion it is more likely that if any whales from the historical WGW population have survived, they are still migrating along the coast of Asia. Recall that Cooke et al. (2017) (Ex. M-0420) considered the Sakhalin and Kamchatka whales that migrated to Mexico as being members of the eastern breeding stock and calculated that there were from 0 to 50 Sakhalin whales that were members of a Western Breeding Stock. The latter group of whales would not migrate to Mexico and would not be susceptible to the Makah hunt. In my opinion, all whales struck during the Makah hunt will most likely be EGWs, because gray whales that migrate through the Makah's hunting area, even those that seasonally feed in the Sea of Okhotsk, are most likely EGWs.

Key Terms and Definitions Pertaining to the Marine Mammal Protection Act (MMPA): In this section, I summarize the terminology used under the MMPA to make it clear how my explanations of population structure of gray whales relate to the terminology and the goals of the MMPA. The reason this is necessary is that the terms used by IWC and the Rangewide Review, which provide the best basis for addressing the stock structure issues related to the proposed Makah hunt, differ from those used by NMFS related to the MMPA.

The MMPA uses the term "population stock" (or just "stock" or "population") to describe the fundamental unit of conservation. A population stock is: *"a group of marine mammals of the same species or smaller taxa in a common spatial arrangement, that interbreed when mature."* This is given in the MMPA (Sec. 3) and discussed in Weller et al. (2013, P. 3) (Ex. M-0473). The two key elements of this definition are that the animals occur in the same geographic location and interbreed. Thus, members of the same population have the opportunity to and in fact do breed with one another, and not, at least to the same degree, with members of another population even if they are at times found together. The latter may be because they are not found together at the critical time of breeding, or potentially because of mating preference (pre-mating reproductive isolation), but this is not likely if they are members of the same species for reasons discussed earlier in my testimony.

The objectives of the MMPA are given in Sec. 2(2) and Sec. 2(6) and include:

(1) *"[marine mammal] species and population stocks should not be permitted to diminish beyond the point at which they cease to be a significant functioning element in the ecosystem of which they are a part, and, consistent with this major objective, they should not be permitted to diminish below their optimum sustainable population."*

(2) *"... the primary objective of their management should be to maintain the health and stability of the marine ecosystem."*

It can be seen from these two objectives that the MMPA's goal is the conservation of marine mammals for the purpose of ecosystem protection. Populations are to be maintained at levels to ensure their

function in the ecosystem, at a level of optimum sustainability. Note that the goal is not to maintain an optimal level of genetic diversity, biological diversity, or evolutionary potential in the populations. Nor is the goal to recover populations to some historical level of abundance. One can surmise that such goals are consistent with the goals of the MMPA and might be achieved. Nonetheless, because populations are defined based on their reproductive relationships to other populations, genetics can be used as an effective means to test population structure hypotheses. Population genetics methods can be used to identify populations that have diverged sufficiently to have statistically significant differences at markers like mtDNA or nuclear loci, and evolutionary genetics can be used to reveal past historical relationships and features such as historical abundance and migration (gene flow) rates.

In 2016 NMFS published new Guidelines for Assessing Marine Mammal Stocks (GAMMS). This follows from a series of workshops that addressed issues of stock assessment called GAMMS I, GAMMS II and GAMMS III. The 2016 document (NMFS, 2016) (M-0454) (81 Fed. Reg. 10830) presents the findings and conclusions of the GAMMS III workshop. The guidelines recognize feeding aggregations may be comprised of members of one breeding population, or multiple breeding populations. Moreover, they can represent a single demographically-independent unit, or be comprised of a mix of two or more demographically independent units.

NMFS explained how an understanding of stock structure and the relationships of populations or feeding groups impacts conservation as part of the response to comment 13 on P. 10835 as follows:

The definition of “population stock” as “a group of marine mammals of the same species or smaller taxa in a common spatial arrangement, that interbreed when mature” is vague from a biological perspective. To some degree, all “groups” within a species interbreed when mature or else they would be considered different species according to the biological species concept. Clearly, population stock was intended to mean interbreeding at some greater level but that level is not specified. Interpretation becomes more difficult when considering known cases of migratory species with strong fidelity to both feeding and breeding grounds. Consider, for example, humpback whales that feed in Southeast Alaska and breed in Hawaii. These individuals can interbreed when mature but can (and do) interbreed with individuals that feed in other areas. If a threat occurred within Southeast Alaska that resulted in unsustainable deaths in that area, then if the “Southeast Alaska whales” were a stock, that stock’s PBR could be used as an indicator that management efforts to mitigate that threat were warranted. In contrast, if “interbreed when mature” considered all the whales in Hawaii, then the human-caused mortality in Southeast Alaska may never exceed the PBR based on Hawaii, and eventually the ecosystem in Southeast Alaska would cease to have humpback whales as a functioning part. Such cases result in an apparent conflict between the words “interbreed when mature” and the goal to maintain population stocks as functioning elements of their ecosystem. Often, changes to stock delineations in the SARs have relied on interpretation of genetic data. The Pacific SRG asks where one draws the line on what level of genetic exchange suffices to qualify as a stock. Interpretation has been based on the guidelines: “Demographic independence means that the population dynamics of the affected group is more a consequence of births and deaths within the group (internal dynamics) rather than immigration or emigration (external dynamics). Thus, the exchange of individuals

between population stocks is not great enough to prevent the depletion of one of the populations as a result of increased mortality or lower birth rates.

In my opinion, this quote is a useful description of NMFS's perspective on the difference between a population and a feeding group. Populations are composed of the members of a species that interbreed (when mature). Despite NMFS's statement, there is nothing vague about the definition of population or stock in the MMPA. It is consistent with how geneticists define a population. And yes, there can be low levels of gene flow (interbreeding) among populations. On the other hand, feeding groups are composed of individuals from one or more populations that occur together for the purpose of feeding, not mating. The quoted paragraph illustrates the dilemma of managing a feeding group that is imperiled. If it is considered a population, then based on the calculation of the Potential Biological Removal (PBR) for the group, the usual management efforts under the MMPA would be initiated upon the discovery of mortality caused by humans that exceeds the PBR calculated for the group. But perhaps the comparison of PBR and human-caused mortality would not trigger a management response under the MMPA if the PBR were derived from the true, interbreeding population and not just the smaller feeding group within that population. The dilemma stems from the fact that the MMPA seeks to protect the ecosystem role or function of marine mammals by conserving population stocks, but some population stocks separate into smaller feeding aggregations that play a role in multiple ecosystems. Unfortunately, this has resulted in efforts on behalf of some to redefine what is a population under the MMPA or to shoe-horn a feeding group to fit the population definition, as I will discuss below.

Are the Current WGW and the PCFG Population Stocks Under the MMPA? Because the nomenclature used by the MMPA to define populations differs somewhat from that used by IWC and elsewhere, I will consider whether or not the current WGW and the PCFG should qualify as population stocks under the MMPA.

In my opinion, the current WGW does qualify for status as a population stock under the MMPA because the genetics data currently indicate some degree of genetic differentiation at nuclear microsatellites and SNPs, as well as at mtDNA, from the EGW. Whereas mtDNA differences alone could be explained as this being a feeding group, the nuclear markers are indicative of some degree of reproductive isolation, or of demographic isolation or independence. Or, to say it another way, they "interbreed when mature" to a degree sufficient to be distinct at these loci. My testimony above, however, explains the uncertainty about this conclusion in that the nuclear microsatellite data show a low level of differentiation ($F_{st} = 0.01$) based on a small number of loci, and the SNP data seem to indicate the presence of two genomes being present at different frequencies at Sakhalin and Mexico. This latter point indicates that the Sakhalin whales represent a mixed-stock assemblage. One might question whether this indicates there is sufficient gene flow and immigration that Sakhalin whales don't currently "interbreed when mature" despite the differentiation of nuclear markers.

Though the existing data indicate differentiation between the current WGW and the EGW, the affinities of the current WGW population are by no means certain. They could be descendants of historical WGWs (western breeding stock) or they could be an isolated population of EGWs (western feeding group). The conservation implications of these two possibilities are quite different in my opinion, although the implementation of conservation measures under both scenarios might be the same. This is because there are only a few things that we can do to protect great whales. These measures include controlling fishing, whaling, shipping and industrial activities. Therefore, an understanding of exactly

what it is that is being protected, part of a large population, a distinct population or stock, a subspecies, etc., is important because it helps managers assess the risk to the species as a whole of the loss of the entity. At the 2018 IWC Scientific Committee meeting, hypotheses 3a and 5a from the Rangewide Review were given priority for modelling because they are considered the most plausible hypotheses. Other hypotheses, including 3b, 3c, 3e, and 6b, were used as sensitivity tests. According to the SC (IWC 2018, p. 39) (Ex. M-0437): “In summary, Hypothesis 3a assumes that whilst two breeding stocks (Western and Eastern) may once have existed, the Western Breeding Stock is extirpated. Whales show matrilineal fidelity to feeding grounds, and the Eastern Breeding Stock includes three feeding aggregations: Pacific Coast Feeding Group (PCFG), Northern Feeding Group (NFG), and the Western Feeding Group (WFG). Hypothesis 5a assumes that both breeding stocks are extant and that the Western Breeding Stock feeds off both coasts of Japan and Korea and in the northern Okhotsk Sea west of the Kamchatka Peninsula. Whales feeding off Sakhalin include both whales that are part of the extant Western Breeding Stock and remain in the western North Pacific year-round, and whales that are part of the Eastern Breeding Stock and migrate between Sakhalin and the eastern North Pacific.” The implication of this for the proposed Makah hunt is that under the two hypotheses considered most plausible by IWC, the Western Breeding Stock does not migrate through the area of the Makah hunt. The Western Breeding Stock is either extinct (3a) or stays in the western North Pacific (5a). The whales from Sakhalin that migrate to North America are considered to be WFG whales, and part of the Eastern Breeding Stock.

The PCFG does not qualify as a population stock under the MMPA, in my opinion, no matter how one parses the definition. This is because members of the PCFG do not “interbreed when mature”, at least to the degree necessary to allow the population to become differentiated at nuclear loci. Let’s imagine a human analogy to the PCFG. There are distinct and small populations of humans, such as the San or bushmen of southern Africa. Such populations are demonstrably genetically distinct and would qualify as populations using the MMPA definition of population stock. But there are other uses of the word population to mean, for example, a group of people with some learned skill. Perhaps the population of people who quilt tend to learn this skill from their mothers and thus are recruited into the quilting population in this way. One can imagine that this small population might be distinct from the overall population in terms of mtDNA haplotype frequencies, that no unique haplotypes exist in this population for obvious reasons, and that nuclear genes do not differentiate this population also for obvious reasons. And notwithstanding the fact that we can refer to such people as a population, it is not a population in the biological sense of the word even though internal recruitment may predominate. So, the quilting population would not qualify as a population under the MMPA because they do not “interbreed when mature.” This analogy closely parallels the feeding groups of whales as we understand them. Despite having qualities that we wish to conserve, and even though internal population dynamics may predominate, neither conforms to a population as defined in biology and the MMPA.

Addressing the Concerns of the Animal Welfare Institute

In a letter dated July 31, 2015 and addressed to Steve Stone of NMFS, DJ Schubert of the Animal Welfare Institute outlined concerns with regard to the Makah Tribe’s application for a waiver under the MMPA. Of the numerous points made in the 130-page letter, one is particularly germane to my testimony. On page 4 of the letter, Mr. Schubert writes:

“Furthermore, before proceeding with this decision-making process, it is imperative that NMFS render a determination as to whether PCFG whales constitute a population stock under the MMPA.”

I agree that the status of the PCFG is an important issue. However, it is important to remember that, as mentioned above, NMFS has proposed regulations to protect the PCFG regardless of its status.

Moreover, I disagree with Mr. Schubert on p. 23 where he states:

“The best available scientific information provides ample support for the designation of PCFG whales as a stock.”

In fact, as I discuss in detail above, the evidence does not support this. Under the MMPA members of a “population stock” occur together in “a common spatial arrangement” and they “interbreed when mature.” Again, the intended definition of a population stock under the MMPA is essentially the same as the typical definition of a biological population in which individuals breed with other members of that population and not, or at least with less frequency, with members of another population. There is no evidence that the PCFG satisfies this definition. Rather the PCFG is a feeding group, which in this case means an aggregation of whales that share a common behavior, feeding in the PCFG area during the summer and fall, but do not predominantly breed among themselves. The significant F_{ST} in mtDNA is the result of the strict maternal inheritance of the molecule, combined with the maternally directed learned feeding behavior.

This is not to say that the PCFG does not deserve to be conserved (and, as noted, NMFS has proposed regulations for that purpose), but it goes to the point that we need to be clear and transparent in our use of scientific terminology. We cannot ascribe a definition to a group that imparts characteristics not possessed by the group. If the MMPA is to be applied to feeding aggregations like the PCFG, then the law should clearly state it. Because it does not do so, I agree with NMFS’s position (Ex. M-0473) Weller et al. (2013), (Ex. M-0453) NMFS, 2015)) that the PCFG is not a population stock under the MMPA.

JOHN W. BICKHAM

CURRICULUM VITAE

Address: John W. Bickham
 Professor Emeritus
 Department of Wildlife & Fisheries Sciences
 Texas A&M University
 College Station, TX 77843
 Mobile: 1-979-777-2873
 email: Bickham@tamu.edu

Mailing Address:
 31526 Lower Oxbow Trace
 Fulshear, TX 77441

Degrees: University of Dayton, Dayton, Ohio, B.S. 1971
 University of Dayton, Dayton, Ohio, M.S. 1973
 Texas Tech University, Lubbock, Texas, Ph.D. 1976

Thesis and Dissertation:
 M.S. Thesis: A cytosystematic study of the Clemmys complex.
 Ph.D. Dissertation: Chromosomal banding and phylogenetic relationships of vespertilionid bats.

Major Interest:
 Molecular Genetics, Genomics, Cytogenetics, Marine Mammals,
 Molecular Systematics, Evolutionary Toxicology, Ecotoxicology

Professional Positions:
 2013-present Professor Emeritus, Department of Wildlife and Fisheries
 Sciences, Texas A&M University
 2012-2016 Principal Scientist, Battelle Memorial Institute
 2006 - 2012 Professor, Department of Forestry and Natural Resources,
 Purdue University
 2006 - 2011 Director, Center for the Environment, Purdue University
 1986 - 2006 Professor of Wildlife and Fisheries Sciences,
 Texas A&M University
 1983 - 1986 Associate Professor of Wildlife and Fisheries Sciences,
 Texas A&M University
 1976 - 1983 Assistant Professor of Wildlife and Fisheries Sciences,
 Texas A&M University

Society Affiliations:
 American Society of Mammalogists
 Southwestern Association of Naturalists
 Texas Society of Mammalogists

Honors: President, Southwestern Association of Naturalists 1985-1987.

Distinguished Performance Award - Graduate Teaching, Texas A&M University System 1985.
 Distinguished Professor Award, Association of Graduate Wildlife and Fisheries Scientists, Texas A&M University 1986.
 Southwestern Association of Naturalists, Donald W. Tinkle Research Excellence Award, 1990.
 Member of the Board of Governors, Southwestern Association of Naturalists, 1977-present.
 Best Paper Award, Texas Chapter of the Wildlife Society, for a paper in J. Wildl. Manage. (1994) with D. L. Ellsworth, et al.
 Distinguished Performance Award – Research, Texas Agricultural Experiment Station 2005
 President, Texas Society of Mammalogists, 2006 (president-elect) – 2007
 Award of Appreciation received from the Alaska Eskimo Whaling Commission at the annual meeting in Barrow, Alaska February 2008 for my participation in the Scientific Committee of the International Whaling Commission and my efforts in helping to obtain a 5-year quota for the harvest of bowhead whales (8-ft plate of baleen with scrimshaw).
 Honorary member, Texas Society of Mammalogists, bestowed February 2009

Editorial Experience:

Managing editor of the Southwestern Naturalist 1982- 1984.
 Associate Editor of the Journal of Mammalogy 1989-1992.
 Presently a member of the review board for *Ecotoxicology*.

University Administrative Experience:

Purdue
 Director the Center for the Environment 2006-2011.
 Texas A&M
 Member of the Executive Committee of the Faculty of Genetics, 1980-82, 1984-86. Vice-chairman of the Faculty of Genetics 1985. Graduate Advisor and Chairman of the Graduate Affairs Committee, Department of Wildlife and Fisheries Sciences, 1988-1989. Chairman of the departmental Tenure and Promotion Committee, 1993-1995. Member of Texas A&M University Laboratory Animal Care Committee 2002-2005.

International Administrative Experience:

Member of the US delegation to the Scientific Committee of the International Whaling Commission, 2003 to present.
 US team leader for the US Department of State “US-China EcoPartnership” 2011-2012.
 Independent International Consultant to BP in Azerbaijan. I advised BP’s environmental program regarding their offshore environmental monitoring program in the Caspian Sea. 2007 to 2009.

Administrative Workshops

Engagement Academy for University Leaders, Virginia Tech University, June 22-26, 2009, Roanoke, VA.

Private Sector Administrative Experience:

Principal Scientist, Battelle Memorial Institute, Houston Texas, 2012 to 2016.
 Vice President for Research (and co-founder), LGL Ecological Genetics, Inc., Bryan, Texas 1990-1995.

Courses Taught:

Texas A&M University:

WFS 302, Natural History of the Vertebrates. A 3-credit undergraduate course designed as an introductory vertebrate zoology course for both science and non-science majors.

WFS 401, General Mammalogy. A 3-credit undergraduate course designed to be an important foundation course in wildlife science. The study of structure, function, phylogeny, classification, biology, and economic relationships of mammals.

WFS 601, Vertebrate Systematics. A 3-credit graduate course designed to be an introduction to systematic theory, practice, and methodology.

WFS 602, Vertebrate Cytosystematics. A 3-credit graduate course that covers applications of cytogenetic techniques to evolutionary studies of vertebrates.

Purdue University

FNR 396B Ecological Genetics of our Natural Resources. A 1-credit graduate seminar on natural resource genetics.

Graduate Students Completed (Texas A&M):

Mike W. Haiduk, M.S., 1979.

Thesis: A Comparative analysis of karyology and hyoid morphology of the Chelydridae (Reptilia: Testudines).

Presently Associate Professor, Lamar University.

Jack W. Sites, Jr., Ph.D. (Co-chair with J. R. Dixon), 1980.

Dissertation: Chromosome, allozyme, and morphometric variation in three cytotypes of the *Sceloporus grammicus* complex. Presently Professor, Brigham Young University.

Robert H. Dean, M.S., 1980.

Thesis: Selected aspects of the ecology of the Central American mud turtle, *Staurotypus salvinii*.

Timothy W. Houseal, Master of Science, 1980.

Thesis: Geographic variation in the yellow mud turtle, *Kinosternon flavescens* from the central and southwestern United States, and northern Mexico.

John L. Carr, M.S., 1981.

Thesis: Phylogenetic implications of chromosomal variation in the Batagurinae (Testudines: Emydidae). Presently Professor, Department of Biology, and Associate Curator, Museum of Natural History, The University of Louisiana at Monroe.

Presently Assistant Profess, NE Louisiana St. Univ.

Robert C. Dowler, Ph.D., (Co-chair with D. J. Schmidly) 1982.

Dissertation: Genetic interactions among three chromosomal races of the *Geomys bursarius* complex (Rodentia: Geomyidae). Presently Professor, Angelo State University.

Mark D. Engstrom, Ph.D. (Co-chair with D. J. Schmidly), 1984.

Dissertation: Chromosomal, morphological, and allozymic variation in the *Oryzomys melanotis* species complex.

Presently Vice President for Research, Royal Ontario Museum, and Professor, University of Toronto.

Priscilla K. Tucker, Ph.D. 1984.

Dissertation: Sex chromosome-autosome translocations in the leaf-nosed bats, family Phyllostomidae.

- Presently Professor, University of Michigan.
- Karen McBee, Ph.D. 1985.
Dissertation: Chromosomal aberrations in resident small mammals at a petrochemical waste dump site: A natural model for analysis of environmental mutagenesis.
Presently Professor, Oklahoma State University.
- David W. Burton, M.S. 1986.
Thesis: Heterochromatin and DNA content in *Geomys attwateri* and *G. breviceps* (Rodentia: Geomyidae).
- Scott W. Ballinger, M.S. 1987.
Thesis: Allozymic and mitochondrial DNA analysis of sympatric white-tailed and mule deer in West Texas.
Presently Associate Professor of Pathology, University of Alabama, Birmingham.
- Samuel F. Lockwood, M.S. 1989.
Thesis: Flow cytometric analysis of DNA content in spawning and coastal samples of Arctic cisco (*Coregonus autumnalis*).
- James N. Derr, Ph.D. (Co-chairman with D. J. Schmidly) 1990.
Dissertation: Genetic interactions between two species of North American deer, *Odocoileus virginianus* and *Odocoileus hemionus*. Presently Professor, Texas A&M University.
- Thomas E. Lee, Jr., Ph.D. 1992.
Dissertation: Mitochondrial DNA and allozyme analysis of pronghorn populations in North America.
Presently Associate Professor, Abilene Christian University.
- Juan Carlos Morales-Muciño, Ph.D. 1992.
Dissertation: Molecular systematics of the tree bats, genus *Lasiurus*.
Presently Program Officer, Systematic Biology, National Science Foundation.
- Luis A. Ruedas, Ph.D. 1992.
Dissertation: Genome size evolution in the Class Mammalia. Presently Associate Professor at Portland State University.
- Michael J. Smolen, Ph.D. 1992.
Dissertation: Variation in the chromosomes of five species of pocket gophers in the genus *Geomys* as detected by differential staining, and the phylogenetic implications.
- James C. Cathey, M.S. 1993.
Thesis: Sequence analysis of a zinc-finger gene for the examination of paternal lineages and introgressive hybridization in North American deer.
Presently Assistant Professor and Extension Wildlife Specialist, Texas A&M University.
- Thomas Barret Lyne, Ph.D. (Co-chair with K. W. Brown) 1995.
Dissertation: The impact of environmental pollution on the genetic integrity of indigenous species and the application of biosassays in risk assessment. Presently working in the private sector.
- Stirling J. Robertson, M.S. 1996
Thesis: A phylogenetic study of *Lasiurus* (Chiroptera: Vespertilionidae) using the Zfx/Zfy loci. Presently Ph.D. student, Florida Institute of Technology.
- Jeffrey K. Wickliffe, M.S. 1997
Thesis: Cell cycle perturbations in *Peromyscus* and *Microtus* inhabiting sites contaminated with radioactive and nitroaromatic waste. Presently

- Assistant Professor, Tulane University.
- Yigong Lou, Ph.D. 1998
Dissertation: Genetic variation of pronghorn (*Antilocapra americana*) populations in North America. Presently Postdoctoral Researcher, Stanford University.
- Donnell S. Frank, M.S. (Co-chair with M. Mora) 1999
Thesis: Chlorinated pesticides, polychlorinated biphenyls, and dioxins in colonial nesting waterbirds of Galveston Bay, Texas.
- William James Rogers, Ph.D. 1999
Dissertation: Development and application of an integrated model for ecological risk assessment employing the spatial habitat equivalency method. Presently Professor and Associate Dean of Academic Environmental Health and Safety, West Texas A&M University.
- Robert G. Trujillo, MS 2001
Thesis: Macrogeographic variation of nuclear Microsatellite loci in an endangered species, *Eumetopias jubatus*. (See below).
- Daniel Musquiz, MS (Co-chair with M. Mora) 2003
Thesis: Cave and Cliff Swallows as indicators of exposure and effects of environmental contaminants on birds from the Rio Grande, Texas.
- Alyson Baker, MS 2003
Thesis: Variation of Mitochondrial Control Region Sequences of Steller Sea Lions, *Eumetopias jubatus*: The Three-Stock Hypothesis.
- Carol D. Swartz, Ph.D. (Co-chair with K. C. Donnelly) 2004
Dissertation: Integrating environmental sampling and wildlife biomonitoring in exposure and effects assessment: genotoxins at multiple levels of biological organization. Presently works for Integrated Laboratory Systems, Incorporated.
- Cole W. Matson, Ph.D. 2004
Dissertation: Integrating environmental sampling and wildlife biomonitoring in exposure and effects assessment: genotoxins at multiple levels of biological organization. Presently Executive Director, Center for the Environmental Implications of NanoTechnology, Duke University.
- Robert G. Trujillo, Ph.D. 2005
Phylogenetics of the genus *Scotophilus* (Chiroptera: Vespertilionidae): perspectives from the nuclear and mitochondrial genomes. Presently Deputy Director – Ecosystem Analysis, Planning, Watershed, & Air Southwestern Region, US Forest Service.
- Devra D. Hunter, M.S. 2005
Did bowhead whales (*Balaena mysticetus*) from the Bering-Chukchi-Beaufort Seas undergo a genetic bottleneck? A Test Using Nuclear Microsatellite Loci.
- Jason M. Sweny, M.S. 2005
A comparison of diversity in the ZFY gene in two species of pinnipeds with different breeding strategies.

Megan A. Sitzlar, M.S. (Co-chair with M. Mora) 2005

P450 aromatase alterations and DNA damage as avian pollution biomarkers in Cliff and Cave Swallows breeding near the Rio Grande region, Texas.

Ryan M. Huebinger, Ph.D. 2007

Genetic Relationships and Evolutionary History of Extant Bowhead Whale Populations, *Balaena mysticetus*. Presently Postdoctoral Instructor, University of Texas Southwestern Medical Center.

Graduate Students Completed (Purdue):

Caleb D. Phillips, Ph.D. 2008

Systematics, molecular evolution, and phylogeography of Steller sea lions, *Eumetopias jubatus*. Presently Assistant Professor, Texas Tech University.

Brian Rinner, MS, 2009

Evolutionary Toxicology of the Invasive Eastern Mosquitofish (*Gambusia holbrooki*) in Azerbaijan.

Geoff Laban, PhD. 2011

The effects of silver nanoparticles on fathead minnow (*Pimephales promelas*) embryos.

Former Postdoctoral Research Associates

Dr. Steven M. Carr. Presently Professor, Memorial University, St. John's, Newfoundland, Canada.

Dr. Christopher W. Theodorakis. Presently Associate Professor, Southern Illinois University Edwardsville

Dr. Dmitri V. Politov. Presently at Vavilov Institute of General Genetics, 3 Gubkin St., GSP-1, Moscow 119991, Russia

Dr. Cole W. Matson. Presently Associate Professor, Baylor University, Waco Texas.

Dr. Ryan Huebinger. Presently Instructor, University of Texas Southwestern Medical Center.

International Agreements

Purdue University and the Chinese Academy of Sciences. September 10, 2010 to September 9, 2015, LOA between Purdue University, Discovery Park, Center for the Environment and the Chinese Academy of Sciences, Institute of Applied Ecology establishes a "China-US Joint Research Lab on Sustainable Ecosystem."

Purdue University and the Azerbaijan National Science Foundation. April 2, 2011 to April 1, 2016, LOA between Purdue University, Discovery Park, Center for the Environment and the National Science Foundation of Azerbaijan to promote collaborative research projects, seminars, and training courses.

Purdue University and Zhejiang University. July 20, 2011 to July 19, 2016, LOA,

Purdue University, Discovery Park, Energy Center and the Center for the Environment and the State Key Laboratory of Clean Energy Utilization to establish the creation of the Clean Energy Research Initiative.

Communicated by Robert T. Paine, University of Washington, Seattle, WA, June 29, 2007 (received for review December 20, 2006)

Ecosystem restoration may require returning threatened populations of ecologically pivotal species to near their former abundances, but it is often difficult to estimate historic population size of species that have been heavily exploited. Eastern Pacific gray whales play a key ecological role in their Arctic feeding grounds and are widely thought to have returned to their prewhaling abundance. Recent mortality spikes might signal that the population has reached long-term carrying capacity, but an alternative is that this decline was due to shifting climatic conditions on Arctic feeding grounds. We used a genetic approach to estimate prewhaling abundance of gray whales and report DNA variability at 10 loci that is typical of a population of $\approx 76,000$ – $118,000$ individuals, approximately three to five times more numerous than today's average census size of 22,000. Coalescent simulations indicate these estimates may include the entire Pacific metapopulation, suggesting that our average measurement of $\approx 96,000$ individuals was probably distributed between the eastern and currently endangered western Pacific populations. These levels of genetic variation suggest the eastern population is at most at 28–56% of its historical abundance and should be considered depleted. If used to inform management, this would halve acceptable human-caused mortality for this population from 417 to 208 per year. Potentially profound ecosystem impacts may have resulted from a decline from 96,000 gray whales to the current population. At previous levels, gray whales may have seasonally resuspended 700 million cubic meters of sediment, as much as 12 Yukon Rivers, and provided food to a million sea birds.

cetacean | coalescence | effective population size | genetic diversity | historic abundance

Studies of ecologically important marine populations from corals (1) to pelagic predators (2) suggest that many current marine ecosystems are far from their natural states because of anthropogenic disruption. Detecting and measuring the impacts of such changes is complicated because information about past marine population abundance is generally difficult to obtain (3). However, knowledge of past abundances can be important for managing and restoring ecologically important populations recovering from overexploitation, such as those of many baleen whale species. Information about past population sizes of baleen whales can be derived from the level of genetic variation in current populations, because genetic diversity increases with long-term effective population size and can be relatively unaffected by moderate short-term changes in census size. Genetically determined past population sizes for Atlantic humpback, minke, and fin whales are surprisingly high (4), prompting the need for further exploration of results from other species and expanded genetic data sets.

Using genetic data to assay past populations depends on the balance between genetic drift reducing variation at individual loci and mutation increasing it. The relationship between genetic diversity and population size also varies with population subdivision, natural selection, changes in population size over time, and departures from perfectly random mating. Because the impacts of these factors generally vary across the genome, measuring patterns of genetic variation among multiple loci

allows more accurate inference of past population sizes than is possible with a single locus. The International Whaling Commission suggested five areas for expanding and improving genetic approaches to inferring past population sizes of whales (5): (i) using multiple unlinked nuclear loci, (ii) confirming locus-specific substitution rates, (iii) estimating overall variance in abundance estimates, (iv) considering the long-term nature of population estimates, and (v) analyzing the effect of unsampled, “ghost” populations. Here, we concentrate on a single species, the gray whale (*Eschrichtius robustus*), and expand previous analyses to include measurements of diversity and mutation rate at many loci. In addition to using multiple loci, we consider the long-term nature of population estimates and analyze the effect of unsampled, ghost populations.

Gray whales were extensively hunted in the 19th century and currently persist as an eastern Pacific population assumed to have fully recovered from whaling, and a western Pacific population that remains critically endangered. For eastern gray whales, the presumption of full recovery is based on recent census counts of between 18,000 and 29,000 (6), including particularly low population estimates in 1999–2001 that roughly match model-based, prewhaling estimates of 19,480–35,430.[†] This presumed recovery has resulted in diminished management concern for eastern gray whales. For example, the recovery factor, a parameter used in marine mammal management to calculate acceptable human-induced mortality (7), has been increased for eastern gray whales compared with all other baleen whales by a factor of 10 (8), a change that will effectively slow, but not prevent, full recovery.

However, other interpretations of gray whale population dynamics suggest there has been no demographic plateau. Instead, the low population estimates in 1999–2001 may have resulted from recent climate change in the Bering Sea (9). Although population models that incorporate the 1999–2001 decline support the idea that this population has reached its carrying capacity,[‡] models that do not include data from these years find some support for an equilibrium population size (N_{eq}) of up to 70,000 (10). Recent resurgence of calving rates to pre-1999 levels[§] and new calving locations (11) also suggest this population has not yet reached its typical long-term abundance but can continue to grow if current ocean conditions permit.

Author contributions: S.E.A. and S.R.P. designed research; S.E.A. performed research; S.E.A., E.R., and S.R.P. analyzed data; and S.E.A., E.R., and S.R.P. wrote the paper.

Fig. 2. Simulation of demographic bottlenecks. Shown is the likelihood of the observed parameter H_d (haplotype diversity) given a bottleneck scenario beginning 15–80 generations ago. A linear regression was used to determine the generation at which the likelihood falls below 0.01 (73 generations ago or $\approx 1,100$ – $1,600$ years).

commercial whaling if a large population decline occurred before the mid-1800s. Tests for departure from neutral distributions of alleles within populations and segregating sites (Tajima's D , Fu and Li's D^* , Fu's F) (SI Table 3) showed no evidence for loci under selection, or for significant population growth or decline. A separate way to estimate past population dynamics is to use coalescent analysis (12, 17). However, the low average mutation rate across whale introns and the large gray whale population size lengthen the time period over which our data provide useful views of population changes. Coalescent analyses performed on our intron data set show no long-term growth or decline, but lack the power to detect relatively recent population swings.

However, loci with relatively high mutation rates and more sensitivity to genetic drift are more useful for testing for changes in population size, so we used current mitochondrial DNA haplotype diversity in gray whales to examine the effects of different bottleneck scenarios. We carried out coalescent simulations of bottleneck events at a variety of times before the onset of commercial whaling, to test whether such an event could explain differences between genetic and historic estimates (see *Materials and Methods*).

We simulated a prewhaling census size change from 96,000 to 22,000, approximately the difference between genetic estimates and average census size today, varying the bottleneck time from 15 generations to 10,000 generations ago. We then tested for significant reductions in mitochondrial haplotype diversity in simulated vs. current populations. These tests show that haplotype diversity (H_d) significantly declines for all bottlenecks occurring longer ago than 73 generations, or $\approx 1,100$ – $1,600$ years ago (Fig. 2). These analyses are therefore inconsistent with the hypothesis that a bottleneck from 96,000 to 22,000 animals further back in time than 1,100–1,600 years can explain the difference between our genetic estimate and prior estimates of historic abundance: such a bottleneck would have eroded haplotype diversity well below the current value.

Quantifying the Effects of Population Structure. A final consideration is population structure, because genetic diversity among subpopulations can inflate N_e . In general, estimates of effective population size exceed real population size in this situation by a factor of $\approx 1/(1 - F_{ST})$, where F_{ST} is the proportion of genetic variance distributed spatially (ref. 18, equation 2.7 based on ref. 19). Available data show no observable structure within the eastern Pacific gray whale population (reviewed in ref. 20). To further confirm this result, we collected data from six microsatellite loci for the same whales used in this study and estimated

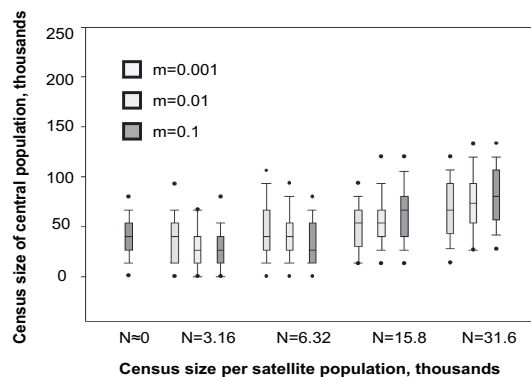

Fig. 3. Simulation of migration from satellite populations. The census size of the central population increases with migration to and from a satellite population, as the size of the satellite population approaches that of the main population and as migration rate increases (m , proportion of migrants per generation). Box plots show median values and 25th and 75th percentiles, whiskers show 10th and 90th percentiles, and dots represent 5th and 95th percentiles across 100 simulated data sets per scenario.

the probabilities of one population ($K = 1$) versus multiple populations ($K > 1$) by using STRUCTURE, version 2 (21). No population subdivision is apparent in our data, suggesting that our estimate of genetic diversity is not inflated by current population substructure.

However, two other populations may have contributed genetic diversity to the eastern Pacific population in the past: the western Pacific population (16) and an extinct Atlantic population (22). A recent study comparing mitochondrial control region data between the eastern and western Pacific gray whale populations (23), potentially inflating our estimate of population size in the eastern population by about a factor of $\approx 9.5\%$ [$1/(1 - 0.087) = 1.095$]. However, this formulation assumes the populations are at migration–drift equilibrium, which is unlikely to be true for gray whales. To capture the complex contribution of potentially nonequilibrium migration scenarios to current-day genetic diversity, we constructed a series of population simulations to estimate the impact of migration from partially isolated western and Atlantic gray whales on genetic diversity in eastern gray whales. Our basic question was whether periodic migration from small satellite populations could significantly increase genetic diversity in a central population.

We simulated a set of scenarios likely to be realistic given the appearance and disappearance of biogeographic barriers over the past 200,000 years (SI Fig. 4). Migration between the eastern and western Pacific populations is allowed during the last glaciation (18–70 kya), and the Little Ice Age (400–750 ya) when sea ice or lower sea level may have blocked migration through the Bering Sea (24). Arctic migration between the eastern Pacific and the Atlantic is assumed to have been possible only during interglacial, warm periods, most recently during the Sangamonian Interglacial period (114–131 kya).

Simulations with a variety of migration rates were conducted by using effective population sizes as input values, but in the following, we converted these effective sizes to estimated census size by using the conversion factors described above. Simulations of an eastern population with an effective size of 11,500 (corresponding to a census size of 40,000) and small populations in the western Pacific and Atlantic (census size, 3,000–6,000 each) show no impact on the genetic diversity of the eastern Pacific (Fig. 3). Large satellite populations, however, can increase the genetic diversity of the eastern population. Of course, at these large sizes (approximate census size of 30,000) (Fig. 3), the western and Atlantic populations contain a substantial fraction

increase the apparent genetic diversity of whale populations. Accounting for past population structure is complex, given a potentially infinite number of past migration scenarios. We simulated a set of scenarios in which genetic diversity might have been injected into the eastern Pacific population from the western Pacific population when it was larger, or from the Atlantic before that population became extinct. Our simulations suggest that small populations in the western Pacific or in the Atlantic would not have appreciably increased genetic diversity in the eastern population. However, historical migration from a large western Pacific population could partially explain high genetic diversity in the eastern Pacific.

As a result, our long-term estimate of 96,000 gray whales was probably distributed between the eastern and western populations. Very few data are currently available on historical abundance and whaling effort in the western Pacific stock (20), but it is possible that this population was substantially larger than it is now. Future analysis of these two populations using multiple nuclear loci and the IM approach used by Won and Hey (25) to investigate ancestral and effective sizes in chimpanzees might be a profitable way to address these issues.

Implications for Management. Conservation efforts have resulted in a steep decline in extinction risk for eastern Pacific gray whales, but our results suggest that full demographic recovery has not occurred and that this population remains depleted. Mean census counts of $\approx 22,000$ (8) are 28–56% of the minimum genetic long-term estimates, assuming up to half the population have typically been western. Because marine mammal populations <50 –70% of historic population size are considered depleted (7), a cautionary response to these data would be to consider the eastern Pacific gray whale as a depleted stock. Such a designation could change the allowable human-caused mortality of this stock under the U.S. Marine Mammal Protection Act from ≈ 417 animals a year to ≈ 208 , assuming the recovery factor (7) used in calculating potential biological removal (7, 8) changes from 1.0 (8) to 0.5 (7, 30). Currently, an aboriginal take of 125 animals per year is allowed by the International Whaling Commission (8, 30).

For gray whales, historic population data help clarify population trends. Models that incorporate census data from 1999–2000 indicate that gray whales have reached their carrying capacity (7), but other interpretations suggest that high mortality in 1999–2000 represented an ephemeral episode due to climatic shifts (9). Genetically determined long-term population estimates support the hypothesis that the current population has not fully recovered and will continue growing if ecological conditions permit.

An important question for current whales is whether carrying capacity has declined over time. If this is the case, gray whales may be depleted relative to historical numbers but may have reached carrying capacity today. Ecological surveys of gray whale feeding areas on the Bering Sea shelf suggest that this area alone could support $\approx 90,000$ whales annually (see *SI Methods*). However, recent evidence suggests that gray whale feeding habitat may be declining as Arctic benthic prey populations are reduced because of changing climate in the Bering Sea (9). Although additional survey data will be critical to determining whether carrying capacity has been reached, our estimate of typical gray whale abundance suggests that recent problems in gray whale feeding, including reports of thin adults or high calf mortality, may result from changing conditions in northern feeding grounds.

Ecosystem-Wide Impacts of Gray Whale Depletion. In addition to implications for management, these data are a first step toward quantification of the ecosystem effects of whale population depletion in the North Pacific. Gray whales are important ecological structuring agents in Bering Sea benthic marine communities (31, 32). Because they are bottom feeders that suck up mouthfuls of

sediment, study of feeding gray whales shows $\approx 1.2 \times 10^8 \text{ m}^3$ of sediment were annually resuspended by the eastern Pacific gray whale population of the early 1980s (33, 34). Assuming a population size then of $\approx 16,000$ individuals, a population of 96,000 gray whales would rework $\approx 7.2 \times 10^8 \text{ m}^3$ in a summer, ≈ 12 times larger than the sediment transport load of the largest river emptying into the Bering Sea, the Yukon River (35, 36). Decreased sediment reworking could dramatically change nutrient recycling, and create shifts in benthic species dominance (32).

Similarly, feeding by gray whales provides nutrient subsidies from benthic marine communities to terrestrial ones, including food subsidies for at least four species of seabirds that feed on benthic crustaceans brought to the surface by gray whale feeding (37). The number of birds attending the foraging activities of a single gray whale averages ≈ 11 , although the number of plumes used per bird and the use of plumes from different whales are not known. If this average is representative across the summer season, we calculate that a population of 96,000 whales could provide food subsidies to 1.03 million birds. The quantitative impact of these subsidies on sea bird reproduction or fitness is currently unexplored. In addition, gray whales may have provided an important food source for predators and scavengers such as orcas (38) and California condors (39).

More numerous gray whales in the past may not have fed only on the Bering and Chukchi shelves, the areas in which the majority of individuals feed today. As gray whale populations have increased, more and more are observed feeding in other coastal locations including Oregon, Washington, British Columbia, and southeast Alaska (e.g., ref. 41). If feeding in other areas was common, the ecological impact of diminished gray whale populations would not be restricted to the Arctic.

Overall, these simple calculations of gray whale impact do not fully document the likely ecological impact of whales; they merely suggest the order of magnitude of effects of gray whales on their environment. Further research on ecological subsidies of whales to seabirds, sediment and nutrient effects, and ecological shifts of whales during population expansion are critically needed to better understand how marine ecosystems have been impacted by reduced whale populations.

Conclusions

Genetic-based abundance data suggest that gray whale populations were typically larger than they are today: the whole Pacific population likely numbered three to five times the current population. These numbers suggest the eastern Pacific population, even if it historically accounted for only half of the entire Pacific population, should be considered depleted and should regain higher management protection. Recently observed changes in the eastern Pacific gray whale population are unlikely to be the result of this population reaching its long-term carrying capacity; rather, these changes may have been transient or they may represent first responses to altered ecological conditions and reduced carrying capacity in the Bering Sea and other habitats (9). Ocean nutrient cycling, sediment transport, and ecological subsidies may have been far different in the past when gray whales were more abundant. Although restoring gray whales to their full former abundance in the North Pacific may be unrealistic because of such large-scale environmental changes in critical feeding areas, an improved knowledge of past abundance allows a more comprehensive assessment of the ecological impacts of gray whale population decline. Historic data have been eliminated from much of conservation management (7, 30, 41). However, our data suggest that such information can provide a critical context for evaluating population trends and in determining the potential ecosystem impacts of ecologically important threatened and endangered species.

Materials and Methods

Estimating Genetic Population Parameters. The diversity parameter Θ was calculated by using LAMARC (12), by jointly estimating Θ across multiple loci while incorporating relative μ and N_e values for each locus. Among genomic regions (seven autosomal nuclear introns, two X-linked introns, and cytochrome *b*), we applied scaling factors of 4 and 4/3 to our mitochondrial and X chromosome N_e values, respectively, and computed Θ by using a scale in which the average relative mutation rate among autosomal loci is unity. These two sets of scaling factors allowed us to calculate the population's Θ from a multidimensional likelihood surface constructed from all loci. To ensure model convergence, we performed each LAMARC analysis 15 times, using three different random number seeds and five different trial values for Θ . For each gene, we performed 10 MCMC searches of 31,000 iterations each followed by two searches of 1,001,000 iterations each, sampling every 20th genealogy estimate after discarding the first 1,000 estimates of each search.

Substitution rate was estimated by comparing pairwise genetic distance between 4 and 14 species of baleen whales and their respective divergence times (27). We used the program MODELTEST (42) to determine the appropriate mutational model, and PAUP* to generate pairwise genetic distances (43).

Bottleneck Simulations. We used SIMCOAL (44) to simulate a sequence of 523 bp for 42 individuals, the length of the control region segment we obtained, and used a mutation rate of 5×10^{-8} bp⁻¹ year⁻¹, which is the mutation rate necessary to obtain the same average effective size of eastern North Pacific gray whales for control region data as we found for intron data. We used an empirically determined transition bias of 0.96 and a rate heterogeneity parameter of 0.8. The empirical likelihood of haplotype diversity (H_d) under each demographic model was calculated as a

one-tailed test [see Belle *et al.* (45)] and decreases as the time of bottleneck becomes more ancient (Fig. 2). Linear regression shows that a likelihood of 0.01 is obtained under a bottleneck occurring 73 generations ago.

Migration Between Subpopulations. To test the effect of immigration from satellite populations on effective population size of females, we used SIMCOAL (44) to simulate a central population with migration of varying levels from satellite populations of varying sizes, and calculated the ratio between $N_{e(f)}$ of the central population computed with and without migration. The central population was assigned an $N_{e(f)}$ of 5,000 individuals, corresponding to the estimated effective size of the female population today. We simulated immigration rates of 0.001, 0.01, and 0.1 (proportion of immigrants per generation) and satellite populations of sizes 500, 1,000, 2,500, and 5,000.

Abstract

Commercial whaling decimated many whale populations, including the eastern Pacific gray whale, but little is known about how population dynamics or ecology differed prior to these removals. Of particular interest is the possibility of a large population decline prior to whaling, as such a decline could explain the ~5-fold difference between genetic estimates of prior abundance and estimates based on historical records. We analyzed genetic (mitochondrial control region) and isotopic information from modern and prehistoric gray whales using serial coalescent simulations and Bayesian skyline analyses to test for a pre-whaling decline and to examine prehistoric genetic diversity, population dynamics and ecology. Simulations demonstrate that significant genetic differences observed between ancient and modern samples could be caused by a large, recent population bottleneck, roughly concurrent with commercial whaling. Stable isotopes show minimal differences between modern and ancient gray whale foraging ecology. Using rejection-based Approximate Bayesian Computation, we estimate the size of the population bottleneck at its minimum abundance and the pre-bottleneck abundance. Our results agree with previous genetic studies suggesting the historical size of the eastern gray whale population was roughly three to five times its current size.

Introduction

Commercial whaling in the 19th and 20th centuries resulted in greatly reduced population sizes in many species, with dramatic impacts on marine ecosystems (e.g. [1]). Despite widespread scientific and public interest in the recovery of whale stocks and the ecological impacts of removal, little is known about how whaling may have altered basic aspects of population ecology including abundance, foraging grounds, migration patterns, or population substructure [2,3].

Of particular interest is the estimation of historic abundance immediately prior to whaling. Genetic diversity in many whale populations is too high to match pre-whaling population sizes estimated from whaling and commercial records, producing a striking discrepancy between historic abundance in baleen whales estimated from historical records versus genetic data (e.g. [4,5]). For example, mitochondrial data from three baleen whale species in the North Atlantic produced estimates 6 to 20 times larger than previous estimates based on historical data [4]. Many potential explanations for this discrepancy have been suggested [6]. For example, abundances estimated from historical data could be too low if whaling records were lost, biased or falsified, or if parameters (such as struck-and-lost rate) used to calculate the numbers of whales killed from these records are inaccurate. On

the other hand, abundances from genetic data could be too high if the mutation rate used is too low, if few genetic markers were used, if population structure is not accounted for, if generation time is underestimated, or if balancing selection was occurring at the genetic loci used to calculate population size. Many of these factors have been and continue to be investigated as sources of error (see [6,7]).

However, the discrepancy between historic and genetic estimates can also be explained by a single scenario: populations of whales were much larger in the past, but declined substantially before whaling began. Under this scenario, both genetic and historic inferences could be correct. However, this hypothesis has proven difficult to test, as it requires estimation of prehistoric population dynamics.

Ancient DNA sequences allow direct estimation of changes in genetic diversity over time, and can greatly improve the reconstruction of historic population dynamics, particularly when demographic histories are complex [8,9]. Temporally-spaced genetic data can improve statistical power to detect bottlenecks relative to modern data alone, even when relatively few ancient samples are available [10]. Demographic reconstruction using ancient sequences has yielded insight into historic population ecology and the context of declines in organisms such as bison [11], woolly mammoths [12], and tuco tuco [13], and has the

potential to provide information about the historical demography of whales before whaling. Ancient genetic data can be particularly powerful when combined with stable isotope data, which can reveal information about feeding ecology from the same population [14,15].

In this study, we investigate the pre-whaling genetic diversity, population dynamics and feeding ecology of the eastern Pacific gray whale using ancient and modern DNA sequences and stable isotope data. Eastern gray whales represent a useful case study for investigating historic population dynamics and in particular the discrepancy between genetic and historical data, because both genetic diversity and historical records have been examined in depth [5,16,17]. According to historic records, eastern Pacific gray whales originally numbered around 15,000–20,000 individuals before whaling [16]; modeling based on census data extends these numbers to 19,500–35,500 individuals [18]. Intensive whaling from 1850 to 1874 and subsequently from the turn of the century until the 1930s reduced this population to some unknown fraction of its former size. In contrast, estimates from multilocus genetic data are consistent with a much higher original population size (78,000–116,000 individuals) [5].

A pre-whaling bottleneck in gray whales could have several potential causes. Because they feed in Arctic and subarctic benthic environments, gray whales are thought to be relatively sensitive to changes in climate, and climatic events such as the Medieval Warm Period (ca. 900–1200 AD) or Little Ice Age (ca. 1300–1850 AD) could have caused a population decline. The nature of the relationship between gray whale populations and climate-sensitive ecosystem features such as sea ice, freshwater input to nearshore benthic ecosystems and benthic species composition is poorly understood [19,20]. However, recent calving rates have been shown to be negatively correlated with ice cover extent, indicating population growth is faster when ice cover is reduced and feeding habitat is extended [20]. Indigenous hunting of gray whales has been occurring for at least 5000 years around the Pacific Rim and could have reduced gray whale populations below original levels. Though it has always been assumed that hunting using traditional techniques had minimal impact on whale abundance [21], the actual effects of indigenous hunting have not been quantified. A final possibility is that killer whales (*Orcinus orca*), the major predator on gray whales, may have increased or switched to feeding primarily on gray whales (e.g. [1]).

The accurate inference of population dynamics from ancient sequences requires multiple, well-dated samples from a single population, and depends on a number of assumptions related to the coalescent including random selection of individuals from a panmictic population [22]. We utilized whale bones excavated from dated archaeological sites on the Makah and Quilleute tribal reservations, dated 150–3500 years before present (ybp). To detect a pre-whaling bottleneck, we used genetic data from these dated ancient samples along with a modern gray whale dataset in two different and complementary analyses: 1) serial coalescent simulations with approximate Bayesian computation to determine posterior probability distributions for demographic parameters; and 2) a Bayesian MCMC method [8], which uses a coalescent approach to compare the likelihood of different histories.

In addition to investigating genetic diversity of modern and ancient samples, we used stable isotope analysis to investigate how feeding ecology may have changed since whaling, particularly around the Olympic peninsula and Vancouver Island. Today, most gray whales feed in the Bering, Chukchi and Beaufort Seas, though a small number of “summer residents” are known to feed near Vancouver Island and other locations in the Pacific Northwest (e.g. [23]). Abundant bones found in archaeological

sites around the Chukchi peninsula (e.g. [24]) suggest the majority of gray whales fed in the Bering Sea and northward in the past. However, the larger population size of gray whales before whaling may also have resulted in alternative foraging habitats or strategies. In particular, productive areas in the Pacific Northwest including the inlets and sounds of Vancouver Island may have supported sizeable feeding populations [25]. Stable isotope analysis, particularly carbon ($\delta^{13}\text{C}$) and nitrogen ($\delta^{15}\text{N}$), can be used to distinguish between marine foraging areas on a broad geographic scale (reviewed in [15,26]), and thus can be used to determine whether the ancient gray whales from the Pacific Northwest represented a local feeding group. Because the samples used in this study come from the same region as the modern feeding aggregation of gray whales in the Pacific Northwest, we compared stable isotope ($\delta^{13}\text{C}$ and $\delta^{15}\text{N}$) values between ancient and modern samples to determine whether ancient samples were derived from individuals representing a local feeding subpopulation.

Materials and Methods

Samples

Modern mitochondrial control region sequences from 120 eastern Pacific and 45 western Pacific gray whales were obtained from NCBI [17]. These datasets are comprised of samples from both stranded individuals across the migratory route (eastern Pacific) and biopsies (western Pacific) across numerous years. Subsequent sampling in the eastern Pacific population [3] found essentially the same distribution of mitochondrial haplotypes as in [17], suggesting this dataset contains a reasonable representation of the haplotype distribution in the population. Forty-two of these samples were reamplified and sequenced in our laboratory and sequenced blind in both directions (see [27] for methods), and sequences were compared with those from NCBI. Subsamples of 40 whale bones were collected from previously excavated sites in Northwest Washington (USA) from the Makah and Quilleute Tribal Reservations, including the Ozette site [28], a shell midden deposit on the Makah Tribal Reservation, and a shell midden on the Quilleute Tribal Reservation (Table 1, Figure 1). Excavations took place between 1971 and 2005. All bones were dated based on previously-established site provenience [28] or AMS- ^{14}C dating at Lawrence Livermore National Laboratory (Livermore, CA) after correction for the marine reservoir (North Pacific surface reservoir) [29,30,31].

DNA Extraction, Amplification and Sequencing

DNA extraction and amplification were performed under strict ancient DNA contamination control measures (see “Authentication” below). The surface of each sample was removed via sanding and ca. 0.1–0.3 g of bone was removed using a dremel tool. Each subsample was ground into a fine powder and incubated overnight at 55°C with 1.25 mL of extraction buffer (0.5 M EDTA at pH 8.0, 0.5% SDS and 0.5 mg/mL proteinase K) in a 1.5 mL tube. DNA was extracted using Qiaquick DNA Extraction columns (QIAGEN) according to manufacturer’s instructions.

We amplified four overlapping fragments of the mitochondrial control region sized 180–250 bp (Table 2). First, a 182 bp fragment was amplified using primers F22 and R258 as described in [32] and sequenced to determine species identity. We amplified all samples identified as gray whales at three additional fragments. Amplification conditions were as follows: 0.1 μM each primer, 2.5 mM MgCl_2 , 0.2 mM dNTP, 1.5 mg/mL spermidine, 2.5 μL DNA template, and 1.25 U Amplitaq Gold (Applied Biosystems). Amplifications were performed on a BioRad cyclor with the

cons were present, using ABI Topo kit. Sequences were cleaned, edited and aligned in Sequencher 4.0 (GeneCodes).

Authentication

Ancient DNA extraction and pre-PCR procedures were performed under strict controls to minimize contamination risk and controls were included at each step to monitor contamination. Primers were designed specifically for cetaceans, and laboratories in which extractions and PCR were performed had never had any modern whale or cetartiodactyl DNA or tissues in the facilities. Ancient DNA extraction and pre-PCR procedures took place in a specialized facility, spatially isolated from facilities in which PCR, cloning and sequencing take place. The ancient DNA facility is equipped with positive airflow to prevent/minimize exogenous contaminants from entering the room, and overhead UV lamps to destroy non-target DNA. No researchers are permitted to enter the clean room within 24 hours of contact with facilities in which PCR occurs. Prior to extraction of DNA from ancient material, all surfaces were cleaned with Alconox detergent and a bleach solution (10–30%), and room, materials (including tubes, tips, pipettors, and foil) and reagents (excluding proteinase K) were UV-irradiated overnight. Extractions and PCR set-up were performed in a Class II laminar flow hood. Samples were stored in separate airtight plastic bags until use. Each sample represents a different individual because subsamples came from the same complete skeletal element, had different ^{14}C dates, or were from different sites.

All extractions and amplifications included negative controls at a ratio of one control for every four samples. Multiple, overlapping amplifications with different primer pairs were used to confirm all SNPs. Amplifications were repeated for 20% of samples. As described above, 10% of amplified fragments were cloned and sequenced to determine the extent of contamination by exogenous DNA. In addition, 25% of gray whale samples were re-extracted and amplified independently by a separate laboratory. New gray whale haplotypes were deposited in NCBI with corresponding sample names (Accession numbers JQ910911–JQ910926).

Genetic Diversity

Ancient sequences were aligned to previously published control region sequences for both eastern and western Pacific gray whales [17] using Sequencher 4.0 (GeneCodes). Haplotype diversity (Hd), the genetic diversity parameters Watterson's θ and nucleotide diversity (π), and Tajima's D were estimated using DnaSP v.5 [33]. We measured genetic differentiation between sample sets using F_{ST} [34], and derived 95% confidence intervals from 20,000 bootstrap replicates using the program Arlequin v. 3.1 [35].

Coalescent Simulations and Demographic Analyses

To explore whether bottlenecks could result in observed patterns, we used a rejection-based approximate Bayesian computation (ABC) approach [36] with serial coalescent simulations. We simulated a range of demographic histories (including population bottlenecks of different sizes/timing and various pre-bottleneck sizes) and used an ABC framework to compare observed and simulated values of summary statistics to estimate the posterior probability distributions of demographic parameters. In these simulations, population size parameters were estimated in terms of female effective size (N_{ef}), or the number of breeding females. To relate these estimates to previously published figures, we converted between effective female size and census size using three steps (see [4,5] for additional details and rationale): 1) female effective size is converted to effective size (N_e) by multiplying by 2 to account for males; 2) effective size (N_e) is converted to all adults

(N_T) by multiplying by 2, and 3) Adult population (N_T) is converted to census size (N), or the total number of individuals in the population including juveniles, by multiplying by 1.5.

We varied demographic scenarios as follows. The time of the bottleneck was varied from 1–100 generations ago, prebottleneck size was varied from $N_{ef} = 3333$ –19,333 (equivalent to $N = 20,000$ –116,000) in the past, and minimum abundance at the bottleneck was varied from $N_{ef} = 17$ –1667 (equivalent to $N = 100$ –10,000 individuals) (Figure 2). The range of original abundance employed in the simulations was derived from today's census size and an analysis of genetic diversity in nuclear introns of gray whales [5], and the range of bottleneck sizes was derived from the highest [18] and lowest [37] estimates available in the literature. Simulations use a generation time of 15.5 years, equal to the median age of reproductive females [38]. The molecular substitution model used (HKY+G) was selected using the program MODELTEST using Akaike Information Criterion (AIC) [39]. A range of mutation rates from 4.00 – $8.00 \times 10^{-8} \text{ bp}^{-1} \text{ yr}^{-1}$ were employed based on the analysis of [27], which used cytochrome-b data to calibrate rate of substitution in the control region of gray whales. The method used to derive this rate, which is 2 to 4.4-fold faster than the phylogenetically derived rate (e.g. [40]), has been found to be consistent with results obtained in subsequent studies of mammalian rates [41,42,43]. To test the sensitivity of results to mutation rate, we also repeated the analysis using rates derived from Bayesian MCMC analysis of ancient and modern data (see below). We chose sample sizes and ages of samples to reflect our empirical dataset. Simulations were generated in Bayesian Serial SIMCOAL [44,45] and rejection-based ABC was implemented in the statistical package R version 2.0 following the algorithm described in [13]. We performed 1,000,000 simulations with 1000 acceptances. We used five summary statistics (π_{modern} , π_{ancient} , F_{ST} (ancient-modern comparison), Hd_{modern} and Hd_{ancient}) to estimate posterior likelihoods for three parameters: 1) bottleneck time in

Figure 2. Simulated demographic scenario. The size of the ancient population is assumed to range from 20,000–116,000 (census size). The modern population is assumed to have a census size of 22,000. The size and timing of the bottleneck (pictured here at 10,000 individuals and 10 generations ago) were varied between 100–10,000 (census size) and 1–100 generations ago.

doi:10.1371/journal.pone.0035039.g002

generations (t_{bot}); 2) minimum size of population ($N_{\text{ef}(\text{bot})}$); and 3) pre-bottleneck abundance ($N_{\text{ef}(\text{prebot})}$).

In addition, all ancient and 120 modern sequences were used to compare the likelihood of different demographic scenarios in a Bayesian MCMC analysis as implemented in BEAST v 1.5.3. MODELTEST [39] was used to determine the best-fitting substitution model. Based on these results, analyses were run using the HKY+G substitution model with a relaxed molecular clock (uncorrelated lognormal) in order to allow rates to vary among branches [46], and 30,000,000 iterations after a burn-in of 100,000 iterations, with sample ages used in the calibration and a uniform prior on mutation rate of $4.00\text{--}8.00 \times 10^{-8} \text{ bp}^{-1} \text{ yr}^{-1}$. We selected the numbers of iterations and burn-in steps to ensure model convergence, and averaged results over five replicate runs. Both genealogies and model parameters were sampled every 3000 iterations. Mixing and convergence were determined to be adequate based on the effective sample sizes (ESS) of each parameter, as evaluated in Tracer v. 1.3. We compared the following demographic models: constant population size, exponential growth, and Bayesian skyline plot (BSP) using 10 temporal groups. We compared support for models by calculating Bayes factors using the harmonic means of sampled marginal likelihoods for each model [47]. Additionally, BEAST v1.5.3 was used to assess levels of post-mortem DNA damage and take account of this damage in demographic analyses (see [48]). The potential for such damage to confound demographic analyses is an important consideration in assessing the ability of ancient or historical sequences to shed light on past population processes (e.g. [49]). However, Rambaut et al. [48] showed through simulations that when damage was measured and accommodated in aDNA analyses, evolutionary parameters and demographic reconstructions were correctly recovered.

Finally, we also evaluated past population dynamics using the Bayesian skyline plot (BSP) method of Drummond et al. [8]. In this method, a sample of gene sequences (including sequences sampled at different points in time) is used to estimate effective population size through time, using an MCMC sampling procedure. The method produces credibility intervals that incorporate both phylogenetic error and uncertainty inherent in reconstructing the coalescent process. However, using limited sequence data from a single locus can reduce the power of this method to detect population dynamics in the past [22]. To determine whether our ancient samples were adequate for detecting the signature of a bottleneck in Bayesian demographic analyses, we repeated the analyses on simulated datasets with identical ancient sampling but known demographic histories. We analyzed two demographic scenarios in which bottlenecks were assumed to have occurred at 800 or 1200 ybp (reducing the population from 96,000 individuals to 22,000). All other parameters (such as mutation rate and generation time) were identical to those used in the demographic simulations described above.

Stable Isotope Analysis

In addition to assessing the stable isotope composition ($\delta^{13}\text{C}$ and $\delta^{15}\text{N}$) of all ancient gray whale samples, we collected bone fragments from modern gray whale bones for the purpose of comparison. Fourteen gray whale bones were analyzed from the USNM collection, Smithsonian Institution. The majority of the USNM samples come from animals harvested in the 1960s and 70s at a California whaling station across different years [38], and are therefore likely represent a random subsample of the population. Bone fragments were demineralized in 0.5 N hydrochloric acid (HCl) for $\sim 12\text{--}15$ hr at 5°C . The resulting material was treated repeatedly with a chloroform/methanol (2:1) mixture

to remove lipids and then lyophilized. Dried samples (~ 0.5 mg) were sealed in tin boats and analyzed using a Carlo-Erba elemental analyzer interfaced with a Finnegan Delta Plus XL mass spectrometer (Geophysical Laboratory, Carnegie Institution of Washington). Results are expressed as δ values, $\delta^{13}\text{C}$ or $\delta^{15}\text{N} = 1000[(R_{\text{sample}}/R_{\text{standard}})-1]$, where R_{sample} and R_{standard} are the $^{13}\text{C}/^{12}\text{C}$ or $^{15}\text{N}/^{14}\text{N}$ ratios of the sample and standard, respectively. The standards are Vienna-Pee Dee Belemnite limestone (V-PDB) for carbon and atmospheric N_2 for nitrogen. Units are expressed as parts per thousand or per mil (‰). Within-run standard deviation of an acetanilide standard was $\leq 0.2\text{‰}$ for both $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values. As a control for the quality of collagen, we measured the $[\text{C}]/[\text{N}]$ ratio of each sample; weight percent $[\text{C}]/[\text{N}]$ ratios of all bone collagen samples were 2.8–3.2, within the theoretical $[\text{C}]/[\text{N}]$ ratio of unaltered collagen [50]. We applied a correction to all carbon isotope values to account for the global decrease in the ^{13}C proportion of atmospheric carbon dioxide (i.e., “Suess Effect”), due largely to fossil fuel burning, over the last 150 years. Based on ice core records [51], we applied a time-dependent $\delta^{13}\text{C}$ correction to historic samples (1912–1975) of -0.005 per mil/year between 1860 and 1960 ($n = 1$), and -0.022 per mil/year since 1960 ($n = 13$). This resulted in relatively minor (mean = -0.3‰) $\delta^{13}\text{C}$ corrections for the modern samples since most of them (12/14, $\sim 85\%$) were collected prior to 1970.

Results

We extracted and amplified DNA from 38 of 40 samples. Alignment of control region sequence with baleen whale sequences from NCBI showed that 16 of the 38 sequences grouped with gray whales (remaining sequences grouped with humpback, blue or sperm whales). No exogenous contaminants or mismatches were detected in any of the cloned sequences or sequences from independently extracted specimens. Blind resequencing of a subset (25%) of modern sequences did not yield any sequence discrepancies with NCBI data. Only genetic data from gray whales (383 bp) were used for the remaining analyses.

Genetic Diversity

The level of haplotype diversity across ancient samples ($H_d = 0.933$) was comparable to that found in modern Eastern samples ($H_d = 0.948$) and higher than that of modern Western samples ($H_d = 0.700$) (Table 3). Nine haplotypes were obtained from the sixteen gray whale samples, including three haplotypes previously unobserved in either the eastern or western Pacific populations. These unique haplotypes differed by four (one individual), two (one individual) and one (two individuals) base pair changes from known haplotypes. All but one of these changes were transitions. Values of $\Theta(S)$ and nucleotide diversity (π) were also similar across modern and ancient eastern Pacific samples. Tajima's D values were nonsignificant for all three sets of samples.

Both a haplogroup network constructed using TCS [52], and a neighbor-joining tree constructed using PAUP* [53] show that ancient samples are not distributed randomly across the distribution of modern eastern Pacific samples, but cluster in one part of the network or tree (Figure 3a, 3b). Significant differences in haplotype frequencies were observed between each pair of samples ($p < 0.001$). The observed F_{ST} value between modern eastern and ancient eastern was 0.1004 (95% CIs: 0.0640–0.1344). The difference between modern western samples and ancient sequences ($F_{ST} = 0.2794$) was greater than the difference between modern eastern and western sequences ($F_{ST} = 0.1125$).

Table 3. Summary statistics (\pm SD) for ancient Eastern Pacific (EP) samples, Modern EP, and modern Western Pacific (WP) samples.

	N	N(H)	Hd	π	$\theta(S)$	Tajima's D
Ancient EP	16	9	0.933 \pm 0.035	0.0130 \pm 0.0016	0.0127 \pm 0.0053	-0.031
Modern EP	120	30	0.948 \pm 0.007	0.0191 \pm 0.0009	0.0189 \pm 0.0041	0.906
Modern WP	45	10	0.700 \pm 0.049	0.0187 \pm 0.0012	0.0190 \pm 0.0045	1.392

N = number of samples; N(H) = number of haplotypes; Hd = haplotype diversity, $\theta(S)$ = Watterson's theta [76]; π = nucleotide diversity [77]. Values of Tajima's D were nonsignificant for all samples ($p > 0.10$).

doi:10.1371/journal.pone.0035039.t003

Coalescent Simulations and Demographic Analyses

Posterior density curves and prior distributions for the three parameters of interest are shown in Figure 4. The maximum a posteriori estimate was for a bottleneck time 6 generations ago (90% highest posterior density interval (HPD) = 5–60 generations). Estimates for minimum abundance ($N_{(ef)bot}$) and pre-bottleneck abundance ($N_{(ef)prebot}$) were translated from units of female effective size ($N_{(ef)}$) to census size (N) using conservative factors to account for sex ratio, the ratio of breeding adults to all adults and the ratio of juveniles to adults [5]. This resulted in maximum a posteriori estimates of $N_{bot} = 9,070$ (90% HPD = 3,750–9,740) and $N_{prebot} = 100,670$ (90% HPD: 59,940–111,550).

Bayesian MCMC methods as implemented in BEAST can also be used to measure mutation rates directly when ancient data are available [54]. These methods can produce upwardly biased estimates of mutation rates in populations that deviate from simple demographic histories, especially in cases where population bottlenecks have occurred or population structure is or was pronounced [55], as is likely to be the case for the population considered here. However, in order to test the sensitivity of the ABC analysis to a range of rates, we implemented this method to derive control region rates. The Bayesian MCMC method gives a rate of 0.032–0.194 (95% HPD; mean 0.11) substitutions/site/My when applied to this dataset, a wide range that overlaps with the full range of rates used in this study. This broader range of mutation rates with a higher mean value produces a wider range of N_e values with smaller MLEs, resulting in MLEs of $N_{bot} = 8,890$ (90% HPD = 2,500–9,610) and $N_{prebot} = 69,890$ (90% HPD: 41,220–109,210), and $T_{bot} = 13$ (90% HPD = 9–68).

We used ancient and modern sequences to compare the likelihood of different demographic scenarios in a Bayesian MCMC analysis. A Bayes factor analysis of sampled marginal likelihoods for each model indicated some support for the Bayesian skyline plot (BSP) model over the demographic models of constant or exponential growth ($BF > 2$). The skyline population trend is also consistent with a recent decline (Figure 5). BSP analyses using simulated datasets showed broad declines that were consistent with the bottleneck dates simulated (e.g. roughly 1200 ybp). However, for both the real dataset and simulated datasets, confidence intervals are extremely wide and the skyline plots do not successfully recreate the most recent fine-scale population dynamics over the past ~ 150 years (population bottleneck followed by regrowth). The mean rate of post-mortem damage estimated in BEAST was 2.37×10^{-8} errors per base pair (95% highest posterior density interval: 6.99×10^{-12} , 7.25×10^{-8}). This estimat-

ed rate is lower than several other D-loop datasets derived from samples of comparable (though generally older on average) age, such as ox (4–8 kya, HPD: 3.87×10^{-7} – 8.57×10^{-4}), moa (1–6 kya, HPD: 1.75×10^{-5} to 3.58×10^{-3}), and musk ox (0–44 kya, HPD: 9.81×10^{-8} – 1.91×10^{-3}) [56].

Stable Isotope Analyses

Ancient gray whales had significantly higher mean $\delta^{13}C$ values (ANOVA or pooled T-test, $p < 0.05$) than the modern whales (Figure 6); there were no differences in mean $\delta^{15}N$ values. The mean (\pm SE) $\delta^{13}C$ value for Suess corrected modern ($n = 14$) and ancient ($n = 16$) gray whales was $-13.7 (\pm 0.2)$ and $-13.1 (\pm 0.1)$ respectively. The mean (\pm SE) $\delta^{15}N$ values for modern and ancient samples were $14.2 (\pm 0.2)$ and $14.7 (\pm 0.2)$, respectively. For modern samples, for which age and sex were sometimes known, no obvious effects were observed based on these factors (though small sample size prevents a thorough analysis).

Discussion

Ancient gray whale sequences show high genetic diversity, but this diversity is not randomly distributed with respect to today's haplotype distribution (Figure 3). There are at least two potential causes for this non-random distribution: past population structure, and a large demographic bottleneck that resulted in the reshuffling of haplotype frequencies.

Population structure in the past could result in significant genetic differences between modern and ancient whales. All ancient samples were collected from the same geographic area (the Olympic Peninsula) and were likely caught in or outside of the Strait of Juan de Fuca, raising the possibility that this area might have harbored a genetically unique population in the past. This possibility is particularly worth exploring because a small subset of the modern gray whale population uses the Strait of Juan de Fuca and Puget Sound as a summer feeding ground, whereas the large majority of gray whales travel north to the Bering Sea and northward to feed [25]. Photoidentification data shows that at least some of these individuals return year after year to the area to feed (Calambokidis et al. 2002). Though an earlier genetic study found no evidence that these animals represented a unique population [23], a more recent analysis detected slight but significant differentiation between the southern feeding aggregation and the gray whale population as a whole [57].

To explore pre-whaling feeding ecology and test the hypothesis of population structure in the past, we investigated the stable isotope signature of the ancient whales and a set of modern gray whale bones from the USNM collection. We presume the USNM whales, which were mostly collected at a whaling station near Richmond, California in the 1970s, represent a random subset of the population because whales were taken in different years along their central migration route, and thus would carry the isotopic signature of the primary northern feeding grounds. Gray whales are unique among large cetaceans in that they migrate and feed close to shore, typically < 80 km [38], and therefore we would not expect distance from shore to be a confounding factor in interpreting isotopic results. If in fact the ancient whales represented a genetically distinct resident aggregation in the past, the most likely scenario is that these whales were feeding in the Strait of Juan de Fuca and Puget Sound, which would result in different isotopic signature due to differences in foraging latitude. Phytoplankton and dissolved organic matter $\delta^{13}C$ and $\delta^{15}N$ values are negatively correlated with latitude in the northeast Pacific Ocean [58,59,60]; temperate latitude systems (e.g., California Current) have higher isotope values by ~ 1 – 2% than high latitude

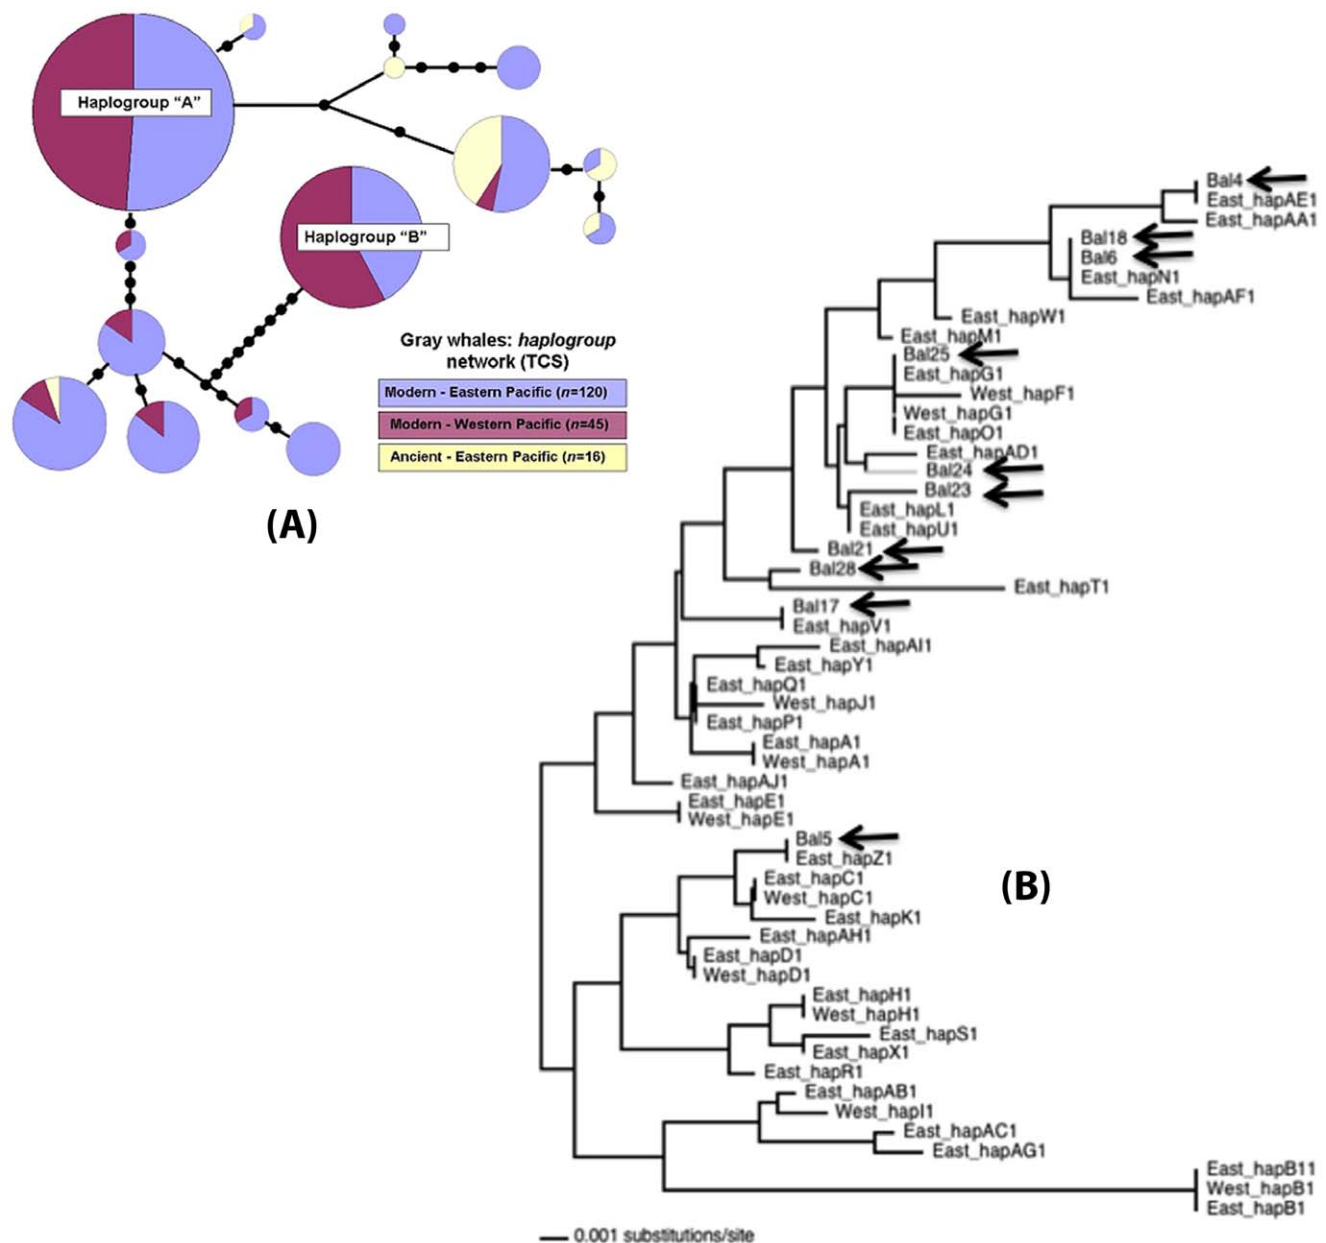

Figure 3. Phylogenetic network and tree constructed from modern and ancient gray whale haplotypes. (a) Haplogroup network for ancient eastern Pacific and modern eastern and western Pacific samples (constructed in TCS [52]). Haplogroups were defined by grouping together sequences with one or zero differences. (b) Neighbor-joining (midpoint-rooted) tree using ancient and modern haplotypes from PAUP* [53]. The HKY85 model [75] was used to correct genetic distances. Ancient samples have the prefix BAL and are denoted with an arrow. Each haplotype is represented only once in the tree. doi:10.1371/journal.pone.0035039.g003

systems (e.g., Bering Sea). As such these isotopes have been used extensively to examine differences in foraging latitude in modern and ancient marine mammals [14,15,61,62]. After correcting for the Suess effect, we found slight but significant differences in mean $\delta^{13}\text{C}$ values between the two groups; mean $\delta^{15}\text{N}$ values were not significant. Assuming ancient and modern groups forage at similar trophic levels, the overall isotopic pattern is in agreement with that expected if ancient Ozette gray whales foraged in lower latitude waters than the modern group, which is known to forage at high latitudes in the Bering Sea. Thus, it remains possible that at least a subset of these whales were occasional summer residents in the area, particularly in light of the recent analysis by [57]. However,

the small observed isotopic differences in $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ and small sample sizes suggest that drawing a firm conclusion about geographic structure from these isotopic data would be premature. Finally, it is also possible that the ancient whales from Ozette represent a genetically unique population, due to structuring along another ecological axis other than feeding. Further tests of the hypothesis of population structure in the past will require additional ancient samples from this region and new locales.

We tested the second possible cause for nonrandom distribution of ancient haplotypes, a demographic bottleneck, using serial coalescent simulations and rejection-based Approximate Bayesian Computation approach. We selected demographic scenarios used

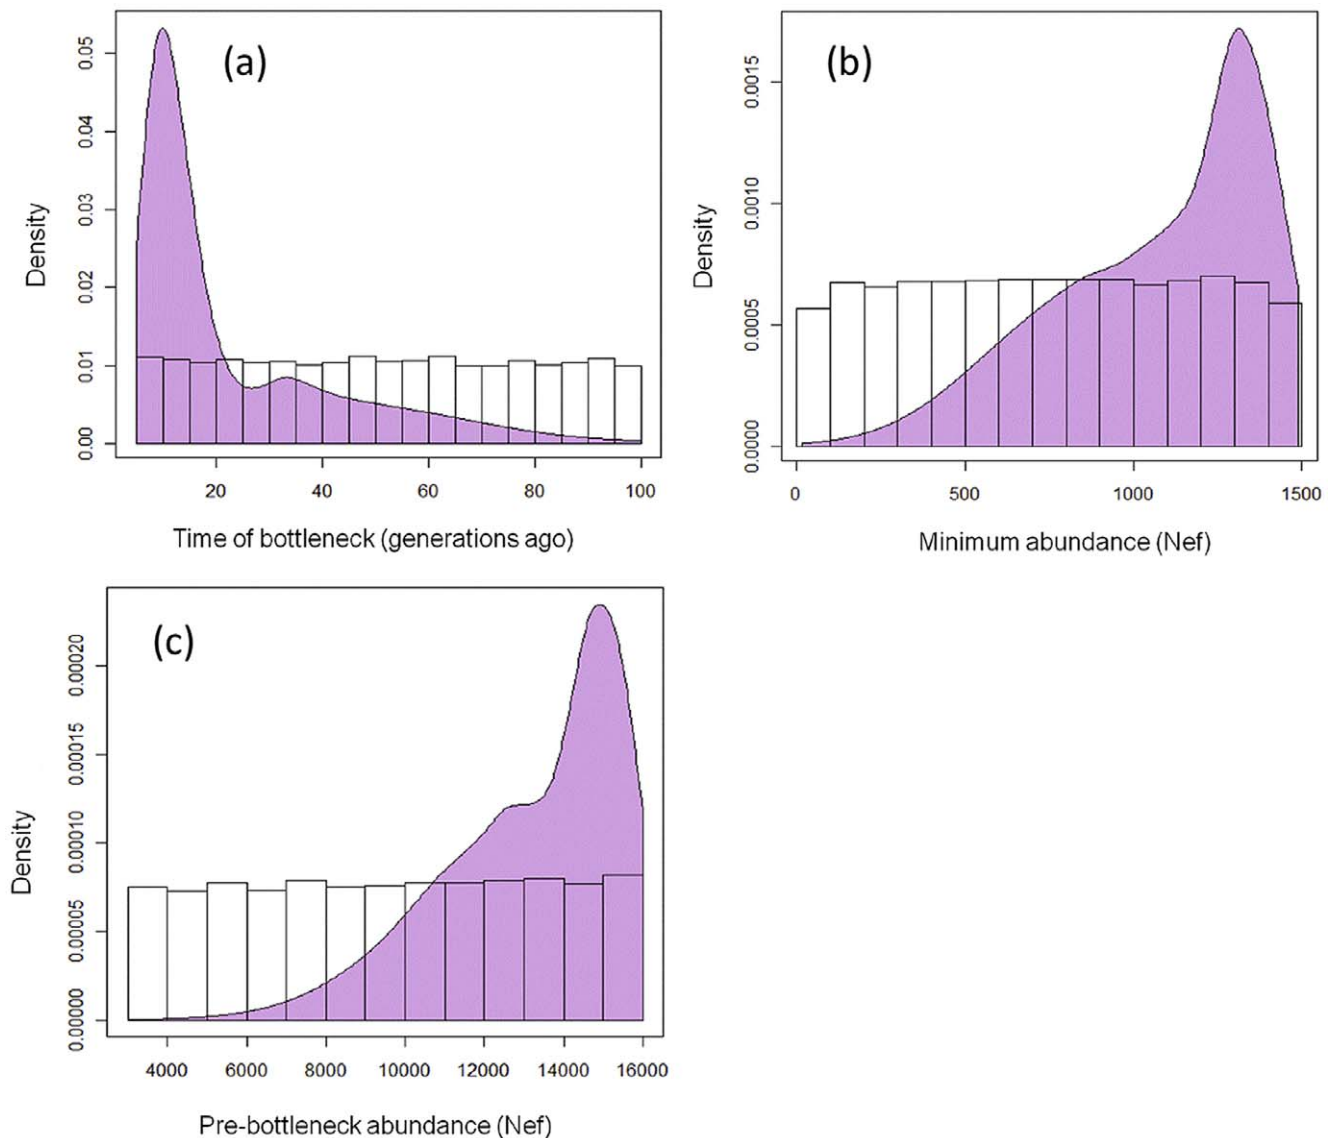

Figure 4. Posterior density distributions for Approximate Bayesian Computation results. Based on ancient eastern Pacific and modern eastern samples (shaded area) and prior uniform sampling distributions based on one million iterations for (a) time of bottleneck in generations (t_{bot}); (b) minimum female effective population size at bottleneck ($N_{ef(bot)}$); and (c) pre-bottleneck female effective population size ($N_{ef(prebot)}$). doi:10.1371/journal.pone.0035039.g004

in coalescent simulations by using a range of values of population size in the past and today from census [63] and genetic data [5], and exploring potential bottleneck dynamics that might have occurred in the interim. These analyses demonstrate that a subset of demographic scenarios are most likely to produce the observed summary statistics in modern and ancient samples. In particular, the observed F_{ST} value can result from a bottleneck followed by rapid population growth. Simulations demonstrate that, as expected, more severe bottlenecks create higher F_{ST} values. Results indicate highest support for a population bottleneck that between 5–60 generations ago (90% HPD), with a maximum likelihood estimate of 93 years or 6 generations, which roughly corresponds to the end of the central period of commercial whaling (Figure 4). Little is known about the size of the gray whale population during the height of industrial whaling around 1890, though it is known that the population was determined to be “commercially extinct” [16]. Previous estimates vary from 150

based on visual census [37] to 10,000 based on population models [18]. Simulation results give an MLE of 9,070 (90% HPD: 3,750–9,740), much closer to the latter value. This larger estimate is in agreement with the rapid growth of the gray whale population during the last half of the 20th century, and brings estimates of pre-whaling abundance from whaling records (which reflect whales killed in addition to the number of individuals remaining at the bottleneck) into slightly closer alignment with those from genetics. The posterior distribution of pre-bottleneck census size (MLE = 100,670, 90% HPD: 59,940–111,550) is higher than those estimated from whaling records, and corresponds to the distribution of 96,000 (78,000–116,000) previously estimated from a separate genetic dataset (nine nuclear introns and cytochrome-*b*; [5]).

In addition to the simulation approach, we used a Bayes factor analysis to determine which demographic model (constant, exponential growth, or Bayesian skyline plot) provided the best

Figure 5. Bayesian skyline plots using empirical ancient and eastern Pacific modern datasets. (black solid line = median; black dashed lines = 95% highest posterior density intervals (HPDIs)), and for a simulated dataset in which bottleneck from 96,000 to 22,000 individuals occurred 1200 ybp (gray solid line = median; gray dashed lines = 95% HPDIs). BSP results were averaged across five replicate runs. NB: The BSP analysis used here assumes a single panmictic population.
doi:10.1371/journal.pone.0035039.g005

fit to the data. The BSP provided a better fit than the other two models ($BF > 2$), suggesting a population decline. The skyline plot analyses based on modern and ancient control region sequences are consistent with a recent decline, and there is no indication of

an earlier major decline. Though the possibility remains that our dataset violates the assumption of panmixia, previous studies indicate that skyline plots are relatively robust to such violations [8,11]. The BSP analysis also successfully reconstructed earlier

Figure 6. Mean stable isotope values for modern (USNM), modern corrected (USNM (maximum Suess)) and ancient (Ozette) samples; error bars represent standard errors. No significant overall difference between ancient and modern samples is observed once modern samples are corrected for the Suess effect. The Suess effect results in an average shift in $\delta^{13}\text{C}$ of 0.3‰.
doi:10.1371/journal.pone.0035039.g006

hypothetical declines in simulated datasets using the same sample size and age distribution as in our empirical dataset, indicating that if a decline from 100,000 to 20,000 individuals occurred earlier in the Holocene, we would expect to detect it with our dataset. However, in both cases credibility intervals are large due to small ancient sample size and uncertainty inherent in the coalescent process and phylogenetic reconstruction, limiting the inferences we can draw from these results. In addition, previous analyses of ancient DNA datasets using Bayesian skyline plots (e.g. [8,11]) and bowhead whales [64] indicate that this methodology was unable to reconstruct very recent declines or bottlenecks. Additional loci and ancient samples would be needed to gain enough statistical power to quantify very recent bottlenecks with confidence.

Estimating demographic parameters from genetic data requires the estimation of evolutionary rates and other uncertain factors. Recent studies have suggested mtDNA mutation rates estimated from phylogenetic data are inappropriate for intraspecific studies because of time dependency of molecular rates (older calibration points produce slower clock rates) [54,65]. In this study, we addressed this problem by using a range of evolutionary rates derived from intraspecific calibration of the control region based on variation at a linked locus [27]. This method utilizes more recent calibration points and is thus better able to detect multiple hits/homoplasy, a common feature of the mammalian control region that may contribute to differences between pedigree-based and phylogenetic rate estimates [66]. Bayesian MCMC methods have been used to measure mutation rates directly when ancient data are available [54], but simulation studies found these methods can overestimate the true rate for populations in which bottlenecks have occurred or those with pronounced structure [55] (however, it is important to note that some of the simulation scenarios used in the latter study included non-representative sampling). In addition, a recent study found that some ancient DNA datasets, including bowhead whale, produced artifactual rate estimates as a result of low information content among other factors including sequence ages [67]. For this reason, we consider the range of rates derived from intraspecific calibration [27] to be the best available estimates for use in this analysis, in the absence of a molecular rate curve [46] for baleen whale species.

Additional uncertainties in the estimates of total population size (N) arise from other parameters needed for the analysis, including the ratio of breeding adults to total adults (N_e/N), generation time, the sex ratio and the ratio of juveniles to adults. While gray whale-specific estimates exist for the latter two values, N_e/N is very poorly known for most species [68]. A review of empirical studies suggested that the number of breeding individuals in a population is typically an order of magnitude below the total number (averaging 0.10–0.11), and that N_e/N rarely falls above 0.5 in natural populations [69]. Theoretical analyses suggest that N_e/N approaches 0.5 in most populations with constant size [70]. Factors that can reduce N_e/N include uneven sex ratios, population bottlenecks and variance in reproductive success (e.g. [71,72]). In this analysis, we used a conservative estimate of N_e/N (0.5), which will produce smaller estimates of total population size; however, it is important to recognize the additional uncertainty introduced by this calculation. While empirical and theoretical studies indicate that this value is unlikely to be an underestimate for gray whales, it is possible that the true N_e/N ratio might be much smaller. Likewise, generation time is difficult to measure with precision in wild populations, and may not necessarily be stable across evolutionary time scales. In this analysis, we use a standard definition of generation time, calculated as the mean age

of reproductive females, assuming no decline in fecundity with age [68]. A decline in fecundity with age would reduce the estimated generation time, causing a proportional increase in the population size estimated from genetic data. If, on the other hand, the average generation time of gray whales across the last several thousand years was greater than estimated here (for example if whaling caused average generation time to decrease), it would cause a proportional reduction in DNA-based N_e estimates. These caveats regarding life history parameters underscore the uncertainties associated with inferring population size and dynamics from genetic data, which have been discussed in depth in previous works (e.g. [6,7,73]).

Overall, the genetic evidence presented here supports the hypothesis that gray whales experienced a major population decline, and that this reduction occurred recently. Stable isotope results show only very slight differences between ancient and modern whales, indicating the hypothesis of population substructure in the past around the area of the Olympic peninsula/Vancouver Island remains a possibility and warrants further investigation using larger sample sizes. Though our ability to infer what was surely a complex demographic history is limited by the number of ancient samples available and large uncertainties associated with the coalescent and evolutionary processes, these first ancient data for gray whales demonstrate the value of paired genetic and isotopic studies of ancient samples, showing that a population bottleneck can result in significant genetic differentiation between ancient and modern samples without requiring spatial structure. Both demographic simulations and coalescent analyses indicate that genetic data are consistent with a recent bottleneck and a pre-bottleneck size of $>ca. 60,000$. Recent models of gray whale carrying capacity during the Pleistocene suggest that enough benthic habitat existed to support a population of this size [74]. Future exploration of the impacts of population structure (particularly between eastern and western populations) and analysis of whaling records may be informative regarding the unresolved discrepancy between whaling estimates and genetic estimates of historic abundance. Understanding the causes and extent of the decline in marine species is important to their future management and aids in reconstructing the past states of ocean ecosystems. The analyses presented here corroborate an emerging body of evidence demonstrating historic baselines for many marine populations much larger than previously estimated.

Acknowledgments

We are grateful to the Makah Tribe, the MCRC, and the Quileute tribe for providing access to samples. We particularly thank J. Bowe chop (MCRC) and G. Wessen (Wessen and Associates, Inc), for logistical assistance. We thank E. Hadly, M. Hofreiter, and M. Meyer for assistance with ancient DNA laboratory work and valuable discussions, and D. Petrov and M. Pinsky for replicating the results in an independent laboratory. A. Drummond and S. Ho provided valuable guidance with the BEAST analyses, and C. Anderson provided helpful guidance with Serial SIMCOAL. Two anonymous reviewers provided comments that improved the manuscript. Finally we thank C. Potter and J. Mead (USNM) for access to modern gray whale bones for isotopic analysis, and T. Guilderson of LLNL for his assistance with radiocarbon dating.

BULLETIN.

The matter in the 'Bulletin' consists of about 24 to 36 articles per volume, which relate about equally to Geology, Palæontology, Mammalogy, Ornithology, Entomology, and (in former volumes) Anthropology except Vol. XI, which is restricted to a 'Catalogue of the Types and Figured Specimens in the Palæontological Collection of the Geological Department,' and Vols. XV, XVII, and XVIII, which relate wholly to Anthropology. Volume XXIII and the later volumes contain no anthropological matter, which is now issued separately as 'Anthropological Papers.'

HISTORY, HABITS AND EXTERNAL ANATOMY.

FOREWORD.

The present paper is the first of a series of monographs which are in course of preparation upon the large Cetaceans of the Pacific Ocean. The collection of specimens and field studies upon this group began in 1908 upon the coasts of Vancouver Island and southeastern Alaska and has since been carried on along the shores of Japan and Korea.

It was originally intended to embody all the results of these investigations in a single volume but continued field work and many interruptions have so delayed the assembling of the vast amount of data secured that it has seemed advisable to bring out the material upon each genus or species as fast as it is prepared for publication.

ACKNOWLEDGMENTS.

It gives me the greatest pleasure to acknowledge the generosity and assistance of the President and Directors of the Toyo Hogeï Kabushiki Kaisha (Oriental Whaling Co., Ltd.) of Osaka, Japan. Not only did these gentlemen freely extend the courtesies of their ships and stations but presented to the Museum the skeletons of the whale which forms the subject of the present paper. At all times the officers and employees of the Toyo Hogeï Kaisha assisted me in every way possible, and it was entirely through their efforts that field studies and the collection of specimens was made possible.

To the untiring efforts of my friend Mr. D. Ogiwara, formerly an officer of the whaling company, much of the success of my two expeditions to Japan is due. Mr. Ogiwara, who is deeply interested in the advancement of science, not only rendered great practical assistance but always stood ready to give me the benefit of his sound advice and intimate knowledge of Japanese business methods.

Mr. T. Shibuya, Manager of the Shimonoseki branch of the Toyo Hogeï Kaisha, was of the greatest assistance in many ways, especially in securing the two skeletons of *Rhachianectes* which were shipped to America.

Mr. Kondo, the station master at Ulsan, Korea, and Mr. T. Matsumoto, his assistant, deserve the greatest thanks not only for contributing materially to my study but also for making my stay in their home most enjoyable as well as profitable.

Thanks are also due to Messrs. Oto, Iku Kita, E. J. Kitson and S. Reed for assistance in various ways.

Captain H. G. Melsom of the S.S. 'Main' was my constant companion at Ulsan. Not only did he entertain me frequently upon his ship but contributed much information from his vast store of knowledge and long experience with Gray Whales. Captain Melsom was the first whaler to learn to take "Devilfish" in Korean waters and it was he who laid the foundation for the winter fishery which has been so successfully prosecuted there by the Japanese for the last fifteen years. Captains Johnson and Hurum also entertained me frequently and gave me much valuable information.

Sincere thanks are due to Mr. Chas. L. Bernheimer of New York City for generous financial assistance during the field work upon which this paper is based.

During the years 1880-1882, Dr. J. A. Allen began work upon an extensive monograph of the Cetacea. A vast amount of material was examined and numerous plates were prepared by the well known artist, Mr. J. H. Blake. Because of ill health, however, this work was later abandoned and has remained in manuscript to the present day with the exception of the portion relative to *Eubalæna glacialis*, which was published in 1908.¹ Dr. Allen has very kindly offered me the use of this material and so far as possible it will be combined with the results of my own research. For the present paper the only available portion was that of the "general history" from the years 1868 to 1879. It is also a pleasure to acknowledge Dr. Allen's invaluable assistance and advice in preparing this paper for the press.

Dr. F. W. True has not only read portions of the manuscript but has devoted considerable time to an examination with me of the fossil genera of baleen whales in relation to *Rhachianectes*, and I was thus afforded the benefit of his thorough knowledge of this difficult material. For his never-failing kindness I wish to express my sincere appreciation. My thanks are also due to Dr. W. K. Gregory for much advice and many valuable suggestions.

My mother, Mrs. C. E. Andrews, kindly prepared the table of percentage measurements and assisted me in other ways, and to her my sincerest thanks are extended.

The photographs of the skull and skeleton were made by Mr. Julius Kirschner, the Museum photographer.

INTRODUCTION.

Knowledge of the habits and external anatomy of the California Gray Whale has rested almost exclusively upon the observations of Captain C. M. Scammon made nearly forty years ago. Shortly after the publication of his book 'The Marine Mammalia,' in 1874, the Gray Whale fishery began to decline and for several years was conducted only in a desultory manner by a number of Portuguese upon the shores of Lower California. During the past twenty years the species had been lost to science and many naturalists believed it to be extinct.

While studying Cetaceans upon the coast of Japan in 1910, the writer learned from the Japanese whaling company of the existence of an animal known as the *Koku kujira* or "Devil-fish," which formed the basis of their winter fishery upon the southeastern shore of Korea.

The descriptions indicated that the *Koku kujira* would prove to be none other than the lost California Gray Whale and I determined to investigate it at the earliest opportunity. Consequently, during the winter of 1911-12, I returned to the Orient and spent the months of January and February at the station of the Toyo Hoge Kaisha at Ulsan, a small village on the southeastern coast of Korea, forty miles north of Fusan.

During this time fifty or more Gray Whales were taken and it was possible to make a careful study of the habits and external characters of the species. Skeletons of two adult individuals were also secured, one of which was sent to the American Museum of Natural History in New York City and the other to the U. S. National Museum at Washington, D. C.

These are the first skeletons of this species to be preserved in any American Museum and are, moreover, the only *complete* specimens in the world.

The British Museum of Natural History, South Kensington, England, contains a skeleton and a second is to be found in the Imperial Museum of Tokyo, Japan. There is also one skull of the Gray Whale from California in the United States National Museum.

¹ Bull. Amer. Mus. Nat. Hist., Vol. XXIV, Art. XVIII, pp. 277-329, pls. xix-xxiv.

The study of this animal has been especially interesting since it was almost an untouched field. The fact that the most diligent search of the literature of the subject discloses only 23 titles, and that the great majority of these papers are either short notices or compilations, indicates how little this whale, which is among the most remarkable of all large Cetaceans, has been studied.

GENERAL HISTORY.

"The California Gray whale was first introduced into scientific literature by Professor Cope in 1868¹ under the name *Agaphelus glaucus*. For our first knowledge of its characters, however, we are indebted to Dr. W. H. Dall whose manuscript notes, outline figures and specimens of baleen transmitted by him to the Museum of the Essex Institute (now the Museum of the Peabody Academy of Science), Salem, Mass., formed the basis of Professor Cope's description. Dr. Dall's notes and figures were based upon an examination of two specimens, and though very incompletely indicating the characters of the species, were sufficient to show it to be one not previously described.

"Shortly afterward the external characters were quite fully given by Captain Scammon together with a detailed account of the habits, habitat and products, and of the California coast whaling of which it formed the chief basis. Captain Scammon's account was accompanied by two rough figures of the animal. At the same time the species was made the basis of a new genus (*Rhachianectes*) by Prof. Cope.² Captain Scammon's account was substantially republished in 1871 in the 'Overland Monthly' magazine,³ and in 1874 was incorporated into his 'Marine Mammals'⁴ with, however, much additional matter and new and creditable illustrations. In 1871 Pechuel-Losch gave a short account and figure of the animal in his 'Wale und Walfang'⁵ but added nothing of importance to its history as given by Scammon in 1869. In 1870 Professor Van Beneden thus refers to the genus *Rhachianectes*: 'Si ce genre ne repose pas sur une balénoptère mutilée, c'est-à-dire qui a perdu sa nagoire dorsale, c'est une des plus belles découvertes qui aient été faites depuis bien longtemps en Cétologie.'⁶

"In view of Scammon's history of the species, the doubt here expressed has a strange aspect, but happily he later had abundant opportunity of satisfying himself that his doubt was groundless and it was also his good fortune to publish in 1877 the first description and figure⁷ of the skull of the 'California Gray' from photographs, transmitted by Dr. O. Finsch."⁸

In 1879, Professor Cope examined at San Francisco, a "schooner-load of bones" of this species brought from Scammon's Lagoon, Lower California, to be ground up and sold as fertilizer and says: "Having examined a large number of the bones I can complete the characters of the genus *Rhachianectes*,⁹ which have been but imperfectly known. The cervical vertebræ are all

⁸ J. A. Allen, manuscript notes.

⁹ Professor Cope's original reference to the genus, embraced in four lines, is as follows: "This genus is now first characterized. Its only known species I originally united with *Agaphelus* Cope, but the form of the scapula is so different that it must be distinguished. While that of *Agaphelus* is identical with that of *Balænoptera*, it is in the present genus quite like that of *Balæna*." — Proc. Acad. Nat. Sci. Phila., 1869, p. 15.

distinct, and the second and third at least enclose a vertebral canal. A first rib (the only one not broken up) has two heads; two other short ribs, perhaps first and second, are united distally into a broad sheet of bone. It is uncertain how far the union of these ribs is constant. The scapula has both coracoid and acromion. The orbital process of the frontal is of medium width, somewhat as in some species of *Megaptera*.”¹

A. W. Malm² described in 1883 fragments of the skeleton of *Rhachianectes* secured by the ‘Vega’ Expedition and figured parts of the skulls of several individuals.

In 1886 Charles H. Townsend published in the ‘Bulletin of the United States Fish Commission’ a brief report upon the condition of the Gray Whale fishery at that time along the coast of California and remarks: “Of the eleven whaling stations mentioned by Scammon as established along the coast ten or twelve years ago, only five remain. . . .” In commenting upon the numbers of the Gray Whale, he says: “At the San Simeon station in December, 1885, I could see whales blowing almost every hour during the day. From the elevated ‘look-out,’ or observation station, on shore an extensive stretch of ocean could be examined with the telescope. During my stay, and for a short time afterward, covering a period of fully a month, Mr. Clark counted forty whales passing southward. Many of these were too far off shore to be pursued by the three boats that were daily cruising outside during the season, and a few may have been other species than gray whales, but counting the forty whales actually seen in December and doubling that number to include those that passed at night during the same period, we have eighty whales per month easily accounted for. Doubling this number again to include those which pass within sight of the lookout station in January (for the ‘down season’ lasts two months), we have one hundred and sixty whales as the number that may readily be seen at the present time from one point alone during the ‘down season.’ What proportion this number bears to the number passing off shore would be hard to say, but it is certainly less than half, since the whales near the coast are mostly females seeking bays and lagoons in which to bring forth their young, which would leave the males and young whales unaccounted for.

“These safe and obviously low estimates, and the above table showing the actual catch during the past three seasons, afford a very fair showing for a species so scarce in 1880 that only one individual could be captured, and indicate a tendency towards its re-establishment while unmolested in its breeding resorts.”³

In the ‘American Naturalist’ for 1888, John Dean Caton⁴ gave a popular compiled account of the Gray Whale and its habits, and twelve years later F. E. Beddard⁵ very briefly described a skeleton of this species in the British Museum.

The last contribution to our knowledge of this interesting animal was made by Dr. F. W. True⁶ in 1904. Dr. True summarized the existing facts relative to the external and internal anatomy of *Rhachianectes glaucus* with enlightening critical comments and also presented detail measurements and photographs of the Monterey skull in the National Museum.

LIFE HISTORY.

Migration.— The Gray Whales begin to appear at Ulsan, southeast Korea, about the end of November on their southward migration. Single pregnant females come first and a little later both males and females are seen but the latter considerably outnumber the former. About January 1, schools of from ten to fifteen males, with perhaps one or two females, appear, the female always leading. From the 7th to the 25th of January, when the migration is completed, only males are present, the females all having passed.

In November and December, when the females are taken, almost every individual will be found to be carrying young nearly ready for birth. As these would necessarily be delivered within two or three weeks after passing Ulsan, the birth must occur in the bays among the numerous small islands at the extreme southern end of the peninsula. Indeed Captain H. G. Melsom, who has hunted Gray Whales for fifteen years along the Korea coast, has often observed them in this vicinity, but because of the abundance of other and more valuable species, they are not killed at this time by the Japanese. When travelling southward the whales are always hurrying straight ahead as though anxious to arrive at the breeding grounds and are never accompanied by small calves; upon the northward migration, however, young have been seen following their parents.

The "Devilfish" again arrives at Ulsan, travelling north, about the middle of March and by the 15th of May they have all passed by. Although the greater portion of the herd goes straight northward, Captain Melsom reports that during the end of April and first week of May he has observed many Gray Whales in Broughton Bay, Korea; these animals seemed to be feeding and had apparently broken the migration by a sojourn in the bay.

A comparison of these observations upon the Korea whales and those made by Scammon on the California coast is interesting. It shows that the breeding grounds of the two herds are in very nearly the same latitude and that their migration dates correspond closely. In regard to this Scammon writes: "The California Gray whale is found only in north latitudes, and its migrations have never been known to extend lower than 20° north. It frequents the coast of California from November to May. During these months the cows enter the lagoons on the lower coast to bring forth their young, while the males remain outside along the seashore. The time of gestation is about one year. Occasionally a male is seen in the lagoons with the cows at the last of the season, and soon after both male and female, with their young, will be seen working their way northward, following the shore so near that they often pass through the kelp near the beach. It is seldom they are seen far out at sea. This habit of resorting to shoal bays is one in which they differ strikingly from other whales. In summer they congregate in the Arctic Ocean and Okhotsk Sea. It has been said that this species of whale has been found on the coast of China and about the shores of the island of Formosa, but the report needs confirmation.¹

"In October and November the California Grays appear off the coast of Oregon and Upper California, on their way back to their tropical haunts, making a quick, low spout at long intervals; showing themselves but very little until they reach the smooth lagoons of the lower coast, where, if not disturbed, they gather in large numbers, passing and repassing into and out of the estuaries,

¹ From personal observation and the statements of the whalers, I doubt if the Gray Whales migrate far south of the peninsula of Korea. During my own travels along the China and Formosa coasts, I have neither seen nor heard of Gray Whales. R. C. A.

or slowly raising their colossal forms midway above the surface, falling over on their sides as if by accident, and dashing the water into foam and spray about them. At times, in calm weather, they are seen lying on the water quite motionless, keeping one position for an hour or more. At such times the sea-gulls and cormorants frequently alight upon the huge beasts. The first season in Scammon's Lagoon, coast of Lower California, the boats were lowered several times for them, we thinking that the animals when in that position were dead or sleeping, but before the boats arrived within even shooting distance they were on the move again" (*l. c.*, pp. 22-24).

As yet it is impossible to state whether or not the Korea and California herds mingle in the north during the summer. Information gathered from the whalers tends to show that a large part of the former herd summers in the Okhotsk Sea and the latter in Bering Sea and further north. Individuals of the two herds may mingle and interbreed during their sojourn in the north, but it is probable that whales which have been born near either the Korea or California coasts will find mates among the members of their own herd during the southward migration and return annually to their birth place. It is quite conceivable that the case of the Gray Whale may be analogous to that of the Fur Seal where it has been shown conclusively that members of the American and Japanese herds do not mingle in the north although separated by comparatively few miles of water at certain times of the year.

Period of gestation and rate of growth.—Because of its regular annual migrations the period of gestation of this species can be more nearly determined than in the case of most other large whales, and appears to be about one year. Mating probably takes place in the south during December or early January, and the calf is ready for delivery the following year.

As stated above (see 'Migration'), the females which appear at Ulsan, Korea, travelling southward are nearly all bearing calves almost ready for birth. Upon the return journey the females are accompanied by young calves, and Capt. H. G. Melsom writes that he killed on March 13 and 14, 1912, at Chan Chien Dogo (near Broughton Bay), Korea, upon their northward migration, two females bearing foetuses 7 and 10 inches long, respectively. These foetuses were probably not more than $2\frac{1}{2}$ months old, which would indicate that the mating had taken place late in the previous December and that the calves would be delivered the following December or January when the whales returned to the south. A female 1300 cm. (42' 8") in length taken at Ulsan, Korea, on January 8, 1912, contained a foetus 476 cm. (15' $7\frac{1}{2}$ ") long, and ready for birth; it would certainly not have been carried more than a week or ten days longer.

Whether or not the females again mate immediately after giving birth to their young it is impossible to state, but from Scammon's observations, quoted below, I believe it to be unlikely and that calves are born but once in two years.

Scammon says that the period of gestation is about one year, and remarks: "This statement is maintained upon the following observations: We have known of five embryos being taken from females between the latitudes of 31° and 37° north, on the California coast, when the animals were returning from their warm winter haunts to their cool summer resorts, and in every instance they were exceedingly fat, which is quite opposite to the cows which have produced and nurtured a calf while in the lagoons; hence we conclude that the animals propagate only once in two years" (*l. c.*, p. 23, note).

Mr. C. H. Townsend, writing in 1886 of the San Simeon (Cal.) station, says: "Unlike Monterey, this station depends almost entirely for its business upon the gray whales, which pass southward with great regularity from December until February. The 'up season,' lasting until

April, is also profitable at San Simeon, but the catch there consists chiefly of males, the females keeping farther off shore when passing northward with their young. During the last ten years Captain Clark has seen but one female accompanied by young in the vicinity of his station. At San Simeon, and all the whaling establishments situated south of it, females exceed the other sex in numbers during the 'down run' and most of them contain well-developed young. At this place and at San Luis Obispo, the nearest neighboring station, I saw four young whales lying on the beach, which had been taken from females killed in the vicinity during that season (December, 1885). Their average length was about 12 feet; the largest, which I sketched, being 17 feet long, and from an adult nearly 40 feet in length. They were probably within two weeks of the time of birth when the parent animals were killed" (*l. c.*, pp. 347-348).

From the above data it may be safely affirmed that the length at birth of the majority of Gray Whales is between 12 and 17 feet. When the females go north in March on the Korea coast, the calves which have been born near the end of the previous December accompany them, and by the time they reach Ulsan are about twenty-five feet in length. This makes a growth of nine or ten feet during a little less than three months. This may seem extraordinary, but it is quite in accord with what apparently takes place in all baleen whales. Without doubt the rate of growth for the calf is very rapid during the first few months after birth and until sexual maturity is reached.

Thirty-two feet is the minimum length for Gray Whales taken at Ulsan, and individuals of this size must certainly have been born during the previous winter. Thus, accepting 14 feet as the average length at birth, we get a growth of 18 feet during a little less than one year.

How long the young nurse is problematical but it must be considerably less than one year because, so far as I am aware, nursing calves or females have not been taken at Ulsan on the southward migration, and some would certainly have been brought in if the suckling period was not over before the animals reached that point upon the coast.

Spouting and diving.— The height and form of the spout varies with conditions. Normally the vapor rises vertically ten or eleven feet in a thick column having the width at the summit about twice that at the base (Plate XXIV, Fig. 7). It may, however, reach a height of fifteen feet if the whale is large and has been submerged for a considerable period. The spout is single in the majority of cases, but Captain Melsom asserts positively that at times it is divided like that of a Right Whale. As in all Cetaceans the initial spout after a period of submergence is generally the highest and fullest.

The number of respirations between the dives is fairly regular. When the whale has been below for several minutes upon rising to the surface it will usually blow two or three times before again going down.

When cruising along the shore the animal generally remains submerged seven or eight minutes and blows three times when it reappears. Captain Melsom assures me that when a large female is taking a straight course it will remain below four or five minutes and rise to make three spouts very regularly; at other times a single whale will remain down ten minutes and a school between fifteen or twenty minutes, depending upon circumstances.

When travelling straight ahead and unmolested the Devilfish swim under water for a distance of 300 or 400 fathoms quite regularly and rise to spout three times.

Under normal conditions the animals 'sound' much as do Humpbacks. As soon as the spout has been delivered, the body begins to revolve and as the dive progresses the flukes are

lifted out of the water and drawn slowly under. The flukes are not invariably shown, however, even when sounding; some animals will almost always 'fluke out' and others, not at all. Under no circumstances do the Gray Whales arch the back as strongly as do the Humpbacks nor do the animals raise themselves so far out of the water.

During the 'surface' or 'intermediate' dives only a small part of the back is shown, the motion is forward and downward, and the flukes are never exposed.

Speed.—The Gray Whales are slow swimmers and cannot exceed seven or eight knots per hour even when badly frightened and doing their best to get away. Ordinarily when 'travelling,' and unmolested, they make about three or four knots, and when cruising along the shore perhaps two or three knots per hour.

The Gray Whale is essentially a shore-loving species and on its annual migration always prefers to swim along close to the beach. At times the whales will go in so close to the shore that they are actually rolling in the surf and seem to enjoy being pounded by the breakers. Seammon has observed the same habit in the California animals and says: "About the shoals at the mouth of one of the lagoons, in 1860, we saw large numbers of the monsters. It was at the low stage of the tide, and the shoal places were plainly marked by the constantly foaming breakers. To our surprise we saw many of the whales going through the surf where the depth of water was barely sufficient to float them. We could discern in many places, by the white sand that came to the surface, that they must be near or touching the bottom. One in particular, lay for half an hour in the breakers, playing, as seals often do in a heavy surf; turning from side to side with half extended fins, and moved apparently by the heavy ground-swell which was breaking; at times making a playful spring with its bending flukes, throwing its body clear of the water, coming down with a heavy splash, then making two or three spouts, and again settling under water; perhaps the next moment its head would appear, and with the heavy swell the animal would roll over in a listless manner, to all appearance enjoying the sport intensely. We passed close to this sportive animal, and had only thirteen feet of water" (*l. c.*, p. 24).

Frequently when being hunted the Korea whales would escape by swimming into water so shallow that the ships could not follow them and remaining there until the men had given up the chase.

Food.—Although the stomachs of a great number of Gray Whales were examined carefully I could never discover what constitutes their food. In every case the stomach was more or less filled with dark green water in which the only solid materials were bits of kelp, a little sea weed, and small masses of a light green gelatinous material. The stomachs of two individuals contained a number of small water-worn pebbles and several masses, six to eight inches long, of what appeared to be finely shredded raw meat still connected by its fibers; this was certainly not fish. It is probable that the kelp and sea weed had been taken in with other material, as in the case of the pebbles. The excrement of all the whales had about the consistency of thick cream and was dark green like the water in the stomach.

All the gunners asserted that when the Gray Whales appear at Ulsan on their migrations they are invariably travelling straight ahead and apparently not stopping to feed. This information, combined with the fact that little except water could be found in the stomachs, lends strong support to the theory that upon their annual migrations the Devilfish feed but very little, if at all. If feeding is indulged in, it would seem extraordinary that no specimens have been brought to the station having food, or its remains, in their stomachs. The presence of fæces in the intes-

tines may be due to the fact that these organs had not entirely emptied themselves since the last period of feeding in the north. The green color of the water in the stomach and of the excrement is probably due to biliary secretions.

It is possible that while upon their migrations the whales eat quantities of the jelly fish which are so frequently seen near the kelp fields just off shore. These animals, consisting largely of water, would be very quickly acted upon by the digestive fluids and the lack of solid material in the stomach be thus explained. Captain Melsom has seen Gray Whales in the Okhotsk Sea during the summer which were not travelling but were swimming slowly about.

It is interesting to note that neither Scammon nor Townsend could get any definite information as to the food of the Gray Whales of the California coast. Scammon remarks: "To our personal knowledge, but little or no food has been found in the animal's stomach. We have examined several taken in the lagoons, and in them we found what the whalers called 'sedge' or 'sea-moss' (a sort of sea-cabbage), which at certain seasons darkens the water in extensive patches both in and about the mouths of the estuaries. Whether this was taken into the stomach as food some naturalists doubt, giving as a reason that the whale, passing through the water mixed with this vegetable matter, on opening its mouth would of necessity receive more or less of it, which would be swallowed, there being no other way in which it could be disposed of. The quantity found in any one individual would not exceed a barrelful.

"From the testimony of several whaling-men whom we regard as interested and careful observers, together with our own investigations, we are convinced that mussels have been found in the maws of the California Grays; but as yet, from our own observations, we have not been able to establish the fact of what their principal sustenance consists" (*l. c.*, pp. 24, 25, note).

Townsend says in regard to the food: "The opinion of the men with whom I talked is that it does not feed to any great extent outside of its arctic habitat. It is certainly much thinner on the northward than on the southward run, a male that would yield 30 or more barrels of oil in the down season yielding less than 25 two months later. Whalers admit their ignorance of what constitutes the food of this animal, and can find nothing in its stomach during the breeding season" (*l. c.*, p. 349).

Affection.—The male Devilfish at all times shows strong affection for the female and Captain Melsom tells me that during the migration, when a school of males led by one or two females is found, if one of the latter is wounded, often the former will refuse to leave until she is dead. One day when hunting a pair he wounded the cow and the bull would not leave, keeping close alongside and pushing his head over her body. Later he struck the male with a harpoon but did not get fast and even then it returned and was finally killed. Captain Melsom assures me, however, that if the male is killed the female will seldom remain.

Scammon has recorded instances of the female's love for her young and it was because of her vigorous defense when attacked on the breeding grounds that the name "Devilfish" was gained. The whalemens in Korea, however, where the hunting is done from small ships by the Norwegian method, do not regard the animals as especially dangerous. They seldom lance one from the 'pram,' as is frequently done with Finbacks because the Gray Whales seem to be very sensitive to pain, and as soon as the iron penetrates the body the animal will raise itself in the water, throwing its head from side to side and sometimes lashing about with its flukes and fins.

Attacks by Killers (Orca orca).—The Gray Whales seem to be objects of continual persecution by the Killers; much more so than any of the other large whales. Among the first

eight or nine Devilfish which I examined at Ulsan, three attracted my attention at once because the entire anterior part of the tongue had been torn away. Teeth marks plainly showed in the remaining portion and upon consulting the gunner, Captain Hans Hurum, who had killed them, he told me that it had been done by Killers at the time he shot the whales. Seven Gray Whales were in the school, and shortly after he began to hunt them fifteen Killers appeared. The whales became terrified at once and he had no difficulty in killing three of the seven. When the Orcas gathered about, the whales turned belly up and lay motionless, with fins outspread, apparently paralyzed by fright. A Killer would put its snout against the closed lips of the Devilfish and endeavor to force the mouth open and its own head inside. This extraordinary method of attack was corroborated by Capt. Johnson who had been hunting the same school of Gray Whales, and, moreover, by all the whalers at the station who had witnessed it upon many other occasions.

Out of the thirty-five Gray Whales which I examined especially, seven had the tongues eaten to a greater or less extent and one had several large semicircular bites in the left lower lip. The Killers do not confine their attention entirely to the tongue for almost every whale which was brought in had the tips and posterior edges of the fins and flukes more or less torn; in several specimens fresh teeth marks were plainly visible where the fin had been 'shredded' as the whale drew it out of the Orca's mouth.

Although none of the Gray Whales exhibited teeth marks on other parts of the body undoubtedly some of them are killed by the Orcas. A female Killer which was brought to the station had several pieces of flesh in its stomach besides a strip of whalebone three inches long; I could not positively identify the latter but believe it to have been from a small Devilfish. A male Killer was taken at the same time by Captain Hurum who told me that in the animal's death flurry it had thrown up two great chunks of flesh.

Captain Melsom brought a Gray Whale to the station one day and I was interested to find the tongue almost gone. He said he had passed a school of Killers in the morning and later, after steaming about fifteen miles, had killed the Devilfish. A short time afterward, a long distance away, he saw the fins of a school of Killers which were coming at full speed straight for the ship. They circled about the vessel and one of them forced open the mouth of the dead whale to get at the tongue. When Captain Melsom fired at the Killer with his Krag rifle the animal lashed out with its flukes, smashing the ship's rail, and disappeared.

As soon as Orcas appear if the Gray Whales are not paralyzed by fright they head for shore and slide in as close as possible to the beach where sometimes the Killers will not follow them. The Devilfish will actually go into such shallow water as to roll in the wash and even try to hide behind rocks. The Orcas are not afraid of the ships and will not leave the whales they are chasing when the vessels arrive, thus giving much assistance to the human hunters.

Captain Johnson, of the 'Rex Maru,' brought to the station at Ulsan a Gray Whale which had been shot in the breast between the fins. He had first seen Killers circling about the whale which was lying at the surface, belly up, with the fins outspread, being absolutely paralyzed by fright. The vessel steamed up at half speed and Johnson shot at once, the iron striking the whale in the breast.

Such is the fear of the Gray Whale that when, as frequently happens, porpoises are playing about a single animal, it will sometimes become terrified, thinking that the Killers have appeared.

I have never personally witnessed it but the gunners tell me that a pod of Gray Whales can

be stampeded much as can a herd of cattle. If three or four ships are near each other when a school of Devilfish are found, they draw together, each vessel going at full speed and making as much noise as possible. The whales at once sound, but as soon as they rise to spout the ships steam at them again. The Devilfish go down once more but do not stay under long, ascending at shorter intervals until finally they are ploughing along at the surface. The animals are 'scared up' as the gunners say, and become terrified to such a degree that everything is forgotten except the desire to get away. It is not always possible to stampede a herd, and often the whales will disappear at the first sound, not rising again until a long distance away. If Killers are about at the time a herd of Gray Whales are being hunted it is very easy for the ships to stampede them.

Even if the Devilfish do exhibit considerable stupidity when danger from Killers threatens, at other times they are the cleverest and most tricky of all large whales. One day the S. S. 'Main,' Captain Melsom, was hunting a Gray Whale in a perfectly smooth sea. The whale had been down for fifteen minutes when suddenly a slight sound was heard near the ship and a thin cloud of vapor was seen floating upward from a patch of ripples which might have been made by a duck leaving the surface. The whale had exposed only the blowholes, spouted, refilled the lungs and again sunk, doing it almost noiselessly. The gunners assert that this is quite a usual occurrence when a single Gray Whale is being hunted.

Diseases.—Most whales are subject to diseases of various kinds and the Devilfish is no exception. One specimen was brought to the station at Ulsan, with all the flesh on the left side of the head badly decomposed and in some places entirely gone, leaving the bone exposed; what remained hung in a soft, green, evil-smelling mass. The whale had evidently suffered considerably from the disease for it was very thin and the blubber dry.

A second specimen had a large swelling on the ventral ridge of the peduncle, which upon being opened, proved to be a large capsular tumor about one foot in depth and of a like diameter.

The skin upon the snout of a third individual was drawn into small circular patches leaving large sections of the blubber exposed.

SIZE.

The available material relating to the size of *Rhachianectes glaucus* consists of the following: From Korea, records of one hundred and twenty-two specimens taken by the whaling company during 1909–10, and of twenty-three measured by myself in 1912; from California, the measurements given by Scammon and Dall of two specimens taken in Monterey Bay, and the record by Pechuel of one from the Bay of San Simeon.

My own measurements of the total length were taken from the notch of the flukes to the tip of the snout, either along the side of the belly as the animal lay in the water or as each section was drawn upon the cutting wharf. Every whale was also measured by a representative of the company, and as the total length was secured by the Japanese in a way similar to mine it may be assumed that all the Korean specimens are directly comparable.

In the following tables measurements of both males and females are arranged according to size.

Like all baleen whales, the female *Rhachianectes* is larger than the male. The maximum size of the 123 specimens measured by the whaling company was 1371 cm. (45'); this length was reached by four females. The maximum for males was 1310 cm. (43'). A female 1317 cm. (43' 3") long and two males each 1250 cm. (41' ½') were the largest of the 23 specimens which I measured in 1912. Dall has recorded an unsexed individual 1554 cm. (51') and a male 1462 cm. (48') in length. If these measurements are correct Dall's specimens must have been of unusual size for the whalers in Korea assured me that examples longer than 1371 cm. were extremely rare. Measurements of his 1462 cm. whale show such a remarkable disagreement with all other specimens that there must have been some error in either taking or recording the dimensions. My friend Capt. H. G. Melsom, who has spent nearly fifteen years hunting Gray Whales in Korea, tells me that he killed two female whales 49 and 47 feet long, respectively; these are the largest specimens he has ever known killed.

The average length for all females measured by the whaling company and by myself agrees closely and is respectively 1254 cm. (41' 2") and 1259 cm. (41' 4"); for all males it is 1188 cm. (39') and 1172 cm. (38' 6"). There can be little doubt that specimens larger than 1371 cm. (45') are exceedingly rare.

It is difficult to arrive at a satisfactory conclusion as to the length at which *Rhachianectes glaucus* becomes sexually mature, for at present there are few data relative to this subject. Town-

send took a foetus 518 cm. (17') long from a female, "about forty feet long," and the only pregnant female which I examined was a specimen 1300 cm. (42' 8") in length. The condition of the skeleton proved this animal to be fully adult.

The measurements of length are arranged in tabular form in the following table (Table III).

Table III. Summary of Measurements.

LOCALITY	Average for all specimens of both sexes		Average for all females		Average for all males		Maximum for females	Maximum for males	Minimum for females	Minimum for males

PROPORTIONS.

In the following tables detail measurements of Korea and California representatives of *Rhachianectes glaucus* will be found. It was possible to take a fairly complete series of measurements of some of the Korea specimens while of others only a few could be secured but all have been presented with the hope that they may be of aid to future students of this species.

In the second table certain of the most reliable measurements have been selected, and their ratios to the total length given, to ascertain the degree of individual variation and to facilitate comparison.

It will be seen upon examination of the table of ratios that there is a greater or less variation in almost all the proportions. The question at once arises as to whether or not this can be due wholly to individual differences or in part to inaccuracy of measurement. The lengths of all specimens were secured while the animals were lying in the water or else were the totals of the different sections as the whales were being "cut in." The length was never taken over the back but usually along the side or breast, and in most cases I believe it to be accurate. In Nos. 2, 9, and 11 there is a possibility of doubt, but none of the ratios of these specimens show unusual variation.

All the measurements, except the total length and the distance from the tip of the snout to the axilla, were secured without difficulty after the sections of the whale had been drawn upon the wharf.

I have included in the table, measurements of the fully grown foetus No. 1a, for as these were taken at leisure with the greatest care there is no doubt as to their accuracy and they furnish a valuable standard for comparison with the adult individuals.

Table IV.—Detail Measurements of Korea and California specimens.

It will be seen from the table that the greatest variation appears in the distance from the notch of the flukes to the dorsal "hump" amounting to 11%; this will be discussed later.

The variation of 5.3% in the width of the flukes from tip to tip may in great measure be accounted for by the fact that the tips of the flukes were very frequently injured. The same can be said of the measurement of the pectoral from the tip to the head of the humerus, but in a less degree, for usually one of the flippers, at least, was uninjured and the correct length could thus be secured.

The measurements of the California examples neither conform to each other nor to those from Korea. In Scammon's specimen the distance from the tip of the snout to the blowholes is 14.2% of the total length. This is much less than in any of the Korea whales and, moreover, gives a difference of 3.6% between the measurements from the tip of the snout to the eye and to the blowhole. This can hardly be correct. The same discrepancy is apparent in Dall's figures, but to a greater degree. The ratio to the total length of the tip of the snout to the eye is greater than in any of the Korea specimens, and that from the tip of the snout to the blowholes is much less, the difference between the two being 11.6%. One, or both, of these measurements is certainly incorrect.

Pechuel's figures give the distance from the snout to the blowhole as 25% of the total length, while the greatest in the Korea specimens is 19.5%. It is impossible to account for this discrepancy.

Scammon's measurements from the snout to the axilla, of the flukes from tip to tip, and of the depth of the peduncle just anterior to the flukes, are all at such variance with the Korea specimens that they must either be incorrect or have been taken in quite a different manner from my own. The same is true of Dall's measurements of the flukes from tip to tip and of the length of the fin. These data in reference to the California specimens are, therefore, of little value either for comparison with the Korea examples or with each other.

COLOR.

Plates XIX and XX.

None of the published descriptions of the color of *Rhachianectes glaucus* which I have been able to find occupy more than three or four lines, or give other than the vaguest impression of the animal's appearance. Scammon says: "The California Gray is unlike other species of baleen whales in color, being of a mottled gray, very light in some individuals, while others, both male and female, are nearly black" (*l. c.*, p. 20). Scammon's figure (*l. c.*, plate ii, fig. 1) shows a rather slender whale, gray, and irregularly marked with white on the entire upper half of the body from the head to the flukes; the lower half is represented as almost plain.

This type of coloration is just the reverse of what was observed in Korea specimens. It is true that several examples were seen which had the back more or less heavily marked, but in every case where this occurred the lower half of the body was so thickly covered with white and gray patches that there was a great preponderance of the light color. Unless the California specimens are very different from those of Korea, which is highly improbable, Scammon's figure is incorrect. This view is strengthened when the drawing of *Balænoptera sulfurea* (*l. c.*, plate xiii) is examined for it is quite unlike a Pacific Sulphurbottom in coloration. Scammon's first figure of *Rhachianectes*, published in 1869,² although very crude, gives in the side view a really better suggestion of the color of the animal than does the plate in his 'Marine Mammalia.' In his first figure the markings are shown evenly distributed over the entire body from the head to the flukes and not confined to the dorsal surface as in the later drawing.

In Cope's article on the Gray Whale (1868), Mr. W. H. Dall's description of two specimens seen by him at Monterey, Cal., is quoted, as follows: "Color above and below, black, with a gray bloom like a plum. This distinguishes this species from the known *Balæna* of the Pacific, which are more or less white on the belly and fin" (*l. c.*, p. 226).

Pechuel's figure of *Rhachianectes* is diagrammatic and there is little attempt at coloration.

¹ This does not include foetus No. 1a.
² Proc. Phil. Acad. Nat. Sci. Phil., 1869, fig. 8.

PLATE XIX.

PLATE XIX.

RHACHIANECTES GLAUCUS.

- Fig. 1. Lateral view of peduncle showing white markings, mostly cirriped scars.
- Fig. 2. Lateral view of peduncle showing normal gray and white markings and total absence of cirriped scars.
- Fig. 3. Head, pectoral fin and section of back blubber.
- Fig. 4. Direct lateral view of peduncle showing dorsal crenulations.
- Fig. 5. Dorsal view of peduncle showing normal gray markings and flukes.
- Fig. 6. Peduncle lying upon the wharf.
- Fig. 7. Posterior portion of body showing inferior outline.

RHACHIANECTES GLAUCUS.

He says in regard to this: "Abweichend von allen anderen Walen ist seine Farbe ein melirtes grau, Manche sind ganz fleckig, selten sieht man gleichmässig dunkel gefärbte."¹

The following description of Korea examples is, therefore, the only detailed account of the color of the Gray Whale that has thus far been published.

There seems to be quite as much individual color variation in *R. glaucus* as in other baleen whales, some examples being abnormally dark with but few gray markings while others are very light, the entire body being so thickly covered with blotches of white and gray that there is a preponderance of the light color. It is obvious, therefore, that no description which will apply to all individuals can be given, but between the light and dark extremes there was a certain type of coloration possessed by a majority of the examples which came under my observation. This may be described as follows: The head, throat, back, and the dorsal and ventral ridges of the peduncle are black, or very dark slate, and are usually unmarked. On the dorsal and lateral surfaces of the distal half of the rostrum there is considerable white and light gray in flecks and small spots; this is frequently true of the chin, lower lips, and both mandibular rami. On the under side of the rostrum just exterior to the bases of the baleen rows, there is a band of flesh pink, or white, about three inches wide. The amount of white on the rostrum and lips varies greatly with individuals but it is seldom entirely absent. The throat and sides to the pectorals are usually unmarked. From the fins to a point opposite the anus, on the sides, breast and belly, are many roughly elliptical and circular markings with irregular edges. These markings have gray centers shading to very light gray, or white, on the edges and are broken by small round, or oval, black spots (Plate XX, Fig. 6). They follow the long axis of the body and generally closely approximate each other.

On the sides of the peduncle the gray markings become scattered and are generally smaller and darker. The whole body from the head to the flukes has many white or light gray circular scars of varying sizes, apparently left by parasitic cirripeds; on some individuals these almost obscure all other markings.

The pectoral fins are dark slate like the body. Above, on the posterior half, there are a few scattered white circles and spots. Below, the white circles are more numerous and on the distal half are two more or less broken bands of white, or very light gray, about 8 cm. wide and 45 cm. long between the 2nd and 3rd and 3rd and 4th fingers; the band between the 2nd and 3rd fingers is usually the longer. The posterior edge of the fin is very frequently white.

The flukes are black or dark slate like the body, a few white circles and spots being scattered over both surfaces, generally more on the lower. Frequently the posterior edges and tips are white.

In connection with the preceding description it is interesting to refer to the color of foetus No. 1a, described below. This specimen was almost ready for birth and gives an excellent idea of the disposition of the markings on the Gray Whale before the body has been scarred by parasites and by contact with rocks. The general color must become much darker after birth than it is during foetal life.

Color Variations.— There are striking variations from the type of coloration described above. Three specimens out of the twenty-one on which color notes were taken were exceptionally light colored. One (No. 8, male) had the entire rostrum, lips and mandibular rami dotted and specked

¹ Pechuel-Loesche, Wale and Walfang. Ausland, Vol. 44, 1871, p. 1186.

with gray and white. The sides of the breast and throat, from the fins forward, were streaked longitudinally with long gray lines, and the center of the throat thickly splashed with white. The back was heavily marked with oblong blotches of white. The only portion of the whale unmarked was the dorsal and ventral ridges of the peduncle.

A second whale (No. 11, male) had almost no white on the lips, rostrum or throat, but the sides of the body and peduncle, from the fins to the flukes, were so thickly washed, circled and blotched with gray and white that there was much more light than dark color.

No. 19, female, had the lower lips and distal portion of the mandible finely dotted and flecked with gray and white. The sides, belly, and the entire peduncle were so thickly covered with small light gray patches, that there was more light than dark color. The ground color of this whale was dark gray and not slate, or black, as usual.

No. 3 was a dark whale and No. 5 exceptionally so. The body was black and had only a few small and rather indistinct gray markings on the sides, back and lower half of the peduncle.

No. 6, female, was black. On the left side of the throat were a few long stripes of white, which seemed to be scars. The remainder of the throat, breast and belly was unmarked save for a single large, irregular, light-gray patch on the belly; the entire peduncle was plain except for a little white along the dorsal ridge. No. 14, male, was much like No. 6; No. 17, male, although a very dark individual, had the rostrum, lips and mandibular rami mixed white and gray, and the sides of the peduncle, body and back streaked with long, narrow gray lines.

There seems to be a tendency among the whalers to believe that all individuals which show a preponderance of light color are of the greatest age. Averages and comparisons of the lengths of the very dark, very light, and normal examples of *R. glaucus* shows but little difference between them and gives no basis for believing that the animals become lighter with increasing years. Only three of the whales which I examined were females, one of these being exceptionally dark and the other somewhat lighter than normal. The males presented both light and dark extremes and every variety of intermediate coloration. I believe, therefore, that the color differences have nothing whatever to do with sex or age, or that they are other than purely individual.

For reference the field descriptions of twenty-one individuals examined at Ulsan, Korea, are given below:

Field color descriptions of 23 Korea specimens.

No. 1. Female. Length, 1300 cm. General color dark slate. Much white on the distal half of the rostrum, snout and upper lips just above the bases of the baleen rows. Many fine, grayish lines on the back, and numbers of irregular white streaks over the entire body; the latter appeared to be scars from old wounds. Inferior half of peduncle from genitalia to flukes thickly marked with irregular elliptical patches of light gray.

Pectoral fins dark slate above, having both margins and tips whitish, the light color extending far up on the superior surface of the fin.

Flukes above dark slate with many white dashes and circles, the latter undoubtedly caused by parasitic cirripeds.

No. 1a. Foetus. Male. Length, 476 cm. General color gray. The entire head and throat to the posterior insertion of the pectoral fins is light gray. A line of small, dark gray spots and dashes extends from the eye to a point a short distance above the pectoral. On the throat are a few small patches of very light gray, almost flesh white, and several large irregular markings of dark gray.

PLATE XX.

PLATE XX.

RHACHIANECTES GLAUCUS.

- Fig. 1. Direct lateral view of head showing few parasite scars.
- Fig. 2. Three-quarters posterior view of head showing many parasite scars.
- Fig. 3. Dorsal view of head and blowholes; note the barnacles *Cryptolepas rhachianecti* embedded in the skin, and the masses of *Cyamus scammoni*.
- Fig. 4. Front view of head.
- Fig. 5. Direct lateral view of head and mandible of foetus No. 1a.
- Fig. 6. Section of peduncle showing normal gray and white markings.

RHACHIANECTES GLAUCUS.

On the sides a slight ridge is formed by the ends of the vertebral transverse processes below which the lateral and ventral surfaces of the body, forward almost to the pectoral fins, bear many irregular oblong and elliptical patches of very light gray; the markings are longitudinal, follow the long axis of the body and are so thick that there is more of the light than of the dark color. The back, above the line of the transverse processes, is light gray thinly marked with irregular, dark gray oval and oblong patches. On the right side, just posterior to the tip of the pectoral laid back, is a circular, pure white spot about 4 centimeters in diameter and a second smaller one above the posterior insertion of the fin.

The pectorals are plain dark gray on both surfaces but have light posterior and anterior edges.

The flukes are plain light gray above with dark anterior and posterior margins. Below, the ground color is light gray but coarse, broken whitish lines run transversely across each fluke from the anterior edge and curve inward toward the notch; this gives more white than dark color to the inferior surface.

No. 2. Male. Length, 1160 cm. Many fine white spots and flecks on snout, symphysis of mandible, and on both rami, but the remainder of the head is plain dark gray. Posterior to the genitalia both sides of the body have many large irregular patches of light gray about thirty cm. long by twelve cm. wide, and numerous blotches, circles and spots of white. There is a large patch of light gray about 150 cm. long by 45 cm. wide on the right side of the back and a large white spot just posterior to the tip of the pectoral fin laid back. The mid-dorsal region has either very few gray markings or none at all. The lower half of the peduncle is covered with rather fine dashes and circles of white.

The pectoral fins are alike on both surfaces. On the distal two-thirds between the second and third and the third and fourth digits there are two broad parallel bands of white. The remainder of the fin is so dotted, barred and circled with white that there is more white than dark.

Both surfaces of the flukes are dark slate thickly covered with irregular bands, spots and dashes of white. The left lobe has the inferior surface of the distal end almost entirely white.

No. 3. Male. Length, 1240 cm. A dark individual. The general color is dark slate, almost black. On the dorsal and lateral surface of the rostrum there is considerable light gray, but except for numerous cirriped scars, especially on the sides of the peduncle, the body has comparatively few light markings.

On both surfaces of the pectoral fins there is a broad longitudinal band of white between the fingers, and a few circles and spots of white on other parts of the flipper. The posterior edges are also white.

No. 4. Male. Length, 1170 cm. General color of body dark slate. The entire rostrum is clear light gray, shading into darker on the head, but does not show much white; neither is there white on the lips or mandibular rami. The dorsal region of the peduncle and body forward to the pectoral fins is unmarked dark slate but the sides have many small spots, dashes, and circular scars of white.

The pectoral fins are dark slate above and have a whitish longitudinal band between the fingers; also a few large cirriped scars. The anterior edge of the fin is dark slate and the posterior edge white.

No. 5. Male. Length, 1143 cm. A very dark individual. Head, back, sides and upper

half of peduncle, black. Lower half of peduncle has a few small, light gray markings and on the back and sides near the pectorals are several rather indistinct, gray patches; scattered over the body are a few large, white circular scars. Mucous membrane in the roof of the mouth light pink as are the lips just above the bases of the baleen rows.

The pectoral fins are black, above, except for two or three large white circles. Below, there is one large oblong patch of white between the fingers.

Both surfaces of the flukes are plain, unmarked black.

No. 6. Female. Length, 1317 cm. A very dark whale. Throat, breast and belly plain black except for a few long white stripes (apparently scars) just above the furrows and a large, irregular, light gray patch on the belly. The back and sides are black, almost unmarked, and on the peduncle *there are no gray patches* and only a few cirriped scars; along the dorsal ridge is a little white.

The superior surface of the pectoral fins is black with a few white circles; inferiorly both flippers are marbled and circled with white.

No. 7. Male. Length, 1202 cm. The entire distal third of the rostrum and the dorsal ridge to the blowholes is greatly roughened, or "cornified," thickly infested with parasitic *Cyamus*. There is no white on the rostrum.

The superior surface of each pectoral fin has but little white. On the inferior surface two broad bands of white run between the fingers to the tip of the fin and there is a large white patch near the base.

No. 8. Male. Length, 1240 cm. The lightest colored specimen which has been brought to the station. The dorsal ridge of the rostrum is almost entirely white having but few gray specks; the left side of the rostrum is like the dorsal surface but the right side is covered with fine gray and white flecks and dots giving a "pepper and salt" effect (apparently many small barnacles had fastened here). From chin to pectorals the sides of the throat and breast are streaked with long, longitudinal gray lines about five mm. wide and the center of the throat is thickly splashed with white. The rami of the mandible and the lower lips are mixed white and gray ("pepper and salt"). The entire back is thickly marked with small white circles and dots and the sides of the body, posterior to the fins, and of the peduncle are covered with blotches of white, fairly regular in size and about 25 cm. long by 10 wide; the edges of the blotches are irregular. The mid-dorsal and mid-ventral regions of the peduncle are plain black except for a circular patch of white about 30 cm. in diameter.

On the inferior surface the pectorals have two broad longitudinal bands between the digits, that nearest the posterior edge being the longest; there are also many smaller patches and scars on the lower surface. Above, the pectorals have much less white, only one band being present.

The flukes are black, above, thinly circled with white but below have much white.

No. 9. Female. Length, 1160 cm. Sides of body and of the peduncle blotched with light gray; the markings are heavier on the body. Ventral region almost plain.

No. 10. Male. Length, 1050 cm. A dark individual. Throat and lips plain dark slate with practically no lighter color. On the sides backward to a point opposite the anus are a good many large, gray, oval and oblong markings having irregular margins; the sides are also thickly studded with barnacles. The dorsal and ventral regions of the peduncle are plain but there are a few white circles and spots on the sides. The dorsal "hump" has patches of light gray, almost white, on either side and a large white spot on the right side; just anterior to the penis is a gray blotch.

Above, the pectoral is black with only one white spot.

The flukes are black on both surfaces save for a few white circles; the distal half of the posterior edge is all white.

No. 11. Male. Length, 1075 cm. A light individual. There is almost no white on the rostrum, lips, or throat. Sides of body and of peduncle so thickly washed, circled and marked with gray and white that there is much more light than dark color present.

No. 13. Male. Length, 1250 cm. Sides of body from the fins to a point opposite the anus, have many large gray and white markings and an extensive area of clear light gray. The peduncle has few gray markings on the sides but many white barnacle scars (many barnacles are still in position).

On the inferior surface, both fins are black but have a number of white spots joining to form a band about 60 cm. long between the second and third fingers. There are a good many other white spots and circles along the posterior edge, the remainder of the fin being unmarked. The superior surface is almost like the inferior but shows somewhat less white.

No. 14. Male. Length, 1160 cm. An exceptionally dark whale. The head is black showing practically no white or gray markings and but few parasites. On the chin and throat and on the breast between the fins there are many white flecks and circles but the remainder of the breast and belly is plain. On the left side from the fin to a point opposite the penis is an area of clear light gray about 60 cm. wide; on the right side its place is taken by a number of rather dark gray, roughly oblong, markings. The peduncle is almost entirely black but has a few gray patches on the inferior half.

No. 15. Male. Length, 1085 cm. The head shows a little white on the dorsal surface of the rostrum and on the sides a good many white barnacle scars. The sides of the body from the pectoral fins to a point opposite the anus have numerous light gray patches with white edges which almost join each other; these also cover the belly but do not extend on to the back. The superior half of the peduncle is plain black and the remainder thinly covered with rather small gray markings.

No. 16. Male. Length, 1180 cm. A light individual. The head, lips, throat and back are black except for a few gray patches just posterior to the blowholes and a white spot on the lips. The sides of the body from the fins to a point opposite the anus are covered with rather small gray patches which become larger and more numerous on the lateral surfaces of the peduncle. (These patches are gray in the center shading to white on the edges and broken by small black spots or dashes). The dorsal and ventral regions of the peduncle are unmarked.

The pectoral fins are black, above, circled with white. The inferior surface has fewer circles but is washed with white in several places. The flukes are black below with a few white circles. (In coloration the tail resembles that of *Megaptera*).

No. 17. Male. Length, 980 cm. A dark whale. The sides of the rostrum, lips and mandibular rami are mixed gray and white ("pepper and salt"). The back, sides of body and peduncle are marked with long gray lines which resemble scratches but seem to be normal.

The flukes are very light colored on the inferior surface and have whitish lines running transversely across each lobe and curving inward toward the notch.

No. 18. Male. Length 1190 cm. The dorsal and lateral surfaces of the rostrum are very light gray; the entire mandible is dark but shades into very light gray about 60 cm. from the symphysis. The sides of the body from the pectoral fins to a point opposite the anus has many,

rather dark gray markings a few of which are present on the proximal half of the peduncle; the remainder of the peduncle is very dark slate. The back is unmarked save for a few small barnacle scars.

No. 19. Male. Length, 1180 cm. A very light whale. The ground color of the body is dark gray and not the usual slate, or black. Distal half of mandible gray and white mixed. The sides of the body, belly and entire peduncle are thickly covered with small gray patches, irregular in shape, but having their longitudinal axes following the axis of the body. The gray markings are about 15 cm. long by 8 cm. wide and coalesce so that there is more of the light gray and white than the darker ground color.

No. 20. Male. Length, 1215 cm. Ground color dark gray. Sides of rostrum and head to the eyes very light gray; just above the bases of the baleen rows is the usual narrow pinkish band. Sides of body to the fins have many gray markings, and the back, belly and, in fact, the entire body is thickly covered with white cirriped scars. The dorsal and ventral regions of the peduncle are unmarked, but the sides have a number of gray patches which become smaller posteriorly and cease about 120 cm. from the flukes.

The pectorals are dark on the superior surfaces with only a few white flecks. There is a considerable quantity of white flecks, spots and circles scattered over the inferior surfaces and the posterior edges are white.

The flukes are dark above and below showing but few white circles and spots.

No. 23. Male. Length, 1235 cm. A light individual. The head, lips and jaws are mostly light gray with flecks of white. There is much light gray on the sides of the body in small patches, bars, dashes and flecks. The sides of the peduncle show some light gray markings and the ventral surface a few irregular white lines resembling scratches.

EXTERNAL ANATOMY.

Plates XX-XXIV.

Outline of Body.—The rostrum is strongly convex, the highest point being just anterior to the blowholes. Directly behind the spiracles there is a shallow concavity about sixty cm. long, and from that point to the "hump" the dorsal outline is regularly convex. From the hump the upper ridge of the peduncle slants very gradually downward to the flukes. The throat is rather flat but opposite a point midway between the eye and the anterior insertion of the fin, the breast and belly swell outward in a gradual curve to the anus broken only by a slight bulge at the penis. At the anus there is an abrupt dip and from that point to the flukes the ventral outline of the peduncle is slightly convex; the greatest convexity is just anterior to a point midway between the anus and flukes. The body is deepest opposite the tip of the pectoral fin laid back.

The outline of the body in Scammon's figure of *Rhachianectes* needs some correction. From the blowholes to the end of the peduncle crenulations the back is straight when it should be convex and there is little indication of a hump. The breast and belly are hardly full enough, the prominent dip just posterior to the anus is not shown, and the ventral outline of the peduncle should be slightly convex.

Head.—The head of *Rhachianectes* is distinctly characteristic and differs strongly from that of all other baleen whales. Its shape, in some respects, is intermediate between that of the

RHACHIANECTES GLAUCUS.

Balæninæ and the Balænopterinæ. It is not so large proportionately, and the rostrum is neither as narrow nor as curved as in the former, but is much narrower and deeper than in the latter.

The rostrum is convex dorsally, narrow and very deep, especially so just anterior to the blowholes. On either side of the rostrum just anterior to, and below, the spiracles is a prominent swelling about forty-five cm. wide which runs forward, narrows, and gradually becomes lost. Immediately below this swelling is a shallow depression extending for the entire antero-posterior length of the rostrum.

The head is deep vertically and in whale No. 3, male, 1240 cm. in length, the distance from the eye to the summit of the head over the curve of the side was 94 cm.

The blowholes are situated in a slight depression just behind the highest point of the rostrum, the anterior ends being slightly higher than are the posterior. They appear as two slightly curved slits, the convexities inward, having a long and rather shallow furrow between them. In whale No. 1, 1300 cm. in length, the blowholes were 25 cm. long, the anterior ends being 7 cm. apart and the posterior ends 23 cm.

In Cope's description from Dr. W. H. Dall's note there is the following statement: "... the blowholes are entirely concealed by four dermal plicæ, which accounts for the small misty spout peculiar to the species" (*l. c.*, 1868, p. 226). I am at a loss to know what is meant by the "four dermal plicæ," as the blowholes of all the specimens which I examined were open and did not differ greatly from those of other baleen whales.

The region immediately about the spiracles was usually thickly infested with parasitic *Cyamus scammoni*.

Eye.—The eye forms a rather prominent swelling above, and a little behind, the corner of the mouth and is surrounded by two furrows the anterior and posterior ends of which almost meet. In some cases the ends of the furrows actually join thus forming a complete circle about the eye but in the majority of individuals the ends stand a short distance apart. The upper lid is considerably fuller and more prominent than is the lower. On whale No. 21, male, 1225 cm. in length, the furrows about the eye were each 18 cm. long, and the eye opening itself 5 cm. from the anterior to the posterior commissure.

The eyeball from an adult male 1158 cm. in length had a circumference of 205 mm. after it had been trimmed of adhering fat. The iris was 26 mm. long and 17 mm. in vertical diameter. The pupil was 10 mm. long and 6 mm. in diameter, oval, with the superior edge somewhat flattened.

The iris was a clear, dark brown band 6 mm. wide, the outer edge of which shaded into a narrow whitish ring. Encircling the iris was a band of light gray, 4 mm. in width, which shaded off gradually into very dark gray.

Auricular orificæ.—The ear opening varies in size, as in all large whales, but is usually about 18 mm. in longitudinal diameter and directed upward at an angle of nearly 30 degrees. The meatus is a little larger than a good sized pencil.

The position of the ear is somewhat variable. In whale No. 1, female, 1300 cm. in length, the ear was 56 cm. behind the eye and 20 cm. above it. In foetus No. 1a, male, from the same whale, the ear was 24 cm. behind the eye and 1 cm. above it. In none of the other twenty-three specimens on which notes were taken was the ear above the eye, it usually being from 2 to 5 cm. below it.

Scammon remarks in this connection: "The ear, which appears externally like a mere slit

in the skin two and one half inches in length, is about eighteen inches behind the eye, and a little above it" (*l. c.*, p. 20). In the table of measurements the distance from the eye to the ear of eleven specimens will be found.

Tongue.—The tongue of *Rhachianectes* is narrow, thick and solid, resembling that of a Right Whale much more strongly than it does the soft, shapeless tongue of *Megaptera* or any *Balænoptera*. The dorsal surface is regularly convex except at the distal end where it becomes concave, and the tip is upturned and deeply cleft. There is a narrow flattened strip on the top which runs from the proximal to the distal end. A cross-section of the tongue would be a semi-circle with a slight dorsal compression. The color is usually flesh-pink becoming bluish gray at the tip.

Whale No. 17, male, 980 cm. in length, had a tongue 145 cm. long, 78 cm. wide over the curve and 50 cm. thick in the center. The tongue of No. 18, male, 1190 cm. in length, was 170 cm. long and 110 cm. wide over the curve.

Baleen.—The baleen plates of *Rhachianectes* differ from those of all other whales in being very thick and heavy, in the almost complete absence of transverse ridges, in having the outer edges thick and rounded instead of thin and sharp, and in the coarseness of the bristles. The baleen rows are not joined anteriorly by a narrow strip of small bristle-like plates as are those of the *Balænopterinae*, in this respect resembling the *Balæninae*.

The basal half of each plate is regularly concave, but in the distal half the concavity gradually disappears and the plate becomes flat. The color of the laminae is yellowish white, or light yellow.

There are decidedly fewer baleen laminae in each row than in any other large whale, the number varying from 138 to 174 on each side, the distance between the plates at the bases is from 5 to 10 mm. Following is a record of the number of baleen plates, *on one side only*, of different individuals, counting in every case the first and last lamina which was more than 50 mm. long and 5 mm. wide; the plates were all counted while *in situ*: 174, 168, 164, 162, 160, 158, 154, 148, 138.

The anterior ends of the baleen rows of whale No. 21, male, 1225 cm. in length were 35 cm. from the tip of the snout and 15 cm. apart; the posterior ends at the bases were 14 cm. apart and at the widest point the tips of the two rows diverged 65 cm.

The mucous membrane in the roof of the mouth between the bases of the baleen rows is white or flesh-pink.

The bristles of the proximal half of each plate are about 13 cm. in length but gradually elongate reaching a length of 25 cm. near the tips; they are round, very coarse and contrast strongly with the finer bristles of all other baleen whales. When seen *in situ* the bristles give the effect of a mat of thick, coarse fibers.

The baleen bristles are either entirely yellowish white like the plates themselves, or those of the posterior section may be gray, or dark gray, and the anterior portion yellowish white. The color of the bristles of twelve individuals was recorded showing that seven had some portion gray and five entirely yellowish white. Following is a list of the specimens in which the color of the bristles was noted:

23	♂	Posterior half gray, anterior half yellowish.

The descriptions given above of the baleen and bristles were written at the whaling station in Korea with fresh specimens at hand. I find upon examination of the set of baleen which was shipped to the Museum that both the bristles and laminæ are now very much darker than when fresh. This is due both to the drying of the plates and from soiling with dirt and grease. The bristles are now a strong brown and the plates yellowish-brown. I believe that in the great majority of cases any light colored baleen while being shipped from the field to a museum will be more or less soiled in transit and consequently the only reliable descriptions of such material are those that have been taken from fresh specimens.

Dall says that *Rhachianectes* has 145 laminæ of baleen on each side and that it is “light yellow,” while Scammon describes it as “light brown or nearly white.” Van Beneden speaks of the baleen in the Vienna Museum as being pale like that of *Balænoptera acuto-rostrata*. The baleen in the U. S. National Museum from San Louis Obispo, Cal., is stated by Dr. True to be yellowish-white except at one end of the series where for a distance of about eight inches the blades and bristles are dull chocolate-brown. He says: “The largest plates measure 18 in. in length without the bristles, and 6 in. at the base. The longest bristles measure $9\frac{1}{2}$ in., and were perhaps originally a little longer” (*l. c.*, p. 290).

Throat furrows.—On either side of the median gular line *Rhachianectes glaucus* has two or more deep furrows. Their anterior ends closely approach each other and stand parallel for a short distance but gradually spread apart posteriorly. The furrows begin about 165 cm. from the tip of the mandible and end opposite a point half way between the eye and ear; the posterior ends are generally almost three times as far apart as are the anterior. Whale No. 24, male, 1225 cm. in length, had furrows 170 cm. long, the anterior ends being 20 cm. apart and the posterior ends 50 cm.; the anterior ends were 75 cm. from the tip of the lower jaw.

Although two furrows seem to be the usual number for *R. glaucus*, three are not infrequently present, and one individual which I examined possessed *four*. Whale No. 3, male, had three grooves, the left being 150 cm. long and the right 116 cm.; between their anterior ends was a shorter furrow 100 cm. in length. No. 4, male, also had three furrows, the two outer being 165 cm. long and the median 130 cm. The two outer furrows of No. 14, male, were 120 cm. in length and the one between them 154 cm. long; this was the only individual in which the median furrow was the longest of the three. In No. 16, male, the median furrow was 62 cm. in length while the two outer measured 150 cm.

No. 20, male, had *four* distinct furrows; the median and two outer ones were of about the

same length and between the middle and left near the *posterior* end was a fourth short groove. Out of the twenty-one specimens in which the number of gular furrows were recorded fifteen had two, and six three, or more. Several whales were brought in which were not measured or described and among them were four or five individuals showing three throat furrows. The grooves are almost 5 cm. in depth and have rounded edges.

The gular furrows of *Rhachianectes* seem to be a specialization in the direction of the throat and breast grooves of the Balænopterinæ. Since in *Rhachianectes* they are presumably present to increase the throat capacity they throw light upon the origin of the folds in the Balænopterinæ and tend to substantiate Prof. Kükenthal's theory that their purpose is to allow the short-headed members of this subfamily to take into the mouth a greater quantity of water containing their food.

The grooves of the Balænopterinæ in their early development were probably few in number and confined to the gular region, as in the case of *Rhachianectes*. As specialization of the entire body continued the furrows increased in number and in length extending backward upon the abdomen to give the greater thoracic expansion made necessary by the extraordinary development of the lungs.

It is well known that the sternum in all baleen whales is reduced to a vestige, and that the proximal ends of the ribs articulate loosely with the vertebral column, the distal ends of all but the first pair being free. Thus the frame-work of the thoracic cavity is capable of great lateral movement. In conjunction with the skeletal changes the lungs become greatly enlarged and adapted to retain the air during a considerable period of submergence. The increased power of lung expansion called for external as well as internal modification of the breast and the furrows which had already developed upon the throat became more numerous and prolonged posteriorly. The greatest number of furrows and their most frequent branching is between the pectoral fins, as might be expected.

In the existing Balænopterinæ, when the lungs are filled with air the whole thorax expands laterally and with it the flexible skin between the folds. Thus the furrows, besides their original function of increasing the throat capacity during the feeding operation, are also of use during respiration. *Rhachianectes* being a shallow water whale and a relatively primitive form, has not as yet developed the furrows upon the breast and abdomen.

In the case of the Balæninæ extensive specialization of the entire head has taken place and it has become of such a proportionately great size that there has been no necessity for increasing the throat capacity by the development of furrows; like the head, the entire thorax has become enormously enlarged by the great thickening of the body and has thus accommodated itself to the processes of respiration.

The Odontoceti, because of the nature of their food and the manner of securing it, are not under the necessity of increasing their throat capacity by the development of furrows.¹ In this group, moreover, which are not as extensively specialized as are the baleen whales, the sternum is long and the "thoracic box" is relatively immobile.

Pectoral limb.—The pectoral fins of *Rhachianectes* are distinctly individual being intermediate in shape between those of the Balæninæ and the Balænopterinæ. They are much broader and thicker proportionately and not so pointed as the fins of the latter subfamily, but are more lanceolate, and not as heavy, as thick or as broad as the pectorals of the Balæninæ.

¹This is not literally true since the Ziphioides have two throat furrows.

RHACHIANECTES GLAUCUS.

If photos of the pectoral of *Rhachianectes* are compared with those of a Right Whale or of any *Balænoptera* it will be seen at a glance that its shape is intermediate between the two types.

The flipper of *Rhachianectes* is broadly lanceolate. The posterior edge is about 3 cm. thick and strongly convex except just behind the rather blunt tip where a shallow concavity is formed; the anterior edge is regularly convex. The greatest breadth of the fin is at a point almost midway between the tip and the axilla, and the four digits are so prominently outlined that each may be traced for almost its full length before the fin has been stripped of blubber. There is considerable variation in the breadth of the pectoral among different individuals due to a greater or less convexity of the posterior border. Out of the twenty-three specimens on which notes were taken all but two had at least one of the flippers more or less injured on the posterior edges or tips. This, I believe, was mainly the work of Killers (*Orca orca*) which apparently keep the Gray Whales in a continual state of terror when upon their annual migrations. It may also be due, in some degree, to contact with rocks, as this species is generally to be found close in shore and frequently rolls about in the surf in very shallow water. Wherever the edges or tips of the fins were injured they were invariably thickly covered with parasitic crustaceans, *Cyamus scammoni*, and frequently the hard barnacle *Cryptolepas rhachianecti* was embedded on both surfaces.

Scammon's figure is hardly an accurate representation of the flipper of *Rhachianectes glaucus*. The outer edge is too straight, the tip is too blunt, and the fin is not broad enough.

In color, the pectorals are dark slate like the body. Above, on the posterior half, are a few scattered white circles, spots and flecks; below, the white circles and spots are more numerous and there are two, more or less broken, bands of white, or very light gray, about 8 cm. wide and 45 cm. long between the 2nd and 3rd, and 3rd and 4th fingers; the band between the 2nd and 3rd digits is usually the longer. The posterior edge of the fin is generally white.

There is much variation in the amount of white on the pectorals. Some individuals had the two bands between the fingers present on both surfaces and the entire fin thickly covered with spots, circles, dashes and flecks of white. Others had the distal third of the flipper washed with light gray, or white, while in still other cases white was practically absent on both surfaces. In almost all cases, however, there was more of the light markings on the lower surface than on the upper. A large proportion of the white circles and spots seemed to be scars left by parasitic cirripeds and were exactly similar to those on the flippers of *Megaptera*.

Flukes.—The flukes of *Rhachianectes glaucus* are quite unlike those of any other large whale. In shape they resemble most closely those of *Physeter macrocephalus* but both the anterior and posterior edges are more convex than in the latter species and the notch is more open and shallower. They are strikingly different from the slender, graceful flukes of *Balænoptera* and equally so from *Balæna* and *Eubalæna*. The resemblances to *Megaptera* are only superficial.

When either lobe of the flukes of *Rhachianectes glaucus* is viewed singly it is strongly suggestive of the pectoral fin in shape. The anterior margin is slightly convex becoming more so near the distal end. The posterior edge for the proximal two-thirds is strongly convex, but the distal third just behind the tip is slightly concave. Since the tips of the flukes in all adult specimens are more or less injured the concavity generally does not show and the posterior edge is evenly convex from the notch to the tip. The posterior edge, instead of being extremely thin as in *Balænoptera*, is almost three cm. in thickness and is broken by shallow, rounded emarginations. These crenulations must be normal as they were present in a foetus (No. 1a) which was almost ready for birth, and in nearly all the adult specimens. They are analogous to the emarginations on the

flukes of the *Megaptera* but are neither so numerous nor so deep and give a wavy effect rather than the scalloped appearance seen in the Humpback.

The entire posterior edge is frequently infested with *Cyamus*, which fasten themselves upon the slightest abrasion, and the posterior outline is often entirely changed by the attacks of these parasites or by other injuries. The notch is deep and usually open but varies considerably in this respect.

The flukes are black above and below like the body. A few circles, flecks and dashes of white are scattered over both surfaces, the lower usually being most heavily marked. As with the pectorals, the amount of white is extremely variable. The white circles and spots in many cases are the scars left by barnacles; two or three individuals had flukes exactly resembling those of a Humpback in color.

The flukes of a foetus (No. 1a) on the inferior surface had wide, dark gray anterior and posterior borders and very light gray central portions. Many broken whitish lines curving inward toward the notch ran transversely across each lobe starting on the anterior edge. In a general way this was suggestive of the inferior surface of the flukes of *Balaenoptera musculus*. One adult individual (No. 17) had flukes marked in exactly the same manner but as it was quite unlike all other specimens examined this must be considered to be an unusual type of coloration.

Dorsal crenulations of peduncle.—On the dorsal ridge of the peduncle, beginning about 100 cm. from the insertion of the flukes, is a series of low, rounded crenulations which end a short distance beyond a point opposite the anus in an evenly rounded bunch, or "hump," about 50 cm. long and 7 or 8 cm. high. The crenulations are about 30 cm. apart, those nearest the flukes being the least developed and those just posterior to the "hump" the most prominent. Their number and size are open to considerable variation, one individual having only 6 rather indistinct tubercles while another had 14, even the most posterior of the row being well developed; 9 or 10 is the usual number as shown by the following table:

Number of crenulations.

Capture Number	Sex	
5	♂	9
6	♀	6
8	♂	10
10	♂	10

These crenulations are very similar to those on the dorsal ridge of the peduncle of the Humpback but are somewhat more prominent. They were noted by Dall, Scammon and Townsend. Dall says: "On the vertebral line, for fourteen feet from the caudal flukes, is a series of 18 ridges, like the teeth of a saw, which are altogether dermal in their character" (*l. c.*, 1868, p. 226). Out of some 30 individuals which I examined only one possessed as many as 14, the next highest being 10; it would appear, therefore, that 18 is rather an unusual number.

Scammon's statement that it "has a succession of ridges, crosswise along the back, from

RHACHIANECTES GLAUCUS.

opposite the vent to the flukes" is misleading for the ridges are certainly never transverse; although he figures them in their proper position he does not show the hump at the anterior end of the series.

Townsend speaks of the crenate ridge as being present in a foetus but says he did not observe it in the adult. He may have seen a specimen in which it was so slightly developed as to have escaped his notice for it is probably never entirely absent.

In a foetus 476 cm. long which I examined it was fully developed and 12 crenulations could be distinguished. Townsend's figure shows the crenate ridge as an elevated phlange which gives a somewhat erroneous idea of its true character for the dorsal ridge of the peduncle is not itself extended.

It seems somewhat remarkable that the presence of the hump or bunch, which ends the series of crenulations anteriorly, has not been previously mentioned, for in nearly all the individuals examined it was prominent and attracted my attention at once. By referring to the table of proportional measurements it will be seen that the relative position of the hump is decidedly variable, there being a difference of 11% between the highest and lowest ratios to the total distance from the notch of the flukes to the hump. Its average position relative to the length of the animal is the same as in the *Megaptera*, and by but little modification a dorsal fin similar to that of a Humpback could be derived from it. The fact that Humpbacks have the dorsal ridge of the peduncle distinctly crenulated from the flukes to the hump, in a way similar to that of the Gray Whales, is exceedingly interesting. There is a greater individual variation in the relative position of the dorsal fin in the *Megaptera* than in the *Balænoptera*; it is situated much further forward in the former genus than in the latter, and it has almost every possible shape between a prominent, falcate fin and a low rounded bunch.

Before the pectoral and caudal fins of the Humpback had reached their present high state of specialization it is very probable that the dorsal may have been much less prominent and that, as in the Gray Whales, it formed the terminal bunch at the anterior edge of the peduncle crenulations. As the specialization of the animal continued the dorsal hump increased in size, its shape became modified, and the crenulations in the remainder of the series grew less prominent.

It is possible, therefore, that we may see *Rhachianectes* developing a dorsal fin in a parallel way to the *Megaptera* and that, if specialization is continued, it may become as prominent as in the case of the Humpback and its relative position be more constant.

Hairs.—Both the foetal and adult *Rhachianectes* possess longer hairs, and they are more widely and more uniformly spread over the entire head, than in any other baleen whale. The hairs were scattered in six irregular rows over the whole rostrum of foetus No. 1a, and a line of 16 on the dorsal ridge extended from the blowholes to the snout. The most posterior hair was on the left side of the head opposite the posterior end of the blowholes.

On each rami of the mandible there were 21 hairs in three irregular rows, the most posterior being a little anterior to a point opposite the corner of the mouth. At the mandibular symphysis three irregular vertical rows, which closely approximated each other, contained 40 hairs. The areas most thickly covered with hirsute remains were the tips of the snout and mandible. Each hair was white, about 20 mm. long, and situated in a small pit surrounded by a dark ring.

On the head and lower jaw of the adult *Rhachianectes* the number and arrangement of the hairs is essentially the same as on the foetus described above. The hairs are generally longer in the adult than in the foetus, sometimes reaching a length of 40 mm.; on whale No. 18, male, in several places on the mandibular rami two hairs were found in a single follicle.

A careful examination was made of all parts of the body, both in the foetus and adult, but in no place other than the head and jaws were there evidences of hair.

Blubber.—The blubber is very thick and fat, and varies in color from red to flesh-pink. Because of this, as noted by Dr. True, the Japanese recognize two kinds of Gray Whale, the “aosaki” (red blubber) and the “shirosaki” (white blubber). Although specimens with blubber strongly red, almost white, and of every intermediate shade, were taken during my stay at Ulsan, I could detect no differences, other than those purely individual, between them.

The blubber varies in thickness with individuals, and on different parts of the body, usually being from 20 cm. at the thinnest to 35 or 40 cm. at the thickest part.

The Japanese consider the meat and blubber to be of poorer quality for eating than those of any other baleen whale. In the winter, during the months of December and January when the price is at its highest, the blubber sells for about 4 sen (2 cents) per pound and the red meat 10 sen (5 cents).

In regard to the blubber Scammon says: “The coating of fat, or blubber, which possesses great solidity and is exceedingly sinewy and tough, varies from six to ten inches in thickness, and is of a reddish cast” (*l. c.*, p. 21).

Parasites.—The entire body of *Rhachianectes* is more or less thickly infested with the parasitic amphipod crustacean *Cyamus scammoni* Dall, and the hard barnacle *Cryptolepas rhachianecti* Dall. The barnacles embed themselves deeply on all parts of the body as well as on the flukes and pectoral fins.

The *Cyamus* are almost invariably to be found about the blowholes, the genital and anal openings, and on the tips and posterior edges of the flukes and flippers. Wherever a cluster of *Cryptolepas* have become embedded, *Cyamus scammoni* will also fasten and frequently cover a wide area having the barnacles as a nucleus; an injury or abrasion of the skin at once becomes the resting place of numbers of parasites. The snout of *Rhachianectes* for a distance of sixty or seventy cm. from the tip is usually cornified in a way similar to the “bonnet” of the Right Whale, and is produced, as in that species, by the action of the parasitic *Cyamus*. In some individuals the entire dorsal ridge of the rostrum from the snout nearly to the blowholes becomes cornified.

When a *Cryptolepas* detaches itself a circular grayish pit remains, which in time becomes white as the wound heals; these scars are exactly like those left by the barnacle *Coronula diadema* upon the *Megaptera*. No barnacles other than *Cryptolepas rhachianecti* were observed upon the Gray Whales, and it seems probable that none other infest this species.

A careful examination of the *Cyamus* taken from Korea specimens demonstrates that they are certainly identifiable with Dall's *Cyamus scammoni* described from the California examples of *Rhachianectes glaucus*. In any case it is doubtful if such highly specialized parasitic forms would show strong changes even if isolated for a long period and thus they furnish little information on the question as to whether or not the Gray Whales of the east and west sides of the Pacific actually mingle in the north.

OSTEOLOGY.

The skeleton of *Rhachianectes*, other than the skull, has never been completely described, consequently a rather detailed account of its principal characters will be given in the following pages; also comparisons with other genera will be instituted whenever individual peculiarities can be emphasized thereby.

The length of the skeleton of the American Museum specimen, measured in a straight line, is 1107 cm. (36' 4"). It was taken from a very old male (No. 20), 1250 cm. (41' $\frac{1}{2}$ ") long, on January 19, 1912, at Ulsan, Korea.

The vertebral epiphyses are all firmly ankylosed, in most cases the lines of union being lost, and there are other evidences of extreme age.

SKULL.

Plates XXV-XXVII.

In general form the skull of *Rhachianectes* is directly intermediate between the skulls of *Eubalæna* and *Balænoptera*, and somewhat resembles *Neobalæna*. The dorsal outline is much curved and especially high from the nares posteriorly, thereby giving to the occipital plane a comparatively slight obliquity, scarcely greater than in *Eubalæna*. The skull, as seen in profile, is thus quite unlike that of a Fin Whale, not only the whole dorsal outline being more convex but the rostral portion more arched. The interorbital region is thus deep and quite constricted.

The rostrum is narrow and elongate and the lateral outline tapers regularly toward the tip. The premaxillæ in the distal portion are very deep and have almost vertical sides, as in *Eubalæna*, but become somewhat flattened where they spread apart for the narial opening. Proximally they end a considerable distance from the vertex of the skull *leaving a wide area of the frontals exposed*, a primitive condition. The proximal portions of the premaxillæ enclosing the nasals appear as broad strips, superiorly placed, and articulate with the frontals by a deep interdigitating suture.

The maxillæ instead of being almost horizontal as in the *Balænopterinae* are sharply oblique. Their inner (superior) edges slope abruptly downward in the distal half of the rostrum but in the proximal half are almost parallel with the skull axis. Each maxilla sends a narrow projection backward toward the vertex of the cranium, ending beside the premaxillæ. The lateral extensions of the maxillæ are remarkable in the fact that each one *overlaps the anterior edge of the orbital process of the frontal*, and bears posteriorly a strong tubercle which, with the anterior end of the orbit, partially encloses a large oblique foramen.

The nasals are very broad and long, joining in the median line to form a prominent crest; they occupy half the space between the nares and the summit of the occipital bone.

Compared with *Balænoptera* and *Megaptera* the orbital processes of the frontals are narrower, shorter and consequently less massive, but are much wider and less elongate than in *Eubalæna*. Viewed from below they have the trumpet-shaped form so characteristic of the fossil genus *Plesiocetus*. The posterior edges of the orbital processes of the frontals from the skull-vertex to the orbits present irregular margins; a primitive character.

The squamosal is comparatively small and has a straight outer edge quite unlike the concave squamosals of either *Balænoptera*, *Megaptera* or *Eubalæna*; in this respect the squamosal of *Rhachianectes* resembles that of fossil genera. The "temporal ridge," formed by the anterior margins of the temporal fossa, is well marked, thus showing an interesting primitive condition.

The supraoccipital presents three deep concavities, and on the superior portion two prominent and peculiar rugosities. These are undoubtedly homologous with the similar processes just under the lambdoid crest on the supraoccipital of dogs and other mammals, where the *rectus capitis posterior major* and *minor* muscles, which assist in raising the snout, are attached.

Their development, and the presence of similar rugosities below upon the basi-sphenoid and basi-occipital bones, are probably correlated with the fact that the cervical vertebræ are all free, and the neck is somewhat less abbreviated than in other large cetaceans thus allowing greater movement of the head.

The most interesting characters of the inferior surface of the skull are the comparatively

Fig. 1. Inner view of tympanic bulla of *Rhachianectes glaucus*.

Fig. 2. Inferior view of tympanic bulla of *Rhachianectes glaucus*.

short posterior extension of the vomer and pterygoid bones, the heavy pterygoids and, as mentioned above, the strongly down-turned edges of the basioccipital and basi-sphenoid which are exceedingly thick and massive.

True remarks in regard to the peculiarities of the skull of *Rhachianectes*: "Most striking are the rugosities of the occipital, the large size of the nasals, the shortness of the nasal portion of the intermaxillæ, and their great depth anteriorly, the overlapping of the orbital processes of the frontal by the proximal portion of the maxilla, and the strong tubercle on the posterior margin of the former. All these characters are seen equally as well developed in the skulls figured by Malm as in the Monterey specimen.

"These and many other characters stamp it as a very distinct form, approaching closely neither *Balæna* nor *Balænoptera*" (*l. c.*, p. 291). Dall, Van Beneden, Malm and Beddard have also more or less completely described the skull of *Rhachianectes*.

The mandibular rami are without coronoid processes these being represented only by flattened tubercles. Each

ramus is moderately bowed and the superior outline from the coronoid rudiment to the distal end is regularly convex; the inferior outline is a succession of slight convexities and concavities as shown by the figures. On the inner side of the superior edge for the distal three fourths of the ramus is a well-marked alveolar sinus which becomes very deep near the tip. Both rami show the effects of a former injury.

The mandible of *Rhachianectes* strongly resembles that of the *Balæninæ*, and shows little concavity on the inner side proximally; it is surprising to find a specialized mandible of this type when the many other primitive characters of the skull are considered.

The tympanic bullæ of *Rhachianectes* are small and remarkable because of their strong lateral compression and slightly grooved internal border (that is, the border nearest the median line of the skull). They are totally unlike those of *Eubalæna* in size and general shape and differ from *Balænoptera* in being much less elongate, wider, and more compressed as well as in other points. In size and general outline they somewhat resemble *Megaptera* but instead of being almost globular, as in the latter genus, are greatly flattened. By their compressed form and concave internal border they strongly suggest the tympanic bones of certain fossil genera.

Hyoid Bones.— The hyoid bones differ from those of all other baleen whales with which I am familiar.

The basihyal and two thyrohyals are ankylosed into a long, extremely massive and rugose bone. The central portion (basihyal) is dorso-ventrally compressed and has two short, anterior, conical projections (ceratohyals), but each thyrohyal rapidly thickens, becoming cylindrical

Fig. 4. Hyoid bones of *Rhachianectes glaucus*.

in the distal two-thirds and curved slightly backward. The shape of this portion of the hyoidean apparatus is distinctly individual but resembles that of *Eubalæna* much more than any *Balænoptera*.

The stylohyals, on the other hand, are decidedly more like those of the latter genus than the former. Each is a massive, rugose bone, slightly curved upward and forward. The anterior edge for its greater part is sharp and the posterior margin rounded so that a cross section of the stylohyal would be an ovoid ellipse. These bones are nearly half again as long and twice wider than are the roughly cylindrical stylohyals of an adult 54 ft. female *Eubalæna glacialis* in this Museum.

VERTEBRÆ.

The vertebræ of *Rhachianectes*, through the combination of characters, differ widely from those of the other known genera of baleen whales, the general resemblance being rather more toward *Megaptera* than *Balænoptera* or *Eubalæna*.

The extremely rugose surfaces of practically all of the bones of the skeleton is interesting. I know of no other large Cetacean, except *Physeter macrocephalus*, in which this condition is so pronounced. Fifty-six vertebræ seems to be the normal number for *Rhachianectes glaucus*, the formulæ of three skeletons being as follows:

C	D	L	Ca.	Total		
7	14	12	23	= 56	Am. Mus. Nat. Hist.	(R. C. A.)
7	14 ¹	12	23	= 56	U. S. Nat. Mus.	(R. C. A.)
7	14	14	21	= 56	British Mus.	(Beddard)

The differences in these formulæ will be discussed later.

Cervical vertebræ.— The cervical vertebræ are all free and show no tendency toward ankylosis.

The atlas differs strongly from that of both *Eubalæna* and *Balænoptera* but bears a considerable resemblance to *Megaptera*. Its most distinctive characters are the massive neural arch, the short transverse processes, and the small size of the condylar facets relative to the height of the vertebræ.

The neural arch is high and exceedingly thick and massive, having an irregular rugose superior surface and an indistinct spine; it is perforated by a transverse arterial foramen. The short bunch-like transverse processes are set obliquely to the vertical plane of the axis, have irregular rounded ends, and are directed slightly upward. They resemble the transverse processes of the *Megaptera* but are shorter and not so wide.

The centrum of the atlas at the bottom slopes strongly upward, and at the sides inward, so that the posterior face is considerably smaller than the anterior. The opening between the condylar facets in conjunction with the neural canal is much shallower than is usual with the atlas of other baleen whales; this character is not so pronounced in the National Museum specimen, the opening being roughly V-shaped, the point directed downward.

On the posterior surface, the internal-superior corners of the facets for articulation with the axis are produced inward appearing as two irregular tubercles when seen from the anterior face of the axis through the space between the condylar facets.

The axis resembles, in general, that of a *Balænoptera*. The neural arch is very thick and massive, has a rugose, truncated summit and an indistinct spine. Each of the posteriorly directed, wing-like transverse processes is perforated somewhat above the center by a rather small oval foramen; the processes are thick and have irregular, rugose surfaces. The articular facets for the atlas are small and between them is a rather prominent odontoid process.

¹ Although but thirteen pairs of ribs are present in the U. S. National Museum specimen, the distal ends of the transverse processes of the twenty-first vertebra show distinct articular facets and indicate that the last pair of ribs has been lost.

Fig. 5. Atlas and axis of *Rhachianectes glaucus*.

Fig. 6. Third and fourth cervical vertebrae of *Rhachianectes glaucus* (right to left).

Fig. 7. Fifth, sixth and seventh cervical vertebrae of *Rhachianectes glaucus* (right to left).

The third cervical vertebra has a circular body, somewhat compressed dorsally, and on either side two well developed transverse processes. The lower process is thick and roughly cylindrical for half its length, projecting somewhat downward but bends up and back in the distal half where it becomes compressed and blade-like. The upper process is straight, except at the distal end, and directed backward; the distal ends of the two processes stand widely apart (on the right side 50 mm.).

Both the upper and lower transverse processes of the fourth vertebra are similar to those of the third in length and direction, but the lower process is less massive and expanded distally.

On the fifth cervical the lower process is compressed throughout, especially so at the distal end where it is thin and expanded; instead of being directed slightly backward, as are those immediately preceding, it projects straight out and turns upward in the distal portion. The superior process is shorter than that of the fourth vertebra and curved slightly backward and downward.

The inferior transverse process of the sixth cervical is more massive than that of either the fifth or fourth, projects upward and forward and bears on the posterior side, proximally, a prominent flattened tubercle. The superior process of this vertebra is the shortest in the cervical series and projects strongly downward.

The seventh cervical has a lower transverse process which, although it is shorter than that of the sixth, is 135 mm. in length, roughly cylindrical and slightly expanded distally. The lower transverse processes of the seventh cervical of the U. S. Nat. Mus. specimen appear on the right side merely as a rounded tubercle and upon the left as a short process 64 mm. in length; neither seem to have been broken or otherwise injured.

The upper process is thick, compressed and considerably longer than that of the sixth vertebra; both are directed downward.

The anterior zygapophyses of the third vertebra are well developed, becoming larger on each succeeding cervical and appearing on the seventh as tubercles 43 mm. in length.

The spines of all the cervicals increase in height and thickness from the third to the seventh.

The laminae of the neural arches of the third, fourth, and fifth vertebrae are wide at the bases, narrowing rapidly and uniting at the apices in erect and prominent spines. The arches of all the cervical vertebrae are high and triangular, considerably resembling those of *Megaptera*.

The cervical vertebrae of *Rhachianectes*, considered as a whole, are unique in the combination of the following characters:

1. An atlas of peculiar shape.
2. An axis having wing-like transverse processes.
3. Triangular neural arches and long inferior transverse processes in all cervical vertebrae posterior to the axis.¹

Dorsal vertebrae.—The most distinctive character of the dorsal vertebrae is the zygapophyses, which are extraordinarily thick and massive with heavily rugose surfaces. They appear on the proximal ends of the transverse processes of the fifth dorsal as well developed tubercles rapidly enlarging on the succeeding vertebrae into prominent projections having massive globular ends.

The transverse processes are heavy throughout the series and have expanded, concave distal ends except in the case of the first and last dorsals; the ends of the transverse processes of the tenth thoracic vertebra are the widest of the series.

The neural spines of the first six dorsals are directed forward, those of the seventh, eighth, and ninth are vertical, and the remainder directed backward.² The spines increase steadily in antero-posterior width from the first to the twelfth dorsal, which bears the widest spine in the entire vertebral column.

¹ As noted above, this was not entirely true of the U. S. Nat. Mus. specimen in which the lower transverse processes of the seventh cervical were small.

² The spines of the first four dorsal vertebrae of the U. S. Nat. Mus. specimen are directed backward, the fifth, sixth and seventh upward and the remainder backward.^{3,†}

The centrum of the first thoracic is circular except for a slight dorsal flattening; the dorsal compression of the centra becomes more pronounced in the posterior members of the series.

Lumbar vertebræ.—The lumbar vertebræ present certain individual peculiarities in the spines and zygapophyses, by means of which they may be distinguished from those of other whales. The spines of the entire lumbar series are directed strongly backward, that of the ninth being the most oblique of the vertebral column; the backward direction of the spines in the posterior vertebræ of the series is much greater than in *Megaptera* and somewhat more than in *Balænoptera*. All of the spines are regularly convex distally and that of the seventh lumbar is the longest.

The zygapophyses are prominent and show, in a modified form, the expanded distal ends so characteristic of the dorsal vertebræ. Those of the anterior half of the lumbar series are directed outward so that they overhang the anterior faces of the centra more strongly than is usual. The spines and zygapophyses differ in numerous minor ways from those of other genera.

Fig. 8. Cervical vertebræ of *Rhachianectes glaucus*.

The transverse processes of the first four units of the lumbar series are curved somewhat upward, the fifth, sixth and seventh are horizontal, and those of the remaining vertebræ directed more or less downward. The transverse processes of the sixth lumbar are the longest.

Caudal vertebræ.—The caudal vertebræ do not agree closely with those of other baleen whales. In the size, shape, and direction of the transverse processes, spines and zygapophyses, and in the appearance and disappearance of the foramina and processes, many differences are apparent.

The spines decrease gradually in height from the first to the eleventh caudal where they become lost. The zygapophyses of the anterior caudal vertebræ in their expanded, globular distal ends resemble those of the dorsal series, and disappear with the neural spines upon the eleventh vertebra. The spines and zygapophyses show a decidedly greater resemblance to *Megaptera* than to *Balænoptera*.

The transverse process of the first caudal is the widest in the entire vertebral column and is directed strongly downward. The transverse process of the fourth, fifth and sixth caudals arise from the posterior part of the centra and project outward and forward, their inner edges almost meeting the expanded outer margins of the anterior faces of the centra; in this way a partially

Fig. 9. Dorsal vertebrae of *Rhachianectes glaucus*.
Fig. 10. Lumbar “ “ “ “ “ “
Fig. 11. Caudal “ “ “ “ “ “

enclosed foramen is formed. On the right side of the sixth caudal this foramen is completely encircled ¹ and the transverse process near the center is also perforated by a second vertical canal.

The antero-posterior diameter of the centrum of the first caudal is the greatest of the entire vertebral column and the anterior face is almost a perfect circle. Although the inferior median carina of the thirty-third vertebra is distinctly bifurcated posteriorly, the thirty-fourth is definitely indicated as the first caudal by the presence of the first pair of chevrons which have become firmly ankylosed to its centrum.

Beddard states that he counted in the British Museum specimen 14 lumbar vertebræ and 21 caudals, whereas both the American Museum and U. S. Nat. Mus. skeletons have 12 lumbar and 23 caudals. Since the total number of vertebræ, and also those of the dorsal series, are alike in the three specimens, I believe they will be found to possess a similar number of lumbar and caudal units. Unless the skeletons have been examined with the chevrons *in situ*, or there happens to be an ankylosis as in the case of our specimen, it is difficult to make an absolutely correct determination of the lumbar and caudal units. Although the inferior median carina is usually first distinctly bifurcated upon the first caudal, the division may sometimes occur upon the last lumbar and cannot, therefore, be taken as an infallible guide.

In the following table data as to the appearance and disappearance of the several processes and foramina in *Rhachianectes glaucus* is given. For convenience of reference similar data of other genera are placed in apposition.

CHEVRONS.

The American Museum skeleton has twelve chevrons and the National Museum ten; apparently two have been lost in the latter case and twelve would seem to be the normal number.

The first chevron in the American Museum series is firmly ankylosed to the centrum of the first caudal vertebra. It is 75 mm. in length, 118 mm. wide and free distally. The second chevron is 180 mm. long and 91 mm. wide, the laminae uniting distally to form a long hæmal spine. The third chevron is the longest of the series, having a maximum length of 240 mm. and a width of 120 mm.

From the third backward, the chevrons increase rapidly in width and gradually decrease in length, the fifth being the widest of the series; its maximum width is 212 mm. The last two members of the series have their distal ends free.

RIBS.

The ribs of *Rhachianectes* are exceedingly interesting. The most important feature of their morphology is to be seen in the proximal ends of the third, fourth, fifth, sixth, and seventh, on each of which a large tubercle, neck and head are developed. The prominent tubercle, and the deep concavity between it and the head in all of these ribs gives them a shape very similar to those of the toothed whales and quite unlike any *Mystacoceti*.

In *Balænoptera* the second and third ribs usually have prominent tubercles and long necks while in the remainder of the series the necks and heads become atrophied, or lost. In *Rhachianectes* the necks and heads do not disappear until the *eighth rib* and up to this point are well developed and prominent. Thus the anterior half of the rib series is articulated to the vertebral column much more firmly than in other baleen whales, and presumably the thorax is capable of less lateral movement.

The proximal end of the first rib is thin and rounded but has a small, outwarding projecting tubercle (the head) near the lower edge. On the second rib this tubercle (the head) is more thoroughly developed, and on the third has become extended into a long neck and an expanded head which project outward at a right angle to the remainder of the rib. The tubercle is very prominent and has a large flattened articular fossa. On the fourth rib the neck is slightly shorter than that of the third and the angle it forms with the shaft is a little wider; its tubercle, however, is considerably larger than that of the third.

Fig. 12. First dorsal, first lumbar and first caudal vertebrae of *Rhachianectes glaucus* (right to left).
Fig. 13. Chevrons of *Rhachianectes glaucus*.

Fig. 14. Ribs of *Rhachianectes glaucus*.

The neck of the fifth rib is shorter and forms a wider angle with the shaft than does the fourth, but its tubercle is larger and more prominent and the concavity of the neck between it and the capitulum is deeper.

The neck of the sixth rib is similar to the fifth in length, size of tubercle and the angle with the shaft. That of the seventh is a little shorter than the sixth, the angle is somewhat wider and the tubercle a little larger.

Upon the eighth rib the neck and head disappear and are represented only by a small projection; the tubercle of the rib is greatly enlarged, however, and is separated from the process representing the neck by a well-marked concavity, which is present to a less extent upon all the succeeding ribs except the last two pairs.

The ribs are all long and massive, considerably exceeding in measurements those of the 40-foot *Megaptera* and the 50-foot *Balaenoptera physalus* recorded by Struthers.¹

The first is of uniform width in its proximal half but rapidly expands in the distal portion where it becomes the widest of the series; the fifth is the longest.

The ribs of the U. S. National Museum specimen differ in the important particulars that upon the first the portion representing the neck and head is considerably more produced than in the American Museum skeleton and that *the second rib bears a fully developed neck and head*; the distance from the tubercle to the end of the head of this rib is 225 mm.

Measurements of the ribs and of the capitular processes of the first eight pairs are given in the appended table:

¹ Journal of Anatomy and Physiology, Vol. XXIII (new ser. Vol. III), 1889, p. 143.

STERNUM.

The sternum belonging to the skeleton of *Rhachianectes* in the American Museum has the form of a Latin cross and closely resembles the corresponding bone of *Balaenoptera acuto-rostrata*. The lateral arms of the cross are short and irregularly rounded and the summit of the superior portion is abruptly truncated and has a shallow concavity. The inferior prolongation of the sternum is irregularly cylindrical terminating in a blunt point, and is remarkable for its length. The entire sternum, but especially the anterior surface, is rugose and covered with small osseous tubercles which apparently are not due to exostosis but have been developed for tendon attachments.

The sternum of the United States National Museum specimen shows an extraordinary difference in shape from that described above and demonstrates the enormous individual variation to which such almost rudimentary bones are subject. The sternum is concave on the superior surface, has two rounded, wing-like lateral processes and terminates inferiorly in a short irregular spine.

Length of lower process	276	165

Fig. 17. Sternum of *Rhachianectes glaucus*; U. S. Nat. Mus. skeleton.

PECTORAL LIMB.

Scapula.— The scapula of *Rhachianectes* is distinctive being intermediate between the wide, low blade of *Balænoptera* and the high, narrower and more symmetrically fan-shaped scapula of *Eubalæna*. In the great height proportional to its width it approaches the latter genus while in the well developed coracoid and large acromion it resembles the former.

The superior margin is quite evenly convex, becoming slightly flattened posteriorly. The glenoid border is almost straight except for a short concavity where it rises from the glenoid fossa and neither it nor the coracoid border overhangs as strongly as in the scapulæ of *Balænoptera*.

The acromion is exceedingly wide throughout, expanded and irregularly rounded distally, and slightly curved.

The coracoid is thick and massive, turned sharply inward and directed somewhat upward from the margin of the glenoid fossa.

The external face of the scapula is quite strongly concave as in *Eubalæna*. It is much thicker and more massive than in *Balænoptera* but not as thick as that of a Right Whale.

Measurements of the scapula are given in Table IX.

Humerus.— The humerus is nearly straight, the superior edge is but slightly concave and the external tuberosity is prominent. In all of these characters the humerus differs from that of *Balæna*, *Eubalæna* and *Megaptera* and strongly resembles the fossil genus *Plesiocetus*; while in *Balænoptera* the head is almost directly upon the summit of the bone, the concavity of the sides gives the humerus quite a different appearance from that of *Rhachianectes*.

Fig. 18. Inner view of right scapula of *Rhachianectes glaucus*; Am. Mus. skeleton.

Radius.— The radius is remarkable for its width. The exterior edge for its proximal half is slightly convex and in the distal portion a little concave. The interior edge presents a shallow concavity due to the broadening of the bone at the carpal end. For the proximal half the radius is of almost uniform width but in the distal half rapidly expands.

Ulna.— The ulna has a nearly straight inner edge but a strongly concave outer margin due to the rapid broadening of the bone in the distal half. The olecranon process is prominent and projects upward.

The radius and ulna differ markedly from those of *Balæna*, *Eubalæna* and *Megaptera* but in general resemble *Balænoptera*. The broad radius is somewhat similar to that of *B. musculus* but the straight ulna is quite unlike the bone in that species. The radius and ulna of *B. physalus* and *B. borealis* are more slender, more curved and less expanded distally than in *Rhachianectes glaucus*.

Manus.—*Rhachianectes* has four digits in the manus. The phalangeal formulæ of the flippers of the U. S. National Museum specimen (which are more nearly perfect than are those of the American Museum skeleton) are as follows:

Fig. 19. Inner view of right scapula of *Rhachianectes glaucus*, photographed at Ulsan, Korea.

Fig. 20. Humerus, radius and ulna of *Rhachianectes glaucus*; Am. Mus. skeleton.

	II	III	IV	V
Right:	3	3	4	1
Left:	3	4	4	1

The terminal phalanx of the third digit of the left pectoral is a shell of bone and seems to be a normal phalanx which has been injured. This has all the appearance of bony tissue and not of hardened cartilage but it is not present in the right manus. Presumably the tips of both flippers were injured and the correct formulæ for the phalanges is that of the left. The terminal phalanx of the fourth digit of the right manus is also a bony shell but in the corresponding finger of the left hand it has a normal shape and size.

PELVIC RUDIMENTS.

The pelvic elements of *Rhachianectes* are exceedingly interesting, the most remarkable features in comparison with other whales being their great size, the less reduction of the pubis and ischium, and the presence of a large foramen.

Those of the American Museum skeleton are two long, slightly curved bones of exactly the same length. The ilium is exceedingly massive, laterally compressed, and has a long dorsal and ventral ridge; a cross-section would be a wide ellipse. The ischium has the same length as the ilium but it is not as massive, is more compressed, and is deeply excavated at the distal end.

The pubis appears as a prominent, roughly cone-shaped tubercle, turned sharply downward and standing at right angles to the remainder of the bone instead of projecting directly outward as in other baleen whales.

Along the inner base of the pubis is a deep longitudinal concavity in the bottom of which, and slightly posterior to the pubis, is a large curved foramen which perforates the bone transversely, emerging on the dorsal surface almost opposite the point of entrance.

Although both the American and U. S. National Museum specimens from which the pelvic elements were secured were males, there is considerable variation in the size and shape of the bones in the two individuals. Those of the U. S. National Museum skeleton are shorter, due to a reduction of the iliac portion, wider through the pubis, slenderer throughout and more

Fig. 21. Pelvic elements of *Rhachianectes glaucus*; Am. Mus. skeleton.

Fig. 22. Pelvic elements of *Rhachianectes glaucus*; U. S. Nat. Mus. skeleton.

curved. In both the ilium is considerably shorter than the ischium, the pubis is not turned as sharply downward as in the American Museum specimen, and the transverse foramen is larger; also there is no excavation of the distal end of the ischium.

The presence of a foramen perforating the pelvic rudiment has been recorded by Struthers in the case of *Balæna mysticetus* but it is rare in other Cetaceans.

It is to be regretted that it was not possible to make a careful examination of the flesh containing the pelvic elements to determine the condition of the femoral rudiments. I believe that *Rhachianectes* will be found to possess a femur larger than that of any other baleen whale when this subject has been more carefully investigated.

CONCLUSIONS.

SPECIFIC RELATIONSHIP OF CALIFORNIA AND KOREA SPECIMENS OF RHACHIANECTES.

Descriptions and measurements of the external anatomy and post-cranial skeleton of California examples of *Rhachianectes* are so general and inaccurate that they furnish few reliable data for use in deciding the specific relationship of the specimens from opposite sides of the Pacific. A discussion of this question, therefore, must rest almost entirely upon the basis of skull characters.

A careful comparison with our Korea specimen of the figures, descriptions and measurements of the American skulls presented by True and Malm shows a remarkably close agreement in all essential points. Examination of the table of measurements shows the only difference worthy of note to be in the proportionately shorter rostrum of the California skull and its less squamosal breadth. Judging from the figures the former difference seems to be due to the fact that the slender prolongations which the maxillæ send backward toward the vertex of the skull are somewhat broken, thus reducing the rostral length. The proportional squamosal breadth of the California skull is somewhat less than in the one from Korea, but since the orbital widths are almost exactly the same, this cannot be considered as of great importance.

There is, so far as I can discover, not the slightest ground for believing the Gray Whales of the east and west Pacific to represent other than a single species. Whether or not the animals mingle in the north during their summer migration has been discussed in the section of this paper relating to habits and need not be again taken up here.

SYSTEMATIC POSITION.

Review of former classifications.

- 1871.— J. E. Gray places *Rhachianectes* in the family Agaphelidæ.
- 1874.— Gill makes Agaphelidæ of Gray a subfamily under Balænopteridæ and divides that family into the three subfamilies Agaphelinæ, Balænopterinæ and Megapterinæ.
- 1891.— Flower and Lydekker combine all genera under the family Balænidæ without subfamily divisions.
- 1897–1904.— Trouessart gives two subfamilies, Balænopterinæ and Balæninæ, under the family Balænidæ and includes *Rhachianectes* in the former.
- 1900–1902.— Beddard considers *Rhachianectes* as an aberrant genus of the family Balænopteridæ.
- 1901–04–05.— Elliot recognizes two subfamilies of the Balænidæ and in the Balæninæ includes *Balæna*, *Rhachianectes* and *Megaptera*.
- 1904.— Max Weber recognizes three families, Rhachianectidæ, Balænidæ and Balænopteridæ.
- 1910.— Osborn, under the family Balænidæ, recognizes the three subfamilies Rhachianectinæ, Balæninæ and Balænopterinæ.

It will be seen from this brief review of the various classifications of the genus *Rhachianectes* that there has been little agreement as to its systematic position. This is partly due to the fact that up to the present time only the skull has been studied, the post-cranial skeleton never having been described. The results of my work upon this remarkable animal, presented in the preceding pages, lead me to believe that it cannot be included in either of the subfamilies of the Balænidæ and must take rank as a separate family. For this designation Weber's Rhachianectidæ is available and a definition of the family and genus may be formulated as follows:

Family *Rhachianectidæ*.— Skull with a broad strip of the frontals exposed upon the vertex. Maxillæ overlapping the anterior edges of the orbital processes of the frontals. Nasals very long and broad. Mandible without a coronoid process. Cervical vertebræ free. Manus consisting of four digits. Ribs of the anterior half of the series provided with tubercles, necks and heads. Furrows few and short.

Genus *Rhachianectes*.— Head less than one-fourth the length of the body. Baleen laminæ few, short, and thick. No dorsal fin. Pectoral limbs of medium width. Furrows only upon the throat. Rostrum of skull narrow and moderately arched. Premaxillæ sending broad, overlapping projections toward vertex of skull. Prominent rugosities upon the supraoccipital and basioccipital bones of the skull. Tympanic bullæ compressed and somewhat concave on internal border. Scapula having both acromion and coracoid processes.

PRIMITIVE CHARACTERS OF RHACHIANECTES.

The external and internal anatomy of *Rhachianectes glaucus* presents certain characters which seem to demonstrate that this animal is more primitive than any other existing baleen whale. These may be summarized as follows:

1. Long hairs scattered over the entire head and mandible and not confined to certain regions as in other whales.
2. Baleen plates very short, thick, fewer in number and more widely spaced than in other whales.

3. Skull:
 - a. Exposure of a wide strip of the frontals upon the vertex of the skull.
 - b. Long nasal bones.
 - c. Comparatively small squamosals having straight outer edges. This is noticeably different from the concave squamosals of existing baleen whales and is a character of fossil genera.
 - d. Proximal ends of the premaxillæ very broad, superiorly placed, and articulate with the frontals by a deep, interdigitating suture.
 - e. Orbital processes of the frontals anteriorly overlapped by the edges of the maxillæ, posteriorly with irregular margins, and trumpet-shaped; all well marked characters of certain fossil baleen whales.
 - f. A well emphasized temporal ridge.
 - g. Prominent rugosities upon the supraoccipital, pterygoids, and basioccipital bones of the skull.
 - h. Compressed tympanic bullæ having concave internal borders.
4. Cervical vertebræ entirely free and showing no evidences of ankylosis between any members of the series.
5. Atlas and axis possessing massive, rugose neural arches; axis with comparatively small foramina through the wing-like transverse processes.
6. Ribs possessing tubercles, necks and heads as far back as the eighth, and in these portions resembling an *Odontocete*.
7. A long and straight humerus of the *Plesiocetus* type.
8. Very large pelvic elements, the presence of a large foramen in them and the comparatively slight reduction of the pubis and ischium.

RELATIONSHIP OF RHACHIANECTES.

Rhachianectes glaucus is apparently not closely related to any of the existing baleen whales but in some respects it stands intermediate between the *Balæninæ* and *Balænopterinæ* being nearer the latter. In many skull characters it approaches closely the Pliocene whales of the genus *Plesiocetus* which is allied to the existing *Balænopterinæ*; in fact, were it not for its specialized mandible it must certainly be considered as nearly related to them. The fossil whales of the *Plesiocetus* group possessed mandibles having the proximal portion of each ramus, internally, widely concave and leading into a large dental canal; in short, much as in the mandibles of the existing toothed whales. *Rhachianectes*, however, although resembling *Plesiocetus* in many important skull characters, possesses a specialized mandible similar to that of the Right Whales; that is the proximal portion, internally, is not concave and the dental canal is small. This type of mandible prevents the phylogenist from taking *Rhachianectes* off from the *Plesiocetus* group, unless he wishes to consider that while persisting until the present day with comparatively little modification of its primitive skull characters, it has undergone considerable specialization of the mandible alone. This is a perfectly possible supposition, which I am inclined to believe is true, since *Rhachianectes* shows such marked affinities to *Plesiocetus* and is so strongly separated from the other known genera of fossil and recent whales. It is, upon the whole, one of the most remarkable of existing Cetaceans and might be called a "living fossil."

EVOLUTIONARY BIOLOGY

Whole-genome sequencing of the blue whale and other rorquals finds signatures for introgressive gene flow

Úlfur Árnason,^{1*} Fritjof Lammers,^{2,3,4*} Vikas Kumar,² Maria A. Nilsson,² Axel Janke^{2,3,4†}

Reconstructing the evolution of baleen whales (Mysticeti) has been problematic because morphological and genetic analyses have produced different scenarios. This might be caused by genomic admixture that may have taken place among some rorquals. We present the genomes of six whales, including the blue whale (*Balaenoptera musculus*), to reconstruct a species tree of baleen whales and to identify phylogenetic conflicts. Evolutionary multilocus analyses of 34,192 genome fragments reveal a fast radiation of rorquals at 10.5 to 7.5 million years ago coinciding with oceanic circulation shifts. The evolutionarily enigmatic gray whale (*Eschrichtius robustus*) is placed among rorquals, and the blue whale genome shows a high degree of heterozygosity. The nearly equal frequency of conflicting gene trees suggests that speciation of rorqual evolution occurred under gene flow, which is best depicted by evolutionary networks. Especially in marine environments, sympatric speciation might be common; our results raise questions about how genetic divergence can be established.

INTRODUCTION

Baleen whales (Mysticeti) are strikingly derived marine mammals that encompass the largest animals living on Earth (1); however, their evolution is only poorly understood. Today, 15 species of extant baleen whales are known, and the fossil record includes many additional extinct species (2). The gigantic blue whale (*Balaenoptera musculus*) with a length of 30 m and a weight exceeding 150 metric tons and the fin whale (*Balaenoptera physalus*) are the largest animals on Earth (1). Both belong to the rorqual family (Balaenopteridae). Baleen whales have undergone significant adaptations to marine life and are characterized by their lack of teeth, which have been replaced by keratin bristles, the baleen that is used for filter feeding (3). It has been estimated that the blue whale takes in up to 3.6 metric tons of krill every day to supply the energy demand of their huge body sizes (3). The large body size of whales allowed them to occupy novel ecological niches by enabling deep dives and to endure long periods of starvation to reach feeding grounds (4). The evolutionary history of baleen whales is debated, despite extensive analyses of molecular and morphological characteristics (2, 5). Moreover, molecular analyses of baleen whale evolution disagree with each other depending on the applied marker and type of phylogenetic analysis (5–8). Of particular interest are the humpback whales (*Megaptera novaeangliae*) and gray whales (*Eschrichtius robustus*), which are each placed in a separate genus or even in its own family, mainly based on analyses of their derived anatomy (1). However, these classifications are not supported by recent molecular studies, which suggest that they evolved from within rorquals, making the latter paraphyletic. To reflect this discordance, we will use the family name Balaenopteridae sensu lato, that is, including Balaenopteridae and Eschrichtiidae.

It is difficult to envision that the baleen whales evolved by allopatric speciation under vicariance because the marine environment largely lacks physical barriers for mobile species like whales (1, 9). The study of the evolution of whales is further complicated by the fact that whales can hybridize. In the case of the blue whale and the fin whale, genetic

analyses have shown that the female hybrid carried a fetus and had mated with a blue whale (10). Thus, these two species, as well as other rorquals, may not be entirely reproductively isolated. In addition, rorquals have a conserved karyotype of $2n = 44$ chromosomes and an identical chromosomal C-banding pattern, which facilitate producing fertile offspring (11).

Genomic analyses allow detailed insight into evolutionary processes such as speciation or past hybridization events (12) and permit examination of long-standing evolutionary questions (13). Introgressive hybridization, speciation with gene flow, and incomplete lineage sorting (ILS) may cause different local genealogies across the genome that can be detected by analyzing whole-genome sequences (14). Compared to terrestrial species, genomic data are limited for marine mammals, and before this study, genomic data were only available for three baleen whales: the bowhead whale (*Balaena mysticetus*), the minke whale (*Balaenoptera acutorostrata*), and the fin whale (15, 16).

Here, we present genomic data of six mysticete species including the humpback and gray whale and the largest extant animal ever lived, the blue whale. The data are analyzed under the multispecies coalescent (MSC) that incorporates the genome-wide heterogeneity of gene trees to accurately infer speciation history (14). In addition, the genomes allow us to study signals of recent and ancestral introgression, to place divergences into a solid temporal context, and to explore genetic diversity and past demographic history of baleen whales.

RESULTS

Genome sequencing and assembly

Genomic DNA from six baleen whales and a hippopotamus (*Hippopotamus amphibius*) were sequenced with Illumina technology. Reference genome mapping of the whale genome data against the bowhead whale genome (16) yielded genome coverages of 6.3 to 27.2× (table S1). RepeatMasker (17) identified 40.3% repetitive sequences in the bowhead whale genome assembly. Of these, 6 and 18% were short and long interspersed elements (SINE and LINEs), respectively (table S2). Except for the genomic fraction of SINEs, these results are consistent with the original analyses of Keane *et al.* (16). We identified, on average, 25 million fixed single-nucleotide differences relative to the bowhead whale genome (table S3). Consensus sequences of all baleen whale genomes were aligned per scaffold, and repetitive sequences, gaps, and ambiguous bases were

removed. Empirical analyses and simulations using the approximate unbiased (AU) test (18) showed that 20-kilo-base pair (kbp) genome sequence alignments contain sufficient information for statistically significant maximum likelihood (ML) gene tree inference (figs. S1 to S3). The aligned scaffolds yielded 34,192 genome fragments (GFs), each 20 kbp long, totaling 643,840 kbp for each whale. This represents 49% of the nonrepetitive genome sequence. Sequencing the hippopotamus genome yielded 1,684,446,285 filtered reads and a sequencing depth of 55× (table S4). The reads were assembled de novo with Minia (19) and scaffolded with SSPACE, resulting in a genome assembly of 2.43 Gbp with a scaffold N50 of 120 kbp. AUGUSTUS (20) identified 29,998 coding sequences (CDSs); 37.0% of the genome were masked as repetitive (table S5).

The evolution of whales

Model testing identified the generalized time-reversible model with gamma-distributed rate variation with invariable sites (GTR + 4G + I) as the best-fitting nucleotide substitution model for the ML analyses of GFs. An MSC species tree of baleen whales based on 34,192 GF trees was supported with posterior probabilities of 1.0 for all branches (Fig. 1A and fig. S4). The topology conforms to previous nuclear gene and mitochondrial DNA (mtDNA) analyses (5, 21) and a Bayesian phylogeny of the mtDNA sequences reported herein (fig. S5). The primary characteristic of the tree is the clear distinction between the Balaenidae

(right whales) and the branch harboring the five rorquals plus the gray whale (*Balaenopteridae sensu lato*). The humpback whale (genus *Megaptera*) groups within the rorquals, resulting in a paraphyly of the current genus *Balaenoptera*. The gray whale of the monotypic family Eschrichtiidae is placed inside rorquals as a sister lineage to fin and humpback whale. However, quartet scores, that is, the support for any of three possible phylogenetic arrangements around an internal branch, identified conflict in resolving the branch leading to the ancestor of the gray, fin, and humpback whale (Fig. 1A, branch no. 3). The three possible topologies for this branch receive similar quartet scores (Fig. 1B), contrasting to a posterior probability of 1.0. Thus, we find highly similar support for placing the gray whale as a sister group to blue whales and sei whales or as a distinct clade outside the blue/sei/fin/humpback whale cluster. Somewhat inconclusive support also marks the first branch inside rorquals (Fig. 1B, branch no. 2) that places the minke whale as a sister lineage to the remaining *Balaenopteridae sensu lato* with a quartet score of 0.7. Phylogenetic conflict is also present in a CONSENSE (22) analysis of the GF trees. Although a majority-rule consensus tree confirms the coalescent-based species tree (Fig. 1A and fig. S6), two alternative phylogenetic positions of the gray whale are equally strongly represented (table S6).

The position of the gray whale in the species tree is supported by 10,315 (30.2%) GF trees compared to 8918 (26.1%) and 8721 (25.6%) GF trees, which place the gray whale in different positions inside rorquals.

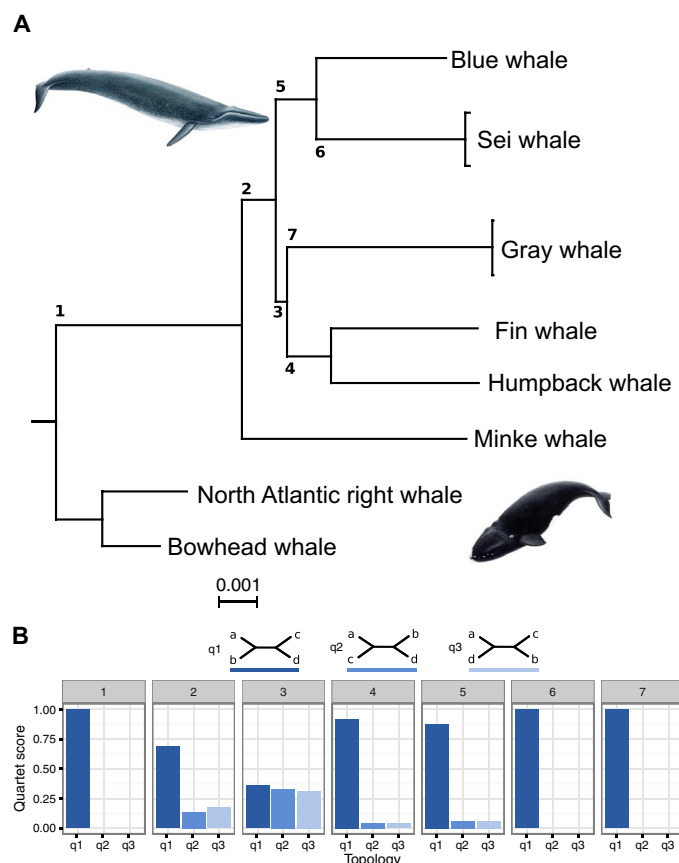

Fig. 1. MSC tree. (A) An MSC species tree was constructed from 34,192 individual GFs. Internal branches within Balaenopteridae are numbered 1 to 7. All branches receive maximal support ($P = 1.0$, ASTRAL analysis). Branch lengths were calculated from an ML analysis. Gray whales, family Eschrichtiidae, are placed inside Balaenopteridae as a sister group to fin and humpback whales. (B) ASTRAL quartet-score analyses for branches 1 to 7 (A). Quartet scores were calculated for the three possible arrangements (q1 to q3) for the respective branch. The principal quartet trees are depicted, with q1 representing the species tree. Branch nos. 2 and 3 receive only limited quartet scores, and no quartet can be significantly rejected.

A placement of the gray whale outside rorquals is supported by 3507 GF trees (10.3%). A consensus network analysis (23) of the GF trees yields a large cuboid structure of connecting alternative branches in the center of the network that indicates conflicting signals for the position of the gray whale inside rorquals (Fig. 2). At a threshold for conflicting edges of 11%, the grouping of the humpback and fin whale, the sei and blue whale, and the bowhead and North Atlantic right whale is unambiguous. At lower thresholds, the phylogenetic signal becomes more complex, indicating additional phylogenetic conflict in the data (fig. S7).

Gene flow analyses

D statistic (24) and D_{FOIL} (25) analyses identified several gene flow signals among rorquals (Fig. 3A and data S1 and S2). We find significant gene flow signals between minke whale and the ancestors of the blue and sei whale and those of the fin and humpback whale, respectively. The D_{FOIL} analyses find a strong signal for gene flow between the ancestor of the blue and sei whale and the ancestor of the fin and humpback whale, which is likely a phylogenetic signal related to a placement of placing the gray whale into different positions (Fig. 3A and data S1 and S2). In addition, signal for recent gene flow was inferred reciprocally from the blue whale to the fin and humpback whale for about 1 to 1.5% of the genome. The D statistic analyses also identified numerous signals for gene flow between the ancestor of the blue/sei whale and gray

whale and that of the humpback whale and gray whale. Note that the D statistic and D_{FOIL} analyses depend on the species tree as in Fig. 1A and the signal may vary for other constellations. Our interpretation, therefore, focuses on signals that are independent of the evolutionary placement of gray whales.

In addition to character-based parsimony analysis, gene flow may preferably be studied by topology-based ML analysis using PhyloNet (26). PhyloNet identifies a statistically significant signal for gene flow between the minke whale and the ancestor of the other rorquals (Fig. 3B). With equal likelihood probability, gene flow occurred from the ancestor of the humpback and fin whale to that of the minke whale (Fig. 3C). Furthermore, with a topology change of the gray whale as a sister group to blue and sei whale, gene flow occurs from the ancestor of the blue and sei whale to that of the minke whale (Fig. 3D). Each of the three reticulations shows inheritance probabilities of about 33%, resembling the quartet-score distribution of the coalescent tree analyses (Fig. 1B).

Genetic diversity and population size history

Genome-wide heterozygosity varies considerably among baleen whales (Fig. 4A and fig. S8). At approximately 5×10^{-4} heterozygous sites per nucleotide, estimates were lowest for the gray whale, the minke whale, and the two sei whales. The blue whale genome shows the highest

Fig. 2. Median network of 34,192 GF ML trees with 11% threshold. Conflicting evolutionary signals characterize the center of the network, which is equivalent to branch no. 3 in the species tree (Fig. 1). In addition, placing the minke whale has some conflicting signal, but the elongated rectangle indicates a higher degree of resolution. The number of supporting GFs is shown for selected splits. Colored circles indicate taxonomic classification. Blue, *Balaenoptera*; red, *Megaptera*; yellow, *Eschrichtius*; green, *Balaena* and *Eubalaena*.

degree of heterozygosity, which is elevated even when compared to other mammals (27). Estimates for heterozygosity in downsampled genomic data of blue whale were similar, minimizing the effects of potential artifacts by higher sequence coverage (fig. S9). The history of the effective population size (N_e) over the last 5 million years (Ma) was modeled from the distribution of heterozygous sites across the genome using a pairwise sequentially Markovian coalescent (PSMC) (28) analysis (Fig. 4B and fig. S10). Ancestral effective population sizes for all baleen whales, particularly the large blue, fin, and humpback whales, were notably higher during the Plio-Pleistocene transition (PPT; 2.6 Ma ago) than recent estimates (Fig. 4B). After the mid-Pleistocene transition (MPT), N_e of most baleen whales was relatively stable, until approximately 100 thousand years (ka) ago, the time of the last interglacial. After this time, baleen whale populations decreased. In contrast, gray whale population size remained stable during the interglacial, and its population size even increased in more recent times. The blue whale maintained a larger population size than other whales, but their numbers decreased at 400 ka ago after the MPT. The minke and fin whale population increased somewhat at 200 to 300 ka ago, followed by a steady decline. The N_e of the humpback whale was rather constant since 1 Ma ago and then shows a decline by two-thirds of its population at some 30 ka ago. Our estimates of historical population sizes of the fin and minke whale are consistent with previous analyses (15).

Divergence time estimates

The phylogenomic reconstruction of a paraphyletic position of Cetacea among Artiodactyla and the placement of the Hippopotamidae are, for the first time, supported by genomic sequence data analyses (Fig. 5). The divergence times are based on five calibration points (table S8). Hippopotamidae diverged at 53.5 Ma ago, close to the appearance of archaeocetes in the fossil record at 50 Ma ago (29). Rorquals diverged in the late Miocene, between 10.48 and 4.98 Ma ago (table S9). The divergence time between baleen and toothed whales at 30.5 Ma ago coincides with the Eocene/Oligocene transition at 33 Ma ago (30), which probably triggered the radiation of modern whales.

DISCUSSION

Our genome analyses have shown that the evolution of Balaenopteridae sensu lato (hereafter referred to as rorquals) is not characterized by an ordered dichotomous divergence of lineages as would be expected with respect to speciation in most other mammals. Coalescent-based analyses of more than 600-Mbp genomic data and network analyses show that the genomes of rorquals are characterized by contradicting genealogies for their central divergence. Thus, the evolution of rorquals appears to be a process of gradual divergences that likely gave rise to three lineages almost simultaneously: (i) blue plus sei whales, (ii) gray

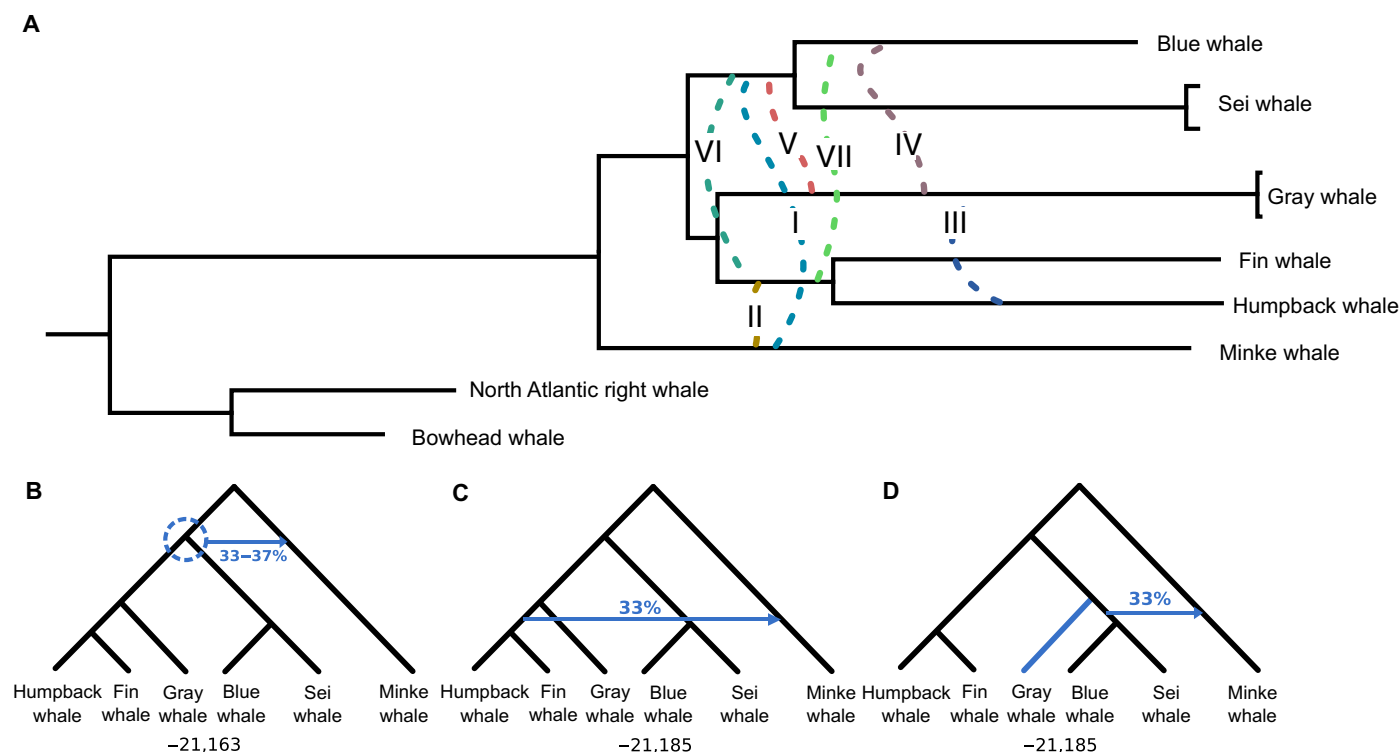

Fig. 3. Gene flow signals for baleen whales inferred by the D statistic, D_{FOIL} , and PhyloNet. (A) The species tree of baleen whales with gene flow signals detected by the D statistic and D_{FOIL} indicated by dashed lines. Signals I to IV were inferred by the D statistic, and signals V, VI, and VII were detected by D_{FOIL} and were partially corroborated by the D statistic. Note that D_{FOIL} cannot infer gene flow involving the minke whale. (B to D) Rooted networks for the Balaenopteridae sensu lato phylogeny with reticulations inferred from PhyloNet based on 34,192 20-kbp GFs. Reticulations are shown as blue arrows with inheritance probability denoted above or below. Log-likelihood scores are shown below the networks. Notably, inheritance probability around 33% resembles the distribution of quartet scores and the phylogenetic signals from GFs (Fig. 1). (B) The three best networks indicated a reticulation originating at the circled three branches to minke whale. Similar likelihood scores do not allow the identification of a single origin of gene flow; therefore, the networks were merged, and a range of inheritance probabilities is given. (C) The fourth best network has only a marginally poorer likelihood score and indicates a reticulation between the ancestor of the fin and humpback whale and that of the minke whale. (D) The fifth best network has the same likelihood as (C) and finds an alternative placement of gray whale (blue branch) and reticulation from the ancestor of the blue and sei whale to that of the minke whale.

Fig. 4. Demographic history and genome-wide heterozygosity. (A) Genome-wide heterozygosity estimated from genomic 100-kbp windows. (B) Historical N_e using the PSMC analyses for all baleen whale genomes. The x axis shows the time, and the y axis shows N_e . Plots were scaled using a mutation rate (μ) of 1.39×10^{-8} substitutions nucleotide $^{-1}$ generation $^{-1}$ and species-specific generation times (g). Generation times are noted next to the species names. Light brown shading indicates interglacials (IG) in the Pleistocene and Holocene, and gray shading indicates the MPT and the PPT.

Fig. 5. Divergence time tree of Cetancodonta (56) including the newly sequenced baleen whales, estimated from 234,947 amino acid sites (2778 orthologs). Rorquals diverged in the late Miocene, 10.5 to 7.5 Ma ago. Four other cetartiodactyl species were also included but not shown due to space constraints; the dog (*Canis lupus familiaris*) was used as an outgroup. Five calibration points were used for dating (table S8) (29, 56–60).

whale, and (iii) fin plus humpback whales. The early rorqual radiation is therefore best understood as a phylogenetic network because different fragments of the rorqual genomes support three different evolutionary histories. This provides the reason why the evolution of rorquals was previously differently reconstructed and poorly supported by molecular analyses of smaller data sets (5–8). Their evolutionary reconstruction needed to be constrained by morphological data to yield a traditional bifurcating tree among rorquals (2).

The apparently unequivocal support for the species tree by the MSC analyses is likely a consequence of a slight imbalance of the evolutionary signal that preferably places the gray whale together with the fin whale and humpback whale. Within the massive amount of genome-scale data, even a minor bias can lead to significantly resolved branches, despite the underlying conflict (31). Therefore, inspection of quartet scores in a coalescent species tree and network and CONSENSE analyses are crucial in identifying and depicting conflict in the evolutionary signal.

Rorqual taxonomy

Despite the conflict for the early divergence among rorquals, other divergences are well resolved by genome analyses that find the humpback whale closely related to the fin whale within the genus *Balaenoptera*. This is consistent with previous mitogenomic studies (5, 7, 21) and makes a separate genus, *Megaptera*, obsolete. If the rules of scientific nomenclature are strictly followed in accord with the phylogenetic relationships, the preferred name of the humpback whale should be *Balaenoptera novaeangliae*.

Because gray whales are morphologically, behaviorally, and ecologically distinct from other balaenopterid whales, placing them in a separate family (Eschrichtiidae) distinct from Balaenopteridae sensu stricto seemed natural (1, 32). This classification has been questioned by some molecular analyses (5, 21), and the current genomic analyses resolve this issue conclusively. Despite their derived morphology, gray whales fall unquestionably within the genus *Balaenoptera*, challenging their status as a separate family or even as a separate genus. Notably, the first described specimen of a gray whale was named *Balaenoptera robusta* (33) but later classified as own family and genus by J.E. Gray in 1865 in honor of the zoologist D. F. Eschricht (32). Consequently, we suggest that the originally proposed scientific name of the gray whale should be resurrected, with its name included in the Balaenopteridae.

Mechanisms of the rorqual radiation

The radiation of extant rorquals is documented by a rich fossil record with a notable diversity of evolutionary distinct lineages, most of which are now extinct. Speciation is generally assumed to occur when biological or geographic isolation results in reproductive isolation (34), and it may be difficult to conceive how whales could diverge. Compared to the terrestrial environment, the marine realm is a three-dimensional continuum, almost devoid of barriers that could aid allopatric speciation for highly mobile organisms such as whales. Mixing of gene pools among rorquals can still occur, and such a process would hinder diversification and consequently speciation (9). Even some 8 Ma (or about 400,000 generations ago) after their initial divergence, some baleen whale species can still hybridize, which might also be facilitated by their strikingly uniform karyotypes (11).

However, ongoing sympatric speciation in marine mammals by the formation of discrete ecotypes has been suggested for the orca or killer whale (*Orcinus orca*) (35). For example, the so-called “transient” and “resident” ecotypes specialized to prey on mammals and fish, respectively (35). Similarly, rorquals have evolved different feeding strategies.

Whereas most baleen whales feed on pelagic prey such as zooplankton and small fish, the gray whales have evolved to feed on benthic invertebrates by scooping up the seafloor. This opened a new ecological niche to which the gray whale adapted, leading over time to sympatric speciation. The adaptation to the benthic food source also led to notable morphological changes, consequently placing the gray whale into an own family. This differentiation may be triggered by climatic change and other environmental disturbances. These different ecological specializations could have led to a speciation continuum in the past that is similar to the one observed in orcas today.

Genomic analyses find the divergence times of baleen whales to be somewhat younger but within the range of previous estimates (5, 8, 21). The rorqual radiation coincides with the late Miocene cooling at ~7 Ma ago (36). This global cooling affected the marine environment by the onset of the current equator-pole temperature gradient. The beginning of the modern oceanic circulation increased productivity in the temperate and polar oceans (36), which may have affected cetacean evolution into different ecotypes.

Network-like evolution in whales

It seems counterintuitive that even whole-genome data do not fully resolve the evolution of whales and other mammals in a bifurcating pattern (12). However, speciation being a continuous process with possible hybridization, rather than a strict dichotomous event, has already been recognized by Darwin (37) and has recently gained new attention (38). In sympatric speciation, genomes can be homogenized by gene flow, and only a few genes need to be under divergent selection to form new species (38). Genome analyses sometimes fail to support the idea that speciation by reproductive isolation can fail to yield a fully resolved bifurcating tree, which has been the ultimate goal of evolutionary studies for many years. The analysis of genome sequences rather allows observing and comprehending evolutionary incongruence to translate this into new evolutionary hypotheses that might be better depicted as networks (39). Recognizing that “divergence with genetic exchange” is a widespread phenomenon in animals (9) makes it necessary to review the biological species concept. Instead of relying on reproductive isolation (34), a modern species concept should incorporate selective processes that maintain species divergence even under gene flow (12).

Signals for introgressive hybridization

Signals for gene flow confirm sightings and reports of current hybridization in whales (10, 40, 41). The signal for gene flow between blue and fin whale confirms introgression in these species. Other reports on hybrids between humpback and blue whales (40) or between bowhead and right whales (42) could not be confirmed by the present genome analyses. The hybridization between these species is likely restricted to few individuals or populations and did not lead to introgression. Further sequencing efforts will give more detailed insights into the extent of introgression of baleen whales and potential ecological implications.

In recent genomic studies of bears, humans, and many other animals, gene flow from introgressive hybridization has been identified as a cause for phylogenetic incongruence (9, 12). Postspeciation gene flow can be analyzed in genomic data with a variety of methods (43). The *D* statistic and its derivative are undoubtedly the widest applied methodology (24, 25), but these approaches assume a fully resolved species tree. If the species tree includes polytomies or, based on inappropriate statistical methods, is misidentified (44), then the basic assumption of the *D* statistic may be violated and the results can be misleading. Therefore, in case of phylogenetic uncertainties, gene flow

analyses should, in addition, apply methods that do not require a known topology such as PhyloNet that infers introgression signals from a set of gene trees (26). However, alternative methods can be computationally intractable for complex phylogenies or a large number of loci.

Demographic history

Genome data from a single individual allow the reconstruction of the effective population size of its species for some 1 to 2 Ma back in time (28). These studies have shown that the demographic histories of many mammals have been influenced by climatic oscillations in the Pleistocene [for example, sheep (45)]. However, baleen whales maintained relatively stable effective population sizes after the MPT, despite major oscillations in the global climate consequently affecting ocean circulation, upwelling, and marine productivity. The general congruence of population size histories of different baleen whale species indicates that they were similarly affected by these factors. Differences in sequence depth may limit the comparison of absolute N_e between our samples; however, chronology of the curves is not expected to be affected (46). Industrial whaling has been too recent to leave a noticeable signal of a declining N_e in the PSMC analyses, especially for long-lived species with long generation times like rorquals. However, compared to other mammals, rorquals, particularly the blue whale, have a comparatively high degree of genome-wide heterozygosity (27). The impact of whaling on the genetic diversity of baleen whales may become apparent only after several generations and require population-scale studies for a detailed assessment (47).

CONCLUSION

Genome data analyses finally resolved the evolutionary history of baleen whales, even if it is not a bifurcating tree that most had expected. The evolution of rorquals can only be accurately understood by phylogenetic networks because a forced bifurcating tree or a hard polytomy would ignore the accumulated evolutionary history that is recorded in their genomes. It is evident that the central rorqual radiation was not along a progressively ordered process. On the contrary, speciation with gene flow is indicated by the nearly equal probabilities for different evolutionary histories across rorqual genomes. In addition, hybridization between blue and fin whales left genome-wide signals of introgression. The gray whale may constitute a striking example of sympatric speciation related to adaptation to and occupation of a particular niche, bottom feeding, as compared to the pelagic feeding of other rorquals. Our results indicate that sympatric speciation should not be neglected as a mode of speciation in highly connected habitats, such as the marine environment.

MATERIALS AND METHODS

DNA isolation and sequencing

Cell cultures (established by the first author, 1969 to 1974) were grown in Dulbecco's modified Eagle's medium supplemented with 10% fetal bovine serum under standard conditions. DNA of *H. amphibius* was extracted from muscle tissue of a naturally deceased individual, provided by M. Bertelsen (Copenhagen Zoo). DNA was isolated from cells or tissue using a standard phenol-chloroform method. Sequencing libraries were prepared with insert sizes between 300 and 500 bp and sequenced using Illumina HiSeq 2000, 2500, and 4000 technology. The minke whale genome data were obtained from the short read archive (accession no. SRR896642) (15). Sequencing library information and mapping statistics are given in table S1. Quality control was performed using FastQC

(www.bioinformatics.babraham.ac.uk/projects/fastqc/), and reads were trimmed. All cell culture work and DNA extractions from tissues were performed according to the ethical guidelines and permission of the respective institutions.

Paired-end reads were mapped to the bowhead whale genome (*B. mysticetus*) (16), with BWA mem version 0.7.12-r1039 (48), and duplicates were marked with picard (<https://github.com/broadinstitute/picard>). The bowhead whale was used as reference genome because it avoids a mapping bias that can affect phylogenetic analyses. The minke whale is phylogenetically placed inside baleen whales, and a possible mapping bias against its genome is likely to affect phylogenetic and gene-flow analyses. Scaffolds shorter than 100 kbp were excluded. Repetitive sequences were annotated for the bowhead whale genome by RepeatMasker (17). From the mapped reads, single-nucleotide variants (SNVs) and short insertion or deletions (InDels) were called by freebayes v0.9.20-16-g3e35e72 (49) with a minimum coverage of four reads and settings: --monomorphic --min-mapping-quality 20, -C 4, -F 0.3. Consensus sequences were created from VCF-files using custom perl scripts. InDels were removed, and ambiguously called sites were masked as "N."

For sequencing the hippopotamus genome, paired-end and mate-pair libraries were constructed with different insert sizes sequenced on Illumina HiSeq 2000/2500 sequencers (table S4). Because of high levels of duplications, mate-pair libraries were deduplicated. All libraries were trimmed for adaptors and low-quality regions, requiring a minimum read length of 90 bp after trimming. All libraries were assembled into contigs using Minia with $k = 49$ (19). Contigs were scaffolded with SSPACE (https://github.com/nsoranzo/sspace_basic) using the mate-pair libraries. Finally, GapCloser (<http://soap.genomics.org.cn/>) was run with all libraries. Scaffolds shorter than 1 kbp were excluded from the final genome assembly of the hippopotamus. Novel repetitive elements were identified with RepeatModeler (www.repeatmasker.org/RepeatModeler/).

The genome assembly was screened for repetitive sequences using RepeatMasker and the previously created de novo library of identified repeats from RepeatModeler and the RepBase Mammalia library. To account for nonoverlapping detected repeats, we combined and applied the genome masks to the genome sequence. Protein coding genes were predicted ab initio with AUGUSTUS v.3.1 (20) using settings -UTR -species human.

Phylogenomic analysis of baleen whales

Consensus sequences of all genomes were aligned per scaffold, and heterozygous sites and repetitive regions were removed. Per-scaffold alignments were split into nonoverlapping GFs of 10, 20, and 100 kbp, respectively. Scaffolds that were shorter than the GF size after removal of ambiguous sites were excluded.

Estimating phylogenetic information in GFs

To analyze the phylogenetic information content of the GFs, we randomly sampled 5000 GFs to count the number of parsimony informative sites and to estimate the genetic distance between the two closest related whales, that is, the bowhead and the North Atlantic right whale. On the basis of real GFs, we simulated GFs between lengths of 1 and 100 kbp to determine which length carries sufficient phylogenetic information to statistically reject alternative topologies (fig. S1). Topology testing was performed using the AU test (18).

Species-tree inference and analysis of phylogenetic conflict

JModelTest2 (50) identified the suitable nucleotide substitution model by evaluating random 20-kbp GFs. For each GF, phylogenetic trees were

computed with RaxML (51) using ML and the GTR + G substitution model that was identified as best fit. Each ML analysis was bootstrapped with 100 replicates. From all 20-kbp GF trees, ASTRAL 4.10.5 (31) computed a species tree under the MSC model (exact method) returning quartet scores and posterior probabilities. The species tree was rooted with the bowhead whale and North Atlantic right whale that are outside Balaenopteridae. CONSENSE from the PHYLIP package (22) explored conflict among the gene trees by identifying identical splits in a set of given gene trees and summarizing their frequency. Consensus networks of the GF trees were generated using SplitsTree4 (23) with different median thresholds. Phylogenetic consensus networks summarize gene tree discordance by drawing alternative edges for each observed split.

Phylogeny of whale mitochondrial genomes

We reconstructed the mitochondrial (mt) genomes from the whale individuals reported herein by mapping the reads to conspecific published mt genomes and generated consensus sequences as described for the nuclear genomes. Mt sequences were aligned to 19 published mt sequences of whales. Accession numbers of mt genomes used as reference for mapping and the phylogenetic analysis are shown in fig. S4. A Bayesian phylogenetic tree was reconstructed using MrBayes version 3.2.2. The analysis was run for 1,200,000 generations with default priors, using the “invgamma” substitution model and an arbitrary burn in of 25% of the samples.

Gene flow analyses

The *D* statistic compares the number of biallelic ABBA and BABA sites in a four-taxon phylogeny and requires a phylogenetic topology following (((H1, H2), H3), O), with H1 to H3 being ingroups and O being the outgroup. For the analyses, the consensus sequences of baleen whales were fragmented into nonoverlapping 100-kbp windows. We applied the *D* statistic to all asymmetric four-taxon phylogenies that can be extracted from the species tree. This resulted in 33 gene flow analyses, such as “(((blue whale, sei whale), fin whale), minke whale).” The direction of gene flow can be estimated in a derivative of the *D* statistic, the *D*_{FOIL} analysis (25), downloaded 15 September 2015 from <https://github.com/jbpease/dfoil>. The test requires an asymmetric five-taxon tree with a specific topology; therefore, not all combinations of five whale taxa could be analyzed. The *D*_{FOIL} analyses used the same genomic windows as the *D* statistic analyses.

Our taxon sampling allowed the analysis of the following topologies when considering the estimated species tree as correct because the *D*_{FOIL} analyses assume a symmetrical five-taxon topology: (i) (((blue, sei), (fin, hump)), NA right); (ii) (((blue, sei), (fin, gray)), minke); (iii) (((blue, sei), (hump, gray)), minke); (iv) (((blue, sei), (hump, gray)), NA right); (v) (((blue, sei), (hump, gray)), bowhead); (vi) (((blue, sei), (fin, gray)), NA right); (vii) (((blue, sei), (fin, gray)), bowhead); (viii) (((blue, sei), (fin, hump)), bowhead); NA right refers to the North Atlantic right whale, whereas the remaining whales are indicated by the first part of their common names.

Maximum likelihood inference for reticulation with PhyloNet

PhyloNet (26) is specifically developed to reconstruct reticulated phylogenies from a set of gene trees. We used the ML approach to analyze a set of every 10th GF ML tree, that is, 3419 trees in a coalescent framework that accounts for ILS while allowing different numbers of reticulations (26). Subsampling of trees reduced complexity and com-

putational demand. In addition, the bowhead whale, North Atlantic right whale, and sei whale individual “B” were pruned from the input gene trees because their phylogenetic position is unambiguous. The “InferNetwork_ML” method was run with 50 iterations, yielding the five networks with the highest likelihood scores. Analyzing networks with more than one reticulation were too complex and not interpretable from the extended Newick format.

Demographic history

Changes in *N_e* for the baleen whales were inferred from genome sequences using the PSMC (28). We applied PSMC v0.6.5-r67 with input files generated using Samtools mpileup version 1.2 (www.htslib.org) and by applying a minimum mapping and base quality of 30. Using vcftools, minimum and maximum depth of coverage thresholds were set to 0.5 and 2× the sample’s average coverage (table S1). PSMC was run with 25 iterations, an *N₀*-scaled maximum coalescent time of 20, and a *p*/θ ratio of 5, and the 64 time intervals were parameterized as “4 + 25 × 2 + 4 + 6.” PSMC plots were scaled with a mutation rate of $\mu = 4.5 \times 10^{-10}$ mutations bp⁻¹ year⁻¹ that has been determined for whales (52).

Bootstrapping was performed on whole scaffolds. Species-specific predisturbance generation times were used to scale the PSMC plots (53). Industrial whaling took place only during the last 200 years, so predisturbance generation times are more accurate for the time frame covered by PSMC. The generation times are shown in Fig. 5.

Genome-wide heterozygosity

To estimate the genome-wide heterozygosity, we randomly sampled 1000 100-kbp nonoverlapping windows for each genome. For these windows, heterozygous SNVs were extracted from the complete set of called variants. Heterozygous sites were excluded if the distance to a called InDel was 10 bp or less or if the sequencing depth at the site was less than 0.5 or 2× the mean sample coverage. This avoids artifacts from assembly errors. For each window, the frequency of heterozygous sites was calculated. In addition, genome-wide heterozygosity and genome-wide sequencing error were inferred using mlRho (54). To exclude the potential effects of higher sequencing coverage in the blue whale, the BAM file was downsampled using GATK (genome analysis tool kit) and genome-wide heterozygosity was estimated for ~10× sequencing data.

Cetartiodactyla phylogenomics

Protein sequences for different representative species among Cetartiodactyla were retrieved from ENSEMBL and RefSeq (table S7). For data obtained from RefSeq, Samtools extracted the CDSs from whole-genome sequences using the annotation provided as a General Feature Format (GFF) file.

The annotated CDS for the bowhead whale was used to extract and translate the corresponding genomic regions from baleen whale genomes that were mapped to the bowhead whale Proteinortho version 5.11 screened protein sequences from all genomes listed in table S7. The baleen whale genomes were mapped to the bowhead whale genome and thus their CDSs have the same genomic coordinates. Therefore, the protein sequences of the baleen whales were added after orthology detection based on orthologous proteins identified in the bowhead whale. All proteins for which orthologs were identified in at least nine species were selected, and their sequences were extracted. Protein sequences were aligned individually and trimmed to exclude ambiguously aligned sites. The trimmed alignments were concatenated and used to date the

cetartiodactyl species tree with MCMCTree (55) using five calibration points across the tree of Cetartiodactyla (table S8).

Acknowledgments: We are grateful to J. B. Hlidberg (www.fauna.is) for artwork. We thank M. Bertelsen (Zoo Copenhagen) for providing the tissue of the hippopotamus, as well as K. Hildebrandt and L. Olson (University of Alaska, Museum of the North) for giving access to the museum’s gray whale tissues (UAM:Mamm:117578 and 99577). We acknowledge Science for Life Laboratory, the National Genomics Infrastructure, and Uppmax for providing assistance in massive parallel sequencing and computational infrastructure. The present study is also a product of the Centre for Translational Biodiversity Genomics (LOEWE-TBG) as part of the “LOEWE—Landes-Offensive zur Entwicklung Wissenschaftlich-ökonomischer Exzellenz” programme of Hesse’s Ministry of Higher Education, Research, and the Arts.

Author contributions: U.A., F.L., and A.J. conceived the study and scientific objectives. U.A. and A.J. funded genome sequencing. F.L. made the computational analyses with the help of V.K. M.A.N. interpreted the population genetic data. F.L. and A.J. wrote the manuscript with contributions from all authors.

Competing interests: The authors declare that they have no competing interests.

Data and materials availability: Raw sequencing reads for the baleen whales and the hippopotamus have been deposited at the National Center for Biotechnology Information under BioProjects PRJNA389516 and PRJNA389773, respectively. The assembled genome sequence of the hippopotamus is deposited as NKPW00000000. Mitochondrial genomes of newly sequenced baleen whales are deposited in GenBank under accession MF409242-MF409249. All other data needed to evaluate the conclusions in the paper are present in the paper and/or the Supplementary Materials. Additional data related to this paper may be requested from the authors.

Changes in the Abundance of Whalebone Whales in the Pacific and the Antarctic since the Cessation of their Exploitation

A. A. Berzin and V. L. Vladimirov

Pacific Research Institute of Fisheries and Oceanography (TINRO) Vladivostok, USSR

ABSTRACT

Sightings data for protected species in the Pacific and Antarctic from 1976–79 are presented. Although the state of the baleen whale populations remains serious, there are indications that some populations are now increasing e.g. the Okhotsk Sea population of bowhead whales, blue and fin whales in the North and South Pacific and humpback whales around New Zealand.

INTRODUCTION

Berzin (1978) summarised data obtained from research vessels and from the whaling fleets *Dalnyi Vostok* and *Vladivostok* in 1973 and the *Sovietskaya Rossiya* from 1973–76, on the distribution and abundance of the protected species of whalebone whales in the North Pacific. This analysis revealed the critical state of some of these stocks, in particular the Okhotsk Sea-Korean gray whales (*Eschrichtius robustus*) and the North Pacific humpback whales (*Megaptera novaeangliae*). The improvement in the state of some of the other stocks, e.g. the Chukotka-Californian gray whales and some of the rorquals in both the North Pacific and Antarctic is testimony to the necessity of timely action by the International Whaling Commission (IWC).

On the recommendation of the IWC Scientific Committee, Soviet whalers now carefully record data on the distribution and abundance of Protected Stocks in both Hemispheres. In this paper we have summarized data obtained from the *Dalnyi Vostok* and *Vladivostok* in the

North Pacific from 1976–78; from the *Sovietskaya Rossiya* in the Southern Hemisphere from 1977–79; from a helicopter survey in the northwest Okhotsk Sea in 1979 (Berzin and Doroshenko, 1981); and research cruises by the whaling boats *Avangard* in the Bering and Chukchi Seas and the *Recordniy* in the waters off Southern Australia (Blokhin, 1981).

NORTH PACIFIC

(a) Balaenopterids

The sightings data from 1976–79 confirm the trends noted by Berzin (1978). The balaenopterids including the blue whale (*B. musculus*), which were considered endangered species, are apparently increasing and in recent years they have been seen throughout the operational area. For example blue whales (ranging from 1–16 individuals) were sighted almost every day in the area between 37° to 45°N and 177°E–150°W by the *Dalnyi Vostok* in 1978 and in fact they were seen in greater numbers than any other protected species (Fig. 1) The United Kingdom's

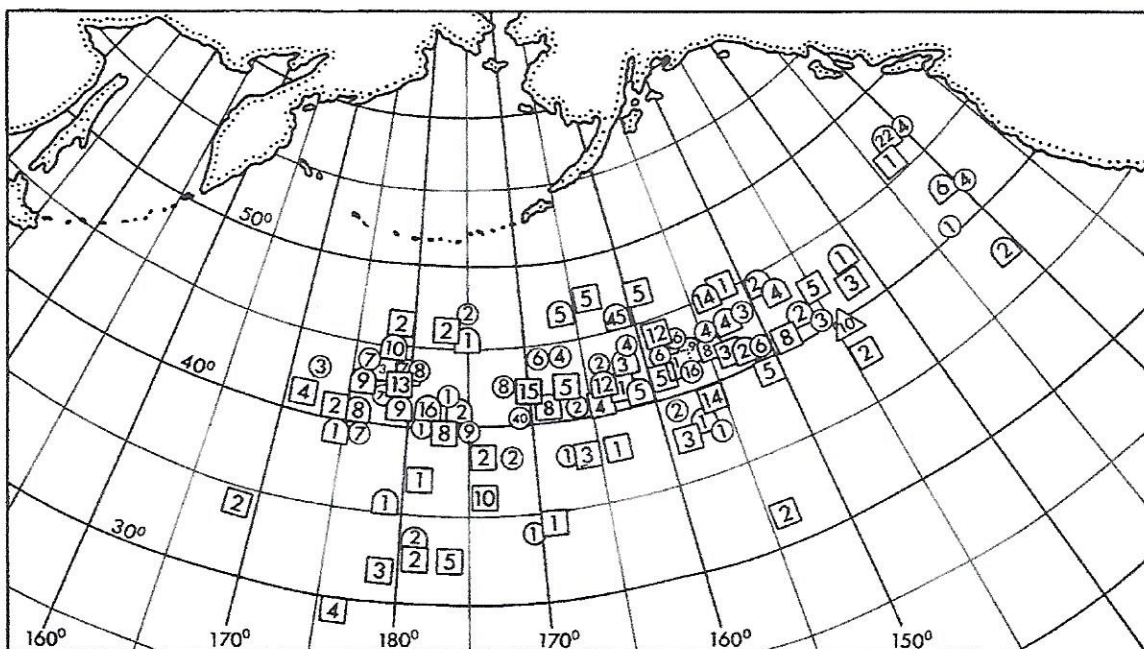

Fig. 1. Sightings of protected whales in the North Pacific, 1976–78. ○: blue whales; □: fin whales; △: humpback whales; ◇: sei whales.

submission to the 2nd CITES Meeting (UK, 1979) states that the initial population of blue whales in the North Pacific was about 5,000 and that the present population numbers 1,400–1,900 (Table 1). Table 1 also shows that the initial fin whale population was about 10 times the blue whale population as is its present population size of 14–19,000. The increase in the numbers of blue, fin and sei whales seen in the North Pacific (Table 2) suggests that these species are recovering under the protection given by the IWC.

Table 1

Abundance of whalebone whales in the North Pacific (000s) based on data presented to the Second Meeting of the Conference of the parties to CITES in 1979 (UK, 1979) and Berzin and Yablokov, 1978 (and see text)

Species	Pre-exploitation	Present abundance
Blue whales	5.0	1.4–1.9
Fin whales	42.0–45.0	14.0–19.0
Sei whales	42.0–50.0	8.6–21.0
Bryde's whales	20.0–30.0	~18.0
Humpback whales	10.0–15.0	1.2–1.6
Gray whales		
(a) Chukotka – Californian	15.0	12.0–15.0
(b) Okhotsk Sea – Korean	1.0–1.5 ¹	0.1–0.2
Bowhead whales		
(a) Bering – Chukchi Seas	18.0	2.26
(b) Okhotsk Sea	6.5 ²	0.1
Atlantic right whales (<i>Eubalaena glacialis</i>)	10.0	0.22–0.5

¹ Estimate for 1910 after some exploitation had occurred.

² Considered too high by Berzin and Doroshenko (1981).

(b) Humpback whales

During the period of observation there has been no increase in the number of humpback whales sighted. Although large areas of the North Pacific have been covered, very few humpback whales have been seen. No humpbacks were seen in 1976 and 1978. In 1977 only one group of ten individuals was observed (on June 5 at 41°40'N, 146°37'W). In 1979 four single whales were seen. Humpbacks have not been seen near the Kuril Islands for many years, an area where they were formerly abundant. Humpback whales are more abundant in Hawaiian coastal waters and in the southern waters of the Gulf of Alaska. These whales may be part of the same population (IWC, 1980, p. 105).

There are insufficient data to estimate the present population size, but it is clear that some previously abundant populations in the North Pacific remain in a critical state.

(c) Bowhead whales

The presence of bowhead whales (*Balaena mysticetus*) in the western Okhotsk Sea was confirmed in 1974 during the research cruise of SRTM *Tamango* (Berzin and Kuzmin, 1975; Berzin, 1978). This area was again covered in August 1979, this time using a helicopter. The bowhead whales were mainly observed in the same areas they had been seen in in 1967 and 1974 (Berzin and Doroshenko, 1981). The largest concentrations were seen in the western part of Ulbanskiy Zaliv (up to 20 whales); in Zaliv Akademii (13 whales); and in the northwestern part of Tugurskiy Zaliv (7 whales). A total of 55 (including 5 cows with calves) bowhead whales was seen during this helicopter survey of the western Okhotsk Sea. This slightly exceeds the number (35 whales) seen in 1974 (Berzin and Doroshenko, 1981). If the much greater speed of the helicopter is taken into account then the number of whales appears even greater than the number seen on the 1974 cruise in larger area. These data suggest that this population of bowhead whales is gradually increasing.

There have been many studies on the population size of the Bering – Chukchi Sea stock of bowhead whales (e.g. McVay, 1973; Berzin, 1974; Marquette, 1976; Tillman, 1977). These studies have primarily been based on observations which have recently been conducted each year off the Alaskan coast (Braham and Krogman, 1977; Braham *et al.*, 1979; Braham *et al.*, 1980). Only occasional sightings have been made in the Soviet zone of the Chukchi Sea near the continental coast (Berzin, 1974; Kuzmin and Berzin, 1975; Fedoseyev and Goltsev, 1975; Berzin and Votrogov, 1978). Before 1979, there was no reliable information about the abundance and distribution of bowhead whales in other areas of the Chukchi Sea. Moreover it was not clear whether the whales which migrated along the Chukotka coast in spring remained in these and more northerly waters in the summer or whether they migrated past Mys Dezhneva and into Alaskan coastal waters as was supposed by observers and whalers from Chukotka (Berzin and Votrogov, 1978).

It was for these reasons that the 1979 joint USSR–USA research cruise was so important. The Soviet whaler *Avangard* undertook a four week cruise in October 1979 with the aim of studying the distribution of whales in the Bering and Chukchi Seas. A significant part of the western Chukchi Sea was covered between 5 and 22 October. The first bowheads were observed in pancake ice near Herald Island on 12 October (a group of two whales and two single whales). The number of bowheads increased as the vessel moved south. On 14 October ten bowheads (mainly single whales) were observed at 70°31'N and 176°16'E. On 16 October large numbers of bowheads (70 whales) were observed near Mys Vankarem. The density of whales in this area was very high—1.0 whales per square mile

Table 2

Number of blue, fin and sei whales in the North Pacific, 1976–79, seen by Soviet fleets (data from USSR Progress Reports) and sightings per unit effort (SPUE)

Year	Effort	Blue		Fin		Sei	
		No. seen	SPUE	No. seen	SPUE	No. seen	SPUE
1976	3.202	2	0.001	12	0.004	7	0.002
1977	3.647	28	0.008	121	0.033	54	0.015
1978	2.646	108	0.041	106	0.040	109	0.041
1979	2.417	90	0.037	173	0.072	140	0.058

(Doroshenko, 1979) and includes sightings of cows with calves. Dense concentrations were noted as far as Kolyuchinskaya Inlet but no whales were seen from there to the Bering Strait. In all, 137 bowhead whales were seen. In view of the heavy seas and poor visibility encountered during the cruise which caused considerable variability in sighting efficiency, and the fact that a systematic survey was not attempted, the approximate estimation of about 1,500 whales in the area covered in the south western Chukchi Sea must be viewed with caution. The currently accepted best estimate for the Bering Strait bowhead stock by the IWC is that of Braham *et al.* (1979): 1,783–2,865 with a mean of 2,264 (IWC, 1980). Bockstoe and Botkin (1980) roughly estimated the current population size of bowhead whales in the Bering and Chukchi Seas to be about 3,000.

(d) Gray whales

There remains much concern over the state of the Okhotsk Sea-Korean stock of gray whales (Brownell and Chun, 1977; IWC, 1981). No gray whales were seen during the helicopter survey over coastal waters of the western Okhotsk Sea in the Shantar – Sakhalin area in August, 1979. The observation of a gray whale on 1 October 1979

(the last gray whale seen in this area had been in August 1974—Berzin and Kuzmin, 1975) by the TINRO research vessel *Ucheny* is thus particularly interesting. It was seen in the coastal waters (250–300 m from the shore) of the southeastern part of Kamchatka, about 2 miles north of Mys Sopochnyi (M. K. Mamivov, pers. comm.). This does not conflict with the proposal that the Japanese part of the Okhotsk Sea – Korean population (or an independent population?) which once bred in the inland Sea of Japan, migrates along the eastern coast of Japan from the Kuril Islands (Omura, 1974). These whales have been previously seen off the south-eastern coast of Honshu Island (Nishiwaki and Kasuya, 1970), off Shikotan (A. N. Belkin, pers. comm.) and off the Shiashkotan Islands (Mizue, 1951).

SOUTHERN HEMISPHERE (Figs 2–4)

Observations of whalebone whales in the Southern Hemisphere by Soviet vessels vary considerably from year to year (Berzin, 1978) due to changes in effort and area of sightings. A brief account of sightings from Soviet vessels in recent years is given in this section.

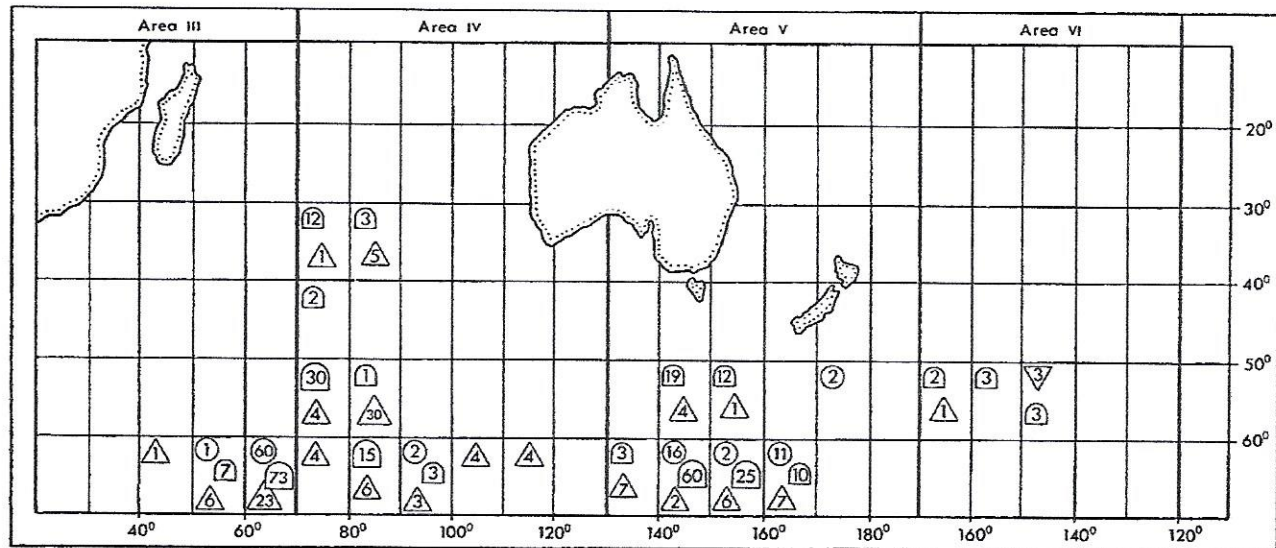

Fig. 2. Sightings of protected whales in 1976/77. ○: blue whales; ▽: right whales; □: fin whales; △: humpback whales.

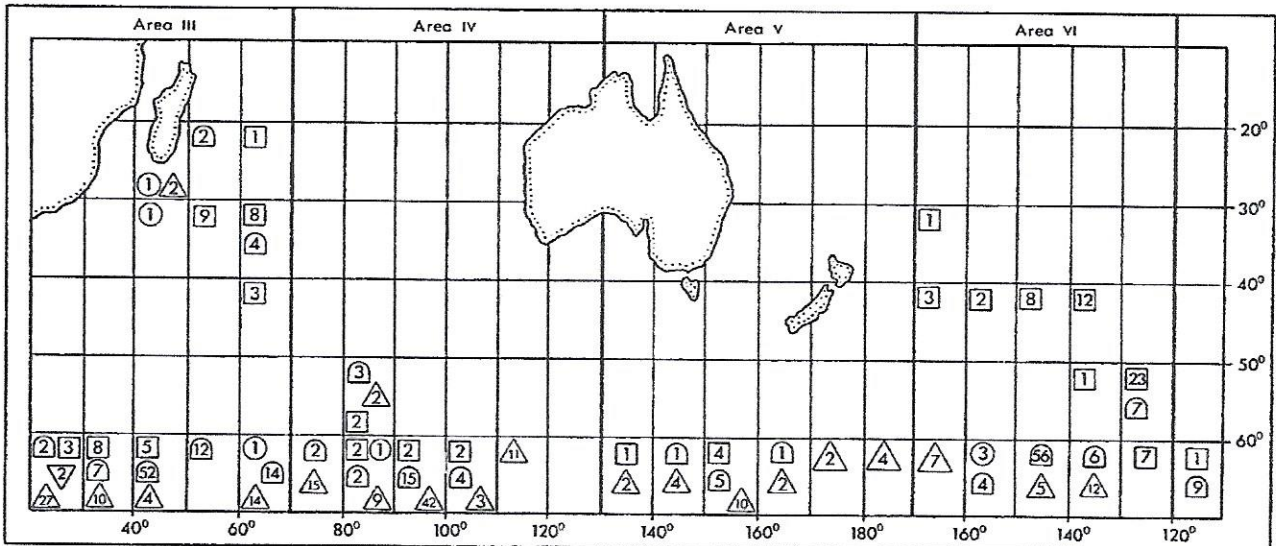

Fig. 3. Sightings of protected whales in 1977/78. ○: blue whales; ▽: right whales; □: fin whales; △: humpback whales; □: sei whales.

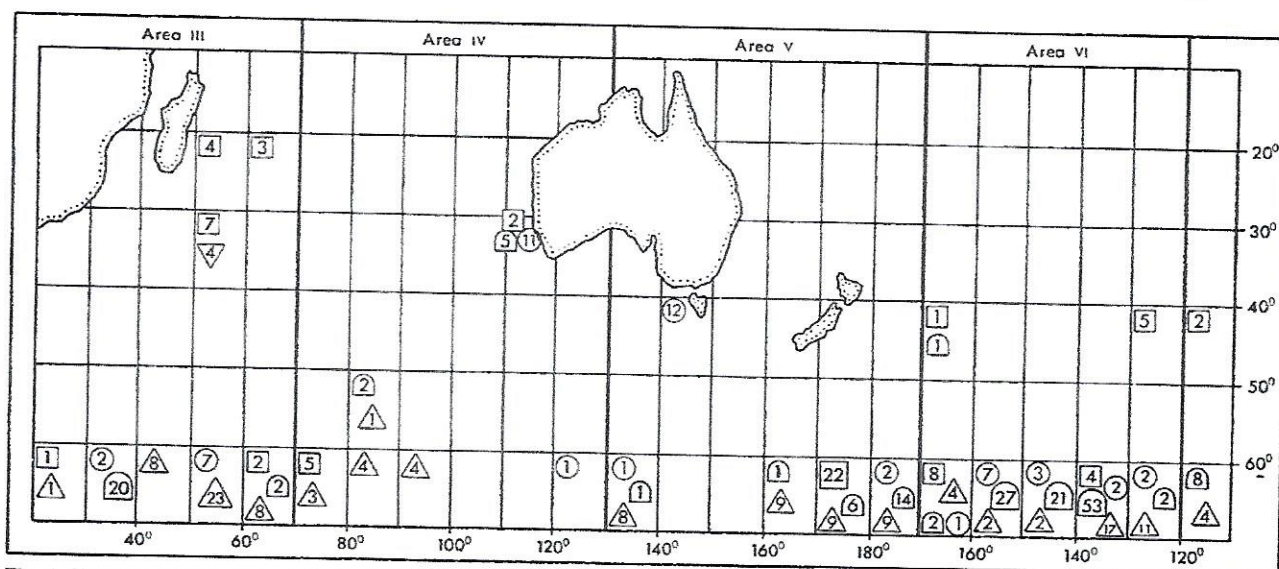

Fig. 4. Sightings of protected whales in 1978/79. ○: blue whales; ▽: right whales; □: fin whales; △: humpback whales; □: sei whales.

(a) Blue and fin whales

Blue whales have been sighted reasonably consistently by Soviet vessels in recent years. In 1978/79, blue whales were seen in each 10° square in Area VI. Zone B (Fig. 4). During the IWC/IDCR research cruise of the whaler *Recordniy* in March and April 1979, relatively large numbers of blue whales were seen. On 6/7 March eleven blue whales (which Berzin considers were possibly pigmy blue whales, *B. m. breviceauda*) were observed on the way from Tasmania to southern Australia on 24/25 March. twelve blue whales (including large individuals of up to 27 m) were seen off the southwestern coast of Western Australia (Fig. 4). Five fin whales and two right whales were observed in the same area (Blokhin, 1981). Large groups of fin whales (up to 30–50 whales) have been seen in recent years (Figs 2–4).

(b) Humpback whales

There is an increasing trend in the number of humpback whales seen off New Zealand: they were observed in Zone B in each 10° square from 130°E–160°W in 1977/78 and from 160°E to 110°W in 1978/79 (Figs 3 and 4). In fact in Series B they have been seen in almost every 10° square from Areas III to VI.

(c) Sei whales

The low abundance of sei whales in the Indian Ocean remains of serious concern particularly in the central area where they used to be common but where now only single animals are seen. In 1978/79 during the two weeks when sperm whaling was carried out by *Sovietskaya Rossiya* in the area between 20°–40°S, only 14 sei whales were seen.

CONCLUSION

The designation of Protection status to many populations by the IWC and the cessation of pelagic whaling has created the most favourable conditions for the recovery of stocks once considered endangered.

The examination of recent Soviet sightings data in the North Pacific and Antarctic suggests that many of the depleted whalebone whale populations are gradually recovering.

We have confidence that present management policies will not only preserve and allow the recovery of all the existing whale stocks but will also ensure their rational utilisation for the benefit of all mankind.

In summary, these data provide the first information regarding blood physiology of the spotted skunk. The values obtained seem to be in general agreement with those obtained for other mammals.

The authors would like to thank Mr. Tom Mabry for help in capturing the skunks, Miss Marie Tullos for aid during bleeding, and the Drs. Pathology Service, Jonesboro, Arkansas, for their generous use of the SMA 12/60 Autoanalyser. This study was financed, in part, by a University of Arkansas at Little Rock Faculty Research Grant.

PROBABLE EXTINCTION OF THE KOREAN STOCK OF THE GRAY WHALE (*ESCHRICHTIUS ROBUSTUS*)

Disappearance of the Korean stock of gray whale (*Eschrichtius robustus*) has been hypothesized for several years. My observations support this hypothesis. This stock ranged from the northern part of the Sea of Okhotsk to the southern tip of the Republic of Korea. The last individual gray whale of this stock apparently was taken from the eastern coast of Korea in 1933 (Mizue, 1951). Since that time, many conservationists and marine mammalogists had hoped for a recovery of gray whale in this area. The extermination of this stock, however, can be confirmed only by repeated negative findings.

The Korean stock of gray whale, the western counterpart of the California gray whale, once migrated between its summer feeding grounds in the northern part of the Sea of Okhotsk and its winter calving grounds among the islands of the southern tip of the Republic of Korea. They followed the shore line closely and could be seen off the coast of central Korea from November through January on their southern migration and from March through May on their northern migration (Andrews, 1914). The Korean stock was relatively unexploited until about 1899. The Oriental Whaling Co., Ltd. of Osaka, Japan, caught 1474 gray whales from 1910 to 1933 off Ulsan, Korea. Rice and Wolman

(1971) suggest that with such a rapid decline the Korean stock of gray whale numbered only 1000 to 1500 whales in 1910.

Since 1933, three gray whales have been captured in the Western Pacific. One of these was captured off the northern Kuril Islands in 1942 (Mizue, 1951). The other two were captured off the coast of southern Japan at 135°55'E, 33°29'N and 136°01.7'E, 33°43'N, in 1959 and 1968, respectively. The 1968 specimen was a young female which resembled members of the California stock in morphological features (Nishiwaki and Kasuya, 1970). The skulls of the other two specimens were not examined or saved. Because these specimens were not captured in the normal migratory path of the Korean stock of gray whale, but were captured to the east of the migratory path, in an area where the Korean stock was not known to have ventured, it is my opinion that these three gray whales should be regarded as strays from the Bering Sea, that is from the California stock.

During 1970-71 and 1971-72, I searched the coast of the Republic of Korea from Pohang to Cheju Island in taxi, boat, and on foot for the missing gray whale, but found none. During January of 1972, I made a short cruise around the southern tip of the Republic of Korea and saw no whale of any species. I visited Ulsan, Korea, which was, and now again is, the whaling center for the Republic of Korea, and saw 16 whaling vessels ranging in size from 20 tons on up to 100 tons. During 1970 a total of 740 whales were taken; 715 of these were minke or small whales. Fishermen and ships captains, whom I or my wife talked to, had never seen a whale that fit the description of the gray whale. No one had ever heard of a whale that enters the waters among the islands at the southern tip of Korea. Whaling has been increasing in the Republic of Korea for many years (Yearbook of Fisheries Statistics, 1971) and because they are not a member of the International Whaling Commission it seems likely that any species is taken.

Based on the foregoing reports and observations the Korean stock of gray whale has apparently disappeared. This extinction should be carefully considered in order to take positive scientific steps to safeguard remaining whale stocks from excessive exploitation and possible extinction.

Acknowledgments.—I am greatly indebted to Raymond M. Gilmore, San Diego Natural History Museum, for guidance before my trip to Korea and for assistance in preparation of this paper. I wish to thank Erling O. Oswald, Project Manager of the Coastal Fishing Training Center, Pusan, Korea, for providing hospitality and information. I also wish to thank Masaharu Nishiwaki, Ocean Research Institute, Tokyo, Japan, for providing valuable manuscripts.

ABSTRACT

**POPULATION ASSESSMENT OF WESTERN NORTH PACIFIC
GRAY WHALES (*ESCHRICHTIUS ROBUSTUS*)**

AMANDA L. BRADFORD

Chair of the Supervisory Committee:
ASSOCIATE PROFESSOR GLENN R. VANBLARICOM
School of Aquatic and Fishery Sciences

Two geographically and genetically distinct populations of gray whales (*Eschrichtius robustus*) occur in the North Pacific, referred to as the eastern and western populations. Subjected to intensive modern commercial whaling during portions of the 19th and 20th centuries, the western population was proposed to be extinct during the early 1970's. This population presently remains in small numbers and is considered one of the world's most endangered populations of large whales. The need for increased conservation efforts indicates the appropriateness of a quantitative western gray whale population assessment. Since 1997, ongoing studies of western gray whales have resulted in a photographic dataset that can be used for mark-recapture survival estimation. A robust design model was fitted to 116 individual whale encounter histories spanning 22 monthly capture occasions from 1997 to 2002. Constant non-calf and calf (first-year post-weaning) survival and random temporary emigration were assumed. Models incorporating individual heterogeneity in residency patterns and higher temporary emigration probabilities for younger whales provided better fits to the data. Non-calf and calf survival were estimated as 0.952 (SE=0.0151, 95% CI=0.912-0.975) and 0.709 (SE=0.1178, 95% CI=0.443-0.882), respectively. These survival estimates and other life history parameters were utilized in conjunction with the Lotka equation to calculate the 1997-2002 population growth rate of western gray whales. A Monte Carlo simulation method was employed ($n=10,000$ trials) to account for uncertainty in the life history parameters. A range of possible fecundity values was examined to estimate a *conservative*, *intermediate*, and *liberal* rate of population growth. These growth rates were estimated as 0.026 (SD=0.0190, 5th-95th Percentiles=-0.008-0.054), 0.031 (SD=0.0194, 5th-95th Percentiles=-0.003-0.061), and 0.036 (SD=0.0198, 5th-95th Percentiles=0.001-0.066), respectively. Each calculated growth rate and historical catch data were fitted to the generalized logistic equation in a 20th century back calculation of the western gray whale population. A Bayesian statistical method and the Sample-Importance-Resample algorithm ($n_1=2,000,000$ initial samples; $n_2=5,000$ resamples) were used to estimate model parameters and indices of population status. Back calculation results suggest that the western gray whale population is currently growing at its maximum net recruitment rate, the carrying capacity of the population is undefined, the population is currently *at most* between 8-9% of its original size, and the population has been highly depleted for over half of the 20th century. Current threats and low-density population effects could inhibit the recovery of western gray whales, emphasizing the necessity of concerted international protection and conservation planning for this critically endangered population.

3.3. Summary of model parameters (r_{MAX} , K , and N_{1900}) and status indices (\hat{N}_{2002} / K and $\hat{N}_{2002} / N_{1900}$) resulting from Bayesian back calculations of western gray whales using the SIR algorithm ($n_1=2,000,000$; $n_2=5,000$), incorporating the <i>conservative</i> , <i>intermediate</i> , and <i>liberal</i> estimates of 1997-2002 population growth rate ($r_{1997-2002}^{LH\ data}$) into the likelihood function.	79

ACKNOWLEDGEMENTS

This work was made possible and accomplished only with the support of an amazing and dedicated group of individuals, who have everlastingly endeared themselves to me. Words will only partially express the extent of my appreciation. Firstly, I would like to recognize my committee members. Glenn VanBlaricom, my committee chair, has been an advisor I have perpetually bragged about to my graduate student friends. He has attentively guided and encouraged my scientific and academic pursuits, while taking the time to intuitively reach out to me during critical moments of both professional and personal struggles. The work of Doug DeMaster on the population dynamics of marine mammals influenced me long before I was a graduate student, and his accomplishments and fair and cheerful professional demeanor inspire me still. During my early tenure as a Master's candidate, a course he taught and his brainstorming ideas served as a foundation for this project. The substance of this effort simply could not have been achieved without the assistance of Paul Wade. He has the incredible gift of quickly, appropriately, and intelligently assessing the whole of a situation, and I greatly relied upon this ability. I'm particularly grateful for his patient support through my venture into 'Bayesian statistics *with tears.*'

The western gray whale project advisors also deserve special recognition and thanks. Their willingness not only to incorporate me into such a difficult study, but to also have faith in my abilities will not be forgotten. Dave Weller has put his heart and soul into the western gray whale project, and has been a long-term friend and mentor. His comprehensive commitment to science and a unique perspective on life have taught me more than he knows. Bob Brownell has been promoting the research and conservation of western gray whales – even when others thought the population was extinct! – for over thirty years. He is truly one-of-a-kind, and I am privileged to have worked in his company. The perseverance and resourcefulness of Alexander 'Sasha' Burdin have been critical to the success of the western gray whale study. He is also one of those rare individuals with true 'joie de vivre' and kept me smiling throughout long days in the field. Bernd Würsig made significant contributions to the western gray whale effort and to my development both as a scientist and a person.

Much appreciation goes to the many participants, both Russian and American, of the western gray whale project. Their involvement has been essential to the study, while their company has made for a more colorful personal experience. Of particular mention are my dear friends Yulia Ivashchenko and Grisha Tsidulko, but thanks go to many others: Stacie Arms, Sergey Blokhin, Galya Fesenko, Bridget Ferriss, Glenn Gailey, Dima and Lena Golovenkov, Toshio Kasuya, Aimee Lang, Yulia Lebedeva, Sergey and Zhana Osokin, Susan 'woman of steel' Reeve-Rickards, Yuri Shvetsov, Olga Sychenko, Karina Tarasyan, Alexey Trukhin, Alexey and Valeriy Vladimirov, Katya Vorobieva, Bridget Watts, Kirill Zcharikov, and Yuri Zhalinsky.

My life has been inexplicably enriched from being able to spend so much time in Russia, working with and amongst some of the most warm and genuine individuals I have yet encountered. They graciously welcomed me into their hearts and homes and humbled me with their kindness. Most of them have been named above, although a few names are written only in my memory. However, to each of them, I offer a heartfelt '???????' for all they have taught me.

Many individuals within the School of Aquatic and Fishery Sciences offered assistance and camaraderie during my time there. Verna Blackhurst, Dede Garcia, Nichole Byrne Lau, and Lin Murdock provided pleasant and helpful support. Andre Punt and Gavin Fay kindly responded to a 'likelihood crisis' and offered invaluable help with the back calculation presented in Chapter 3. Working alongside the members of the VanBlaricom Lab has been delightful. I am especially grateful for the friendship and commiseration of Laura Hoberecht, Josh London, and 'Captain' Alex Zerbini over the years. Much needed gabbing has occurred in office 260D with Melinda Chambers and Shannon McCluskey. Michelle Lander, Tony 'Macaroni' Orr, Heather Smith, and Susan Wang have brought a new vitality to our group. Carlos Alvarez-Flores, Kristin Laidre, and Robert Suydam have also been fine colleagues.

My family and friends have granted me with unfailing love and encouragement throughout this process. My extended set of 'parents' – including my mom Ruth, dad Mike, Bobby, Kay, Shirley, and Larry – and my brother Jason and sister Michelle have stood by me, even though following my dreams has taken me far from home. My friends Kecia Kerr and Kate Willis are my kindred spirits, and have brought vast fulfillment to my life. Jamal Moss, Stephanie Paff, Sarah Pralle, Sarah Stienessen, and Pam Woods have given me much needed on-the-ground friendship here in Seattle, while Gretchen Brown, Scott 'Skippy' Edmondson, Brian Knezek, Charles 'Chubby' Littnan, Mindy McDonough, John Schivone, Mandy Toperoff, and especially Aili Grasso, Stephanie Cobb, and Gina Johnson – it's been over 15 years, girls! – have all supported me from afar. My gratitude is limitless.

Funding and support for this work and the western gray whale project were provided by the Washington Cooperative Fish and Wildlife Research Unit, the School of Aquatic and Fishery Sciences at the University of Washington, Texas A&M University, the National Marine Fisheries Service, Sakhalin Energy Investment Company, Exxon Neftegas Limited, the International Fund for Animal Welfare, the National Fish and Wildlife Foundation, the Marine Mammal Commission, and the U.S. Environmental Protection Agency. The western gray whale project (1995-2002) was conducted as part of the Marine Mammal Project under Area V: Protection of Nature and the Organization of Reserves within the U.S.-Russia Agreement on Cooperation in the Field of Environmental Protection.

DEDICATION

At the risk of appearing overly sentimental, I would like to dedicate this work to the western population of gray whales. First and foremost, as a scientist, my hope is that this effort can be used objectively in the formulation of increased protection and conservation measures that are needed to promote the recovery of this critically endangered population. However, a particularly interesting aspect of studying such an extremely small population of recognizable individuals is that I have spent a significant amount of time over the years in the company of known whales. Memories of countless encounters with Pirate, Otter, Svetlana, Ponchik, Tooman, Speedy, Vova, and many other whales are permanently etched in my heart and mind. Out of respect and gratitude for such a privilege, concurrent with my scientific aspirations, I will be anxiously rooting for this population – as a *person*, who sincerely wishes western gray whales the opportunity to thrive in the years to come.

CHAPTER 1

THE WESTERN POPULATION OF GRAY WHALES

INTRODUCTION

The present status of the two extant gray whale populations in the North Pacific Ocean is a study in contrasts. The eastern gray whale population, reduced by commercial harvesting to a few thousand individuals by the end of the 19th century, has rebounded in size to levels most likely approaching carrying capacity. The western population, also depleted by commercial whaling during portions of the 19th and 20th centuries, was suggested to be extinct during the early 1970's. This population currently exists in small numbers and is considered one of the world's most endangered populations of large whales. The present thesis project explores the demography and population dynamics of western gray whales, offering a quantitative description of this population for incorporation into future conservation and management plans.

BACKGROUND

Two populations of gray whales (*Eschrichtius robustus*) occur in the North Pacific, the eastern (California/Chukchi) population and the western (Korean/Okhotsk) population (Rice and Wolman, 1971). The two populations can be differentiated genetically at the population level, and should be considered geographically and genetically distinct population units (LeDuc *et al.*, 2002). Historically, gray whales also occurred in the eastern and western North Atlantic, possibly as two populations, but were extinct by the early 18th century (see Lindquist, 2000 for a review). Although the direct

cause of their extinction is unknown, it has been linked to human activity (Mitchell, 1973).

Eastern gray whales have long been known to migrate along the western coast of North America from winter breeding grounds off Baja California to summer feeding grounds in the Bering and Chukchi Seas (e.g., Pike, 1962; Rice and Wolman, 1971). Western gray whales, also annual migrators, return to summer feeding grounds in the Okhotsk Sea (Berzin, 1990). Winter breeding grounds for this population are unknown, but are suspected to be along the coast of southern China (Wang, 1984; Omura, 1988; Kato and Kasuya, 2002).

Throughout their range, gray whales typically do not occur outside the shallow waters of the continental shelf. Their coastal distribution made them accessible to both aboriginal and commercial whalers (see Table 1.1 for definitions of whaling terminology used frequently in this text: Aboriginal Whaling, Commercial Whaling, Japanese Hand Harpooning, Japanese Net Whaling, Modern-type Whaling, and Yankee-type Whaling). Both populations were subject to intensive commercial whaling during portions of the 19th and 20th centuries. Yankee-type commercial whaling of eastern gray whales reportedly began in 1846 (Scammon, 1874). Prior to that time, eastern gray whales were taken solely by aborigines, although the extent and duration of the aboriginal whaling is unknown (Mitchell, 1979). By the late 19th century, the eastern population was reduced to levels of commercial ‘extinction’ (Henderson, 1972, 1984), and was suggested to number anywhere from 2,000 to 10,000 individuals (see Scammon, 1874; Henderson, 1972, 1984; Ohsumi, 1976; Reilly, 1981 for various estimates). After receiving

international protection (see below), recovery of the population was observed (Reilly, 1992). Abundance estimates of approximately 26,600 whales in 1997/98 (Hobbs and Rugh, 1999) and 18,800 and 17,400 in 2000/2001 and 2001/02, respectively, (Rugh *et al.*, 2002) suggest that this population is above its pre-commercial exploitation population level (i.e., 1846 population size) and is possibly equilibrating at its current carrying capacity (Reilly, 1992; LeBoeuf *et al.*, 2000; Moore *et al.*, 2001; Rugh *et al.*, 2002).

Before the onset of modern-type commercial whaling in 1891 (Kato and Kasuya, 2002), western gray whales were subject to a long but poorly documented history of takes. Groups of maritime Koryak natives along the northeastern Okhotsk Sea hunted whales, presumably including western gray whales (Krupnik, 1984). In Japan, western gray whales were probably taken by hand harpooners dating back to the late 16th century, and were definitely taken by net whalers beginning in the late 17th century (Omura, 1984). Omura (1984) estimates that Japanese net whalers took 50-60 gray whales annually during the net whaling period (1675-1890). However, Japanese net whalers caught at least 78 western gray whales between 1891 and 1899, concurrent with the spread of modern whaling techniques (Tada, 1978; Omura, 1984; Park, 1987; Kato and Kasuya, 2002). From the middle to the late 19th century, Yankee-type pelagic whalers operating in the Okhotsk Sea also caught western gray whales, taking possibly around 500 individuals during this period (Henderson, 1984).

A Russian whaling company initiated modern-type commercial whaling for western gray whales off the coast of the Korean peninsula in 1891 (Kato and Kasuya, 2002). Russian western gray whaling there lasted until 1904 (Kato and Kasuya, 2002),

although Yablokov and Bogoslovskaya (1984) noted that western gray whales were sporadically hunted by Russians near Peter the Great Bay, Russia, during World War II (WWII). Modern whaling began in Japan in 1898 (Omura, 1984), although few western gray whales were caught there (less than 3% of total commercial catches; Appendix A), as they were no longer abundant (Omura, 1984). Instead, Japanese modern whalers began operating off the northeastern and southeastern Korean coasts in 1900, where they worked until the end of WWII in 1945 (Kasahara, 1950; Kato and Kasuya, 2002). The majority of modern commercial western gray whale catches occurred during this operation (Figure 1.1; Appendix A).

Modern western gray whaling off the Korean peninsula was resumed following WWII by the Republic of Korea (South Korea), although the dwindling catch numbers (Figure 1.1) reflect the depleted status of the population (Brownell and Chun, 1977; Kato and Kasuya, 2002). Although western gray whales had previously been taken by the Japanese in the vicinity of the Democratic People's Republic of Korea (North Korea), nothing is known about whaling in these waters subsequent to WWII (Kato and Kasuya, 2002). Little is known about Chinese modern commercial whaling, but records exist of at least 14 takes in the waters adjacent to China (Appendix A; Kasahara, 1950; Mizue, 1951; Wang, 1978, 1984; Omura, 1988; Kato and Kasuya, 2002). Wang (1984) indicated that half of these whales were caught by Japanese whalers. In total, a minimum of 1,868 western gray whales were taken in the 20th century, the period when they were taken predominately by modern commercial whalers (Figure 1.1; Appendix A).

Gray whales were first accorded international protection in 1937 with the International Agreement for the Regulation of Whaling (Committee for Whaling Statistics, 1942; Reeves 1984). At the time, none of the range states of western gray whales (Russia, Japan, North Korea, South Korea, and China) were signatories to this agreement (Committee for Whaling Statistics, 1942; Reeves, 1984). When the International Convention for the Regulation of Whaling was established in 1946, gray whales legally became a protected species exempt from commercial whaling by the International Whaling Commission (IWC) (International Whaling Commission, 1950; Scarff, 1977; Reeves, 1984). Russia was a signatory to this agreement (International Whaling Commission, 1950), and Japan formally adhered by 1951 (International Whaling Commission, 1951). South Korea and China did not join the IWC until 1978 and 1980, respectively (International Whaling Commission, 1980, 1982). North Korea is presently not an IWC member.

Each gray whale population remained an IWC *Protected Stock* until 1978, when eastern gray whales were reclassified as a *Sustained Management Stock* (International Whaling Commission, 1979; Reeves, 1984). Both populations are listed in *Appendix I* (i.e., most endangered) of the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES). Russia, Japan, South Korea, and China are all CITES member parties. Despite international protection of western gray whales throughout most of their range, at least one direct take occurred between 1980 and the present (Brownell and Kasuya, 1999).

The western gray whale population has failed to exhibit the successful recovery demonstrated by its eastern counterpart (Clapham *et al.*, 1999; Weller *et al.*, 2002c). Western gray whales were proposed to be extinct during the early 1970's (Bowen, 1974), but they do survive as a remnant population (Brownell and Chun, 1977; Blokhin *et al.*, 1985; Weller *et al.*, 1999; 2002c). Blokhin (1996) and Vladimirov (1994) reported population estimates of 100 and 250 whales, respectively. However, these estimates were not quantitatively derived. Recent studies indicate that the population may currently consist of approximately 100 individuals (Figure 1.2; Wade *et al.*, 2003). The current depleted status of western gray whales is possibly a result of intense harvesting prior to the onset of modern-type whaling (Omura, 1984), a prolonged period of modern commercial whaling (Kato and Kasuya, 2002), a pre-exploitation population level that may never have been very large in size (Yablokov and Bogoslovskaya, 1984), or more likely, a combination of these factors.

In 2000, the World Conservation Union (IUCN) designated western gray whales as *Critically Endangered*, that is, "...facing an extremely high risk of extinction in the wild in the immediate future, as defined by criteria (A to E)" (Hilton-Taylor, 2000). Western gray whales are listed according to *Criterion D*, which states that the "population [is] estimated to number less than 50 mature individuals." Mature is defined as "...capable of reproduction." For western gray whales, the number of mature individuals is approximately 47 (see Weller *et al.*, 2002c for details of the estimation). The small population size and low number of mature individuals emphasize the western

gray whale's status of one of the world's most endangered populations of large whales (Clapham *et al.*, 1999; VanBlaricom *et al.*, 2001; Weller *et al.*, 2002c).

Whereas eastern gray whales are one of the better-studied baleen whale populations, western gray whales have only recently come under concerted study (Brownell *et al.*, 1997; Weller *et al.*, 1999, 2000, 2001, 2003a, 2003b; Würsig *et al.* 1999, 2000). Initiated in 1997, an ongoing study of western gray whales takes place on their only presently known summer feeding ground, located off the northeastern coast of Sakhalin Island, Russia, in the near-shore waters proximate to Piltun Lagoon (Figure 1.3). This research has documented the regular use of the feeding ground by western gray whales of both sexes and multiple age classes, including reproductive females and their weaning calves. The Piltun study is being conducted by Texas A&M University (TAMU) and the National Marine Fisheries Service (NMFS), in collaboration with the Kamchatka Institute of Ecology and Nature Management (KIENM)¹.

PROJECT OBJECTIVES

This thesis project uses available population data and life history information to examine the demography and population dynamics of western gray whales. Specific objectives of the population assessment are: 1) mark-recapture estimation of non-calf and calf survival and associated mark-recapture parameters (Chapter 2); 2) Monte Carlo simulation estimation of current population growth rate (Chapter 3); and 3) Bayesian back calculation of the population to determine the population level prior to concerted

¹ Over the six years of the TAMU, NMFS, and KIENM study, I have participated in data collection and analysis for five and six years, respectively.

modern commercial whaling (Chapter 3). Given a previous lack of quantitatively based knowledge regarding western gray whale demography and population dynamics, results from the assessment will be a valuable contribution to conservation efforts of this critically endangered population. This project is one component of the aforementioned larger study being carried out by TAMU, NMFS, and KIENM.

Table 1.1. Definitions of terminology used frequently in this text to describe gray whaling. Definitions were adapted from Mitchell and Reeves (1980) unless noted otherwise.

Term(s)	Definition
Aboriginal Whaling	Whaling conducted by endemic local people, for a period generally exceeding their documented history, who consume the products locally.
Commercial Whaling	Whaling conducted by anyone for the primary purpose of selling the products in a cash economy.
Japanese Hand Harpooning	Whaling conducted by Japanese villagers who formed small teams of vessels and took whales using hand harpoons*.
Japanese Net Whaling	Whaling conducted by Japanese villagers who formed large, coordinated fleets and used nets to secure whales for subsequent harpooning*.
Modern-type Whaling (Norwegian-type Whaling, Modern Whaling)	Whaling based on mechanical means of transport (i.e., gas, diesel, or steam-powered vessels) and the use of firearms and explosives to take whales.
Yankee-type Whaling (19 th Century Whaling)	Whaling conducted from oar- and/or wind-driven vessels that involved the use of harpoons and lances to take whales.

*Definition adapted from Omura (1984).

Figure 1.1. Minimum numbers of western gray whales caught during the 20th century, predominantly by modern-type commercial whalers off the Korean peninsula. Catch history compiled from Andrews (1914), Kasahara (1950), Mizue (1951), Nishiwaki and Kasuya (1970), Brownell and Chun (1977), Tada (1978), Wang (1978, 1984), Omura (1984, 1988), Park (1987), Brownell and Kasuya (1999), and Kato and Kasuya (2002). See Appendix A for details of catches.

Figure 1.2. Yearly estimates of the number of western gray whales associated with the Piltun study area from 1997 to 2002 determined using closed-capture mark-recapture techniques (Wade *et al.*, 2003). The trend in the estimates is considered to overestimate the present population growth rate, although the 2002 estimate is thought to closely approximate current population size. Circle = point estimate. Bars = standard error.

CHAPTER 2

SURVIVAL ESTIMATES OF WESTERN GRAY WHALES INCORPORATING INDIVIDUAL HETEROGENEITY AND TEMPORARY EMIGRATION²

INTRODUCTION

The use of marked individuals and mark-recapture theory in assessing biological populations is well documented (see Pollock, 1991 for review). In many whale populations, individuals can be identified from photographs of their natural markings (e.g., scars and pigmentation patterns) in a method known as photo-identification (see Hammond *et al.*, 1990 for overview). In the application of mark-recapture theory to photo-identification methodology, the first photographic sighting of an individual constitutes the *mark* and subsequent sightings the *recaptures*. The complete individual sighting record serves as the *encounter history* (White and Burnham, 1999). Encounter histories are fitted to an appropriate mark-recapture model (see Seber, 1982 for examples) to estimate the population parameter of interest. Mark-recapture photo-identification studies can be used to estimate the abundance (e.g., Hammond, 1986), survival (e.g., Buckland, 1990; Caswell *et al.*, 1999), and fecundity (e.g., Barlow and Clapham, 1997) of whale populations. However, for most mark-recapture whale studies, care must be taken to reduce bias in the parameter estimates that can arise from individual heterogeneity in capture probabilities (Buckland, 1990). Individual

² The text of this chapter has been submitted to the Scientific Committee of the IWC with the following citation: A. L. Bradford, P. R. Wade, A. M. Burdin, Y. V. Ivashchenko, G. A. Tsidulko, G. R. VanBlaricom, R. L. Brownell, Jr., and D. W. Weller. 2003. Survival estimates of western gray whales (*Eschrichtius robustus*) incorporating individual heterogeneity and temporary emigration. Paper SC/55/BRG14 submitted to the International Whaling Commission (unpublished).

heterogeneity in capture probability can occur if some whales are more easily identified (e.g., possess distinctive markings or are more approachable) or spend more time in the study area than other whales (Buckland, 1990).

Gray whales (including calves) are individually identifiable by natural pigmentation patterns and in some cases scarring from dead barnacles. Numerous multi-year studies have shown photo-identification to be a reliable and effective research technique for this species (Hatler and Darling, 1974; Darling, 1984; Swartz, 1986; Jones 1990; Weller *et al.*, 1999). Photo-identification has been the main research tool of the TAMU, NMFS, and KIENM western gray whale study being conducted off Piltun Lagoon, Sakhalin Island, Russia (Figure 1.3). Photo-identification results have demonstrated that many individuals exhibit a consistent annual return and strong seasonal fidelity to the study area, while other whales are absent for all or part of any given field season. The Piltun study has generated the multi-year (1997-2002) photographic dataset used for the mark-recapture survival estimates presented here.

An unusually low return to the Piltun feeding ground of whales first observed as calves has been continuously noted prior to the 2002 field season (Weller *et al.*, 2000, 2001, 2002c, 2003a). Of the 16 calves identified between 1997 and 2000, only six (37.5%) had been resighted subsequent to their year of weaning (Weller *et al.*, 2003a). Ensuing mark-recapture estimates of calf survival (0.389, SE=0.1255) suggested that survival of post-weaned calves was extremely low (Bradford *et al.*, 2002). With the inclusion of results from 2002, 14 of the 22 (63.6%) calves identified between 1997 and 2001 have currently been resighted post-weaning (Weller *et al.*, 2003b). Five of the eight

returned whales were yearlings (i.e., weaned in 2001), while the remaining three were initially identified in 1997, 1998, and 2000, respectively. Anecdotally, a whale not seen in the study area since it was first observed as a calf during a 1995 pilot study (Brownell *et al.*, 1997) was also resighted in 2002 (Weller *et al.*, 2003b). These findings indicate that the low calf survival reported in Bradford *et al.* (2002) can partially be attributed to the temporary emigration of some whales first identified as calves, prompting the testing of additional temporary emigration models in the present survival analysis.

METHODS

Photo-identification

For a detailed description of western gray whale photo-identification data collection and analysis protocols, see Weller *et al.* (1999). From 1997 to 2002, 237 photo-identification surveys collected during 22 months produced the 116 individual whale encounter histories analyzed here (Appendix B; Weller *et al.*, 1999, 2000, 2001, 2003a, 2003b; Würsig *et al.*, 1999, 2000).

Survival Estimation

Pollock's robust design model (Pollock, 1982; Kendall and Pollock, 1992; Kendall and Nichols, 1995; Kendall *et al.*, 1995, 1997), combining the Cormack-Jolly-Seber open recapture model (Cormack, 1964; Jolly, 1965; Seber, 1965) and Huggins' closed capture estimator (Huggins, 1989, 1991), was fitted to the encounter histories using maximum likelihood parameter estimation. The field seasons in each of the six years of the study (1997-2002) were treated as the open *primary* sampling periods (i.e.,

mortality is assumed to occur between years). Months within a field season (3, 3, 5, 4, 4, and 3 months in each year, respectively) were treated as the closed *secondary* sampling periods (i.e., mortality is assumed to be zero between months in a year). The following parameters were estimated, although non-calf and calf survival are the primary parameters of interest:

f_g	=	survival probability of group g , where g is either non-calf or calf (first-year post-weaning);
$?_{gi}$	=	probability of group g being unavailable for capture in <i>primary</i> period i , given being alive during period i (i.e., temporary emigration), where g is either >2-yr-old, <2-yr-old, >3-yr-old, <3-yr-old, >4-yr-old, or <4-yr-old and $i = 1998, 1999, \dots, 2002$;
p_{ij}	=	probability of being captured in <i>secondary</i> sample j of <i>primary</i> period i , given being alive and in the study area during period i , where $j = \text{June, July, } \dots, \text{October}$, and $i = 1997, 1998, \dots, 2002$.

Assumptions of the parameter estimation are: 1) general mark-recapture assumptions for sampling open and closed populations (Seber, 1982); 2) all western gray whales used or passed through the study area during the study period, but not necessarily in each year; 3) constant non-calf and calf survival during the study period; and 4) random temporary emigration (Kendall and Nichols, 1995; Kendall *et al.*, 1997) that is either constant, group varying (between whales >2-yr-old and <2-yr-old, >3-yr-old and <3-yr-old, or >4-yr-old and <4-yr-old), time varying, or group and time varying. Thus, one model of survival was tested in conjunction with eight models of temporary emigration:

$$f(gc)$$

where gc = group varying between non-calves and calves;

$\lambda(.)$
 $\lambda(g2)$
 $\lambda(g3)$
 $\lambda(g4)$
 $\lambda(t)$
 $\lambda(g2+t)$
 $\lambda(g3+t)$
 $\lambda(g4+t)$

where . = constant (no group or time influence)
 g2 = group varying between whales >2-yr-old and <2-yr-old
 g3 = group varying between whales >3-yr-old and <3-yr-old
 g4 = group varying between whales >4-yr-old and <4-yr-old
 t = time varying by *primary* period
 + = additive model.

The >2-yr-old and <2-yr-old group-varying temporary emigration model was developed to account for some of the low return to the study area and reduced apparent survival of whales first sighted as calves (Bradford *et al.*, 2002; Weller *et al.*, 2000, 2001, 2003a, 2002c), by allowing the temporary emigration probability of yearlings to differ from older whales. Yet, given the return in 2002 of three whales that had been absent from the study area since their respective weaning year of 1997, 1998, and 2000 (Weller *et al.*, 2003b), two more explicit models were constructed. In these models, whales first observed as calves were allowed to temporarily emigrate with a characteristic probability for up to two and three years post-weaning (i.e., <3-yr-old and <4-yr-old temporary emigration, respectively). The aforementioned anecdotal return in 2002 of the whale not seen in the study area since it was initially observed as a calf in 1995 (Brownell *et al.* 1997; Weller *et al.*, 2003b) suggests that temporary emigration from the Piltun feeding ground can function in the life history of juvenile whales for up to seven years post-weaning. However, estimating juvenile temporary emigration for up to only three years

post-weaning permits the temporary emigration probability of younger whales to differ from older whales, but minimizes potential positive bias to the non-juvenile estimate caused by the incorporation into that probability of young whales not first sighted as calves. Furthermore, few whales would contribute to extending the estimate up to four or five years post-weaning (nine and two, respectively), and a longer interval would exceed the length of the study.

Given the constant survival and variable temporary emigration parameters, the effects of various combinations of time, survey effort, and an individual *residency* covariate were examined in nine models of capture probability:

$p(t)$
 $p(T)$
 $p(\text{Eff})$
 $p(\text{Res})$
 $p(t+\text{Res})$
 $p(T+\text{Eff})$
 $p(T+\text{Res})$
 $p(T+\text{Eff}+\text{Res})$
 $p(\text{Eff}+\text{Res})$

where t = time varying by *secondary* period
 T = trend over time
 Eff = *effort* (time covariate)
 Res = *residency* (individual covariate).

Testing for a trend over time in capture probability served to address the hypothesis that capture probability could temporally increase because of improved efficiency in survey ability over the *primary* sampling period. *Effort* is the number of photo-identification surveys conducted each month. *Residency* is defined as the number of days a whale was captured per month divided by the mean number of days all whales

were captured that month averaged over all months that the whale was captured. This value acts as an index of the duration of residency of an individual whale in the study area, given the whale is seen once, and should reduce individual heterogeneity in capture probability (Figure 2.1). In other words, *residency* indicates whether an individual whale tends to remain over long periods in the study area, or to stay for shorter amounts of time before leaving the area. *Residency* is based on the daily sighting records because these data were not used in the parameter estimation. Likewise, the calculation is conditioned on the individual being seen in a given month, so the residency index does not repeat information in the encounter history used to estimate model parameters. In calculating *residency*, scaling to the mean of each month allows the duration of residency detected monthly to be relative to sampling effort. A histogram of residency values used to model capture probability is shown in Figure 2.2.

With the one survival model, the eight temporary emigration models, and the nine models of capture probability, a total of 72 models were fitted to the encounter histories. The analysis was conducted using Program MARK (White and Burnham, 1999). Models were selected using Akaike's Information Criterion (Akaike, 1973) corrected for small sample size (AICc) (Hurvich and Tsai, 1989). Non-calf and calf survival estimates were averaged across the best models in order to account for model uncertainty (Burnham and Anderson, 2002).

RESULTS

Incorporating *residency*, time, and *effort* into models of capture probability provided the best fits to the data (Table 2.1). As expected, capture probability was positively correlated with residency time and also varied by *secondary* sampling period (Figure 2.3). That is, the positive correlation between capture probability and residency time was characteristically represented during each *secondary* sample (Figures 2.3-2.4). The pattern of monthly capture probabilities differed by *primary* sampling period, although capture probability tended to increase and decrease at the beginning and end, respectively, of each yearly field season (Figure 2.4).

The influence of temporary emigration on model selection was secondary to the effect of capture probability (Table 2.1). However, for each representation of capture probability, the constant and group-varying temporary emigration models fit the data better than models allowing temporary emigration to vary by time or group and time (Tables 2.1-2.2). Specifically, allowing temporary emigration to differ between whales >4-yr-old and <4-yr-old was primarily selected in every case of capture probability (Table 2.1). Values of all temporary emigration parameters estimated in combination with the highest weighted capture probability model are shown in Table 2.2. For the constant and group-varying models, >4-yr-old, <4-yr-old, all-whale (constant), >3-yr-old, <3-yr-old, >2-yr-old, and <2-yr-old temporary emigration were estimated as 0.147 (SE=0.0274), 0.407 (SE=0.1054), 0.175 (SE=0.0269), 0.162 (SE=0.0279), 0.293 (SE=0.1018), 0.171 (SE=0.0275), and 0.244 (SE=0.1219), respectively (Figure 2.5). The time-varying temporary emigration estimates exhibited a similar relative relationship as

the constant and group-varying estimates. For each *primary* sampling period, estimates for younger whales were higher than the corresponding estimates for older whales, while the all-whale estimates were only slightly higher than those of older whales (Figure 2.6). The time-varying temporary emigration estimates varied by *primary* sampling period, and were lowest during the 1999 and 2001 field seasons (Figure 2.6).

Non-calf and calf survival estimates were averaged across the 13 best models and a weighted average point estimate, unconditional standard error, and weighted 95% confidence intervals were obtained. Results of model averaging are shown in Tables 2.3-2.4 for non-calves and calves, respectively. Non-calf and calf survival were estimated as 0.952 (SE=0.0151, 95% CI=0.912-0.975) and 0.709 (SE=0.1178, 95% CI=0.443-0.882), respectively (Figure 2.7).

DISCUSSION

Capture Probability

The individual *residency* covariate was included in the 24 best models, indicating that it helped to explain capture probability (Table 2.1). As anticipated, capture probability was higher for whales with longer residency times (Figures 2.3-2.4). In other words, the more often whales used the study area, the more likely they were to be encountered. By allowing capture probability to vary by *residency*, bias resulting from individual heterogeneity was minimized. The seven best models, which received the majority of the AICc weight (see Burnham and Anderson, 2002 for description), allowed capture probability to vary by time and *residency* (Table 2.1). Thus, capture probability

differed between *secondary* sampling periods, but residency pattern was an important factor in determining the capture probability of an individual whale.

During each *primary* sampling period, the monthly capture probabilities tended to increase and then decrease as the field season progressed (Figure 2.4). This pattern could reflect many sources of intra-seasonal variation that similarly affected the monthly capture probabilities of all whales. For instance, weather conditions influenced not only the number of photo-identification surveys conducted each month, but also survey duration and coverage. The typically milder weather conditions during August facilitated more frequent and extensive surveys, which may have contributed to the higher capture probabilities consistently observed during that month. The extremely low June capture probabilities are most likely attributable to the small numbers of completed surveys. However, in this case, the reduced survey effort was probably related more to the late-June arrival of the research team and less to the weather.

Other sources of intra-seasonal variation may have had a more direct effect on the overall distribution and abundance of whales in the study area, resulting in the apparent trend in monthly capture probabilities. For example, prey density and availability in parts of the study area could have declined over each feeding season in response to whale foraging. Alternatively, the preferred prey of whales may have changed during each season, as has been suggested for eastern gray whales off Vancouver Island, British Columbia (Darling *et al.*, 1998). In either scenario, whales would have then had to locate, and possibly spend more time looking for, other concentrations of prey. These alternate foraging locations might have been positioned more towards the periphery or

outside of the study area, which would have generally lowered capture probabilities as the season progressed. This foraging-based hypothesis was offered to explain a seasonal offshore shift in pod distribution detected by shore-based observations of whales in the study area during some years (Ivashchenko, 1999; Würsig *et al.*, 1999, 2000). The late-season decrease in capture probabilities may also have been attributable to the movement of some whales out of the study area in preparation for or initiation of the southbound migration, particularly during the lengthy 1999 field season.

Finally, the Piltun feeding ground overlaps with two of nine major multinational oil and gas projects situated offshore of Sakhalin Island, and associated industrial activities have potentially influenced the behavior and distribution of whales in the study area (Würsig *et al.*, 1999, 2000; Weller *et al.*, 2002d). For instance, whales appeared to shift their distribution away from a region where geophysical seismic surveys were being conducted during August 2001 (Weller *et al.*, 2002d). This shift concentrated whales in an easily accessible portion of the study area, and may have been a factor in the high capture probability noted during that month. The effects of other industrial activities (e.g., well-drilling, production operations, shipping and aircraft traffic) have not yet been evaluated, but could have played a part in shaping patterns of capture probability.

Temporary Emigration

Although model selection was primarily controlled by capture probability (Table 2.1), temporary emigration demonstrated a characteristic influence within each representation of capture probability (Tables 2.1-2.2). Namely, in every case of capture probability, the constant and group-varying models of temporary emigration provided

better fits to the data than the time-varying and additive models. This outcome could indicate that temporary emigration probabilities did not vary by *primary* sampling period. However, given that the latter models required the estimation of more parameters, a more likely interpretation is that the data could not support the additional model complexity. That is, the former models were more parsimonious (Burnham and Anderson, 2002).

Out of the constant and group-varying temporary emigration models, the model allowing temporary emigration to differ between whales >4-yr-old and <4-yr-old was always selected, followed by the models of constant, >3-yr-old and <3-yr-old, and >2-yr-old and <2-yr-old temporary emigration (with the exception of the lowest AICc weighted model of capture probability) (Tables 2.1-2.2). Interestingly, the constant temporary emigration model was repeatedly selected over the latter two group-varying models, when the data otherwise suggested that temporary emigration probability was different for younger whales. However, with the large standard errors associated with the estimates for younger whales (resulting from small sample sizes) and the influence of whales three and two years post-weaning on the samples of the corresponding older whale estimate, the data were most likely not able to detect a clear difference between the temporary emigration probabilities of older and younger whales in those two models. Nonetheless, in each of the three group-varying models tested, temporary emigration probabilities were higher for younger whales, particularly for whales <4-yr-old (Figure 2.5).

The order of the time-varying and additive temporary emigration models closely resembled that of the constant and group-varying models. That is, the model estimating

temporary emigration over time for whales >4-yr-old and <4-yr-old was primarily selected, proceeded by the models where estimates were solely time-varying, time-varying between whales >3-yr-old and <3-yr old, and time-varying between whales >2-yr-old and <2-yr-old (Tables 2.1-2.2). Likewise, the relative relationship of the time-varying estimates was analogous to that of the constant and group-varying estimates. Within each *primary* sampling period, the temporary emigration estimates were higher for younger whales than the corresponding estimates for older whales, and the all-whale estimates were somewhat higher than those of older whales (Figure 2.6). All the time-varying estimates of temporary emigration differed between *primary* sampling periods, with the lowest probabilities occurring during the 1999 and 2001 field seasons (Figure 2.6). Potentially, the distribution and density of prey in the study area was higher in those years, resulting in lower temporary emigration probabilities for all whales. Alternatively, industrial activities conducted during those seasons may have influenced the presence of whales in the study area. However, interpretation of this finding is difficult, given the lack of data related to the suggested hypotheses and the aforementioned uncertainty in the time-varying temporary emigration models.

Presumably, the temporary emigration of whales from the study area is related to foraging activity (Weller *et al.*, 1999; Burdin *et al.*, 2002). The present temporary emigration estimates indicate that higher temporary emigration probabilities may play a significant role in the life history of young whales first sighted as calves for at least up to three-years post-weaning. Age-class segregation of eastern gray whales on their feeding grounds has been noted, with observations ranging from the complete separation of

younger whales (Zenkovich, 1937), to a less straightforward division (Bogoslovskaya *et al.*, 1981), to a combination of both patterns (Darling *et al.*, 1998). However, many juvenile western gray whales initially identified as calves did return to the study area and represented some of the most frequently sighted whales throughout each field season (Weller *et al.*, 1999, 2000, 2001, 2003a, 2003b; Würsig *et al.*, 1999, 2000). With the exception of a potential preference for nearshore areas, these young whales did not appear to differ appreciably in overall distribution and habitat use from older whales. Thus, given the constant use of the Piltun feeding ground by juvenile whales and the lack of segregation by age exhibited there, the mechanism prompting relatively high temporary emigration probabilities for younger whales is unclear.

Survival

The survival estimates reported here are the first direct survival estimates for gray whales. The non-calf survival estimate is similar to mark-recapture estimates by Buckland (1990) and Barlow and Clapham (1997) for humpback whales (*Megaptera novaeangliae*) in the Gulf of Maine (0.951, SE=0.010 and 0.960, SE=0.008, respectively). Caswell *et al.* (1999) estimated survival of another highly endangered whale population, the western North Atlantic right whale (*Eubalaena glacialis*), but these time-varying mark-recapture estimates (from about 0.99 to about 0.94) are of crude survival and are not directly comparable to the non-calf survival estimates presented here. Likewise, a mark-recapture estimate of adult western Arctic bowhead whale (*Balaena mysticetus*) survival (0.984) by Zeh *et al.* (2002) and indirect estimates of adult female southern right whale (*Eubalaena australis*) survival off South Africa (0.986) and

Argentina (0.981) by Best *et al.* (2001) and Cooke *et al.* (2001), respectively, are not directly comparable. Finally, the western gray whale non-calf survival point estimate is lower than an indirect estimate of 0.987 by Wade and Perryman (2002) for the eastern gray whale population. However, the level of uncertainty in that estimate makes direct inter-population comparisons premature at this time.

Due to the small size of the western gray whale population, relatively few calves can be produced each year. Thus, the calf survival estimate presented here was expected to be imprecise, as only 22 calves were available in the study area between 1997 and 2001. However, if the estimate is assumed to be accurate, it is markedly lower than a 'reasonable' first-year post-weaning calf survival estimate of 0.875 ($SE \approx 0.047$) suggested by Barlow and Clapham (1997) for Gulf of Maine humpback whales. It is important to note that Barlow and Clapham (1997) were simply attempting to bracket the likely range of calf survival values, and the authors caution that 'little credence' should be placed in their estimate. However, it is the only known direct estimate of first-year post-weaning calf survival available for comparison.

As the data used for the western gray whale survival estimation were collected during the feeding season, the resultant calf survival estimate represents survival of calves during their first year post-weaning. Gabriele *et al.* (2001) estimated the survival rate of central North Pacific humpback whale calves, from the breeding season to the subsequent feeding season, using sighting records of individually identified females with calves. Multiple rates were calculated in order to address the effects of various biases, leading to a minimum and maximum survival estimate of 0.759 and 0.850, respectively

(Gabriele *et al.*, 2001). These calf survival estimates characterize survival of humpback whale calves from birth to weaning and are therefore not comparable to the western gray whale calf estimate. Similarly, an indirect estimate by Best *et al.* (2001) of first-year survival (0.913) for southern right whale calves born off South Africa also cannot be compared. The survival rates of western gray whales from birth to weaning and first-year post-birth are currently unknown, but are important for better understanding the dynamics of this population.

The estimate reported here suggests that survival of post-weaned western gray whale calves is considerably low, which could be a result of both natural and anthropogenic factors. Possible sources of natural calf mortality are killer whale predation and insufficient nutritional reserves due to natural changes in prey availability. Potential anthropogenic causes of calf mortality are entanglement in fishing gear within the migratory corridor (see Weller *et al.*, 2002c for overview of range), direct catching, and inadequate nutritional reserves because of human-related shifts in prey availability.

Killer whale predation on eastern gray whale calves has been documented (Baldrige, 1972; Goley and Straley, 1994). Although killer whales are frequently sighted in the Piltun study area, aggressive interactions with western gray whales have not been observed. However, Weller *et al.* (2002c) recorded that between 1997 and 1998, at least 33% of the western gray whales identified, including calves, had visible killer whale tooth rakes on their bodies, suggesting that they are threatened by killer whales in some portion of their range (Weller *et al.*, 2002c). Heyning and Lewis (1990) summarized the entanglements of eastern gray whales in fishing gear off southern

California from 1980 to 1989. Length measurements were obtained from 16 of the 20 whales found dead after entanglement. Of the 16 measured whales, one was considered a calf (i.e., from 4.4 to 6.0m), 12 were deemed yearlings (i.e., from 6.5 to 8.8m), and three were estimated to be two or three years old (i.e., from 8.9m upwards). These findings suggest that younger whales become entangled in fishing gear more frequently or are less likely to survive entanglement than adults (Heyning and Lewis, 1990). The level of western gray whale entanglement in fishing gear within the migratory corridor is currently unknown. However, Zhou and Wang (1994), Kato (1998), and Kim (2000) have reported incidental catches of other cetaceans in coastal net fisheries off southern China, Japan, and Korea, respectively.

At least one direct take of a western gray whale has occurred in recent years (Brownell and Kasuya, 1999). In 1996, the anterior portion of a gray whale was found floating off Suttsu, Hokkaido, presumably killed by Japanese Dall's porpoise fishermen (Brownell and Kasuya, 1999). Although the Suttsu whale was adult-sized, both non-calves and calves are at risk from an undetermined level of illegal hunting. The discovery of gray whale products in Japanese commercial meat markets in 1999 (Baker *et al.*, 2002) further heightens this concern. Unusually thin non-calf western gray whales in the study area have been observed since 1999 (Weller *et al.*, 2002b), suggesting possible effects of natural or anthropogenic nutritional deficiencies. The cause of this physical deterioration is unknown (Brownell and Weller, 2001; Weller *et al.*, 2002c), but could be having a more severe effect on calves. Furthermore, calves born to thin mothers may be susceptible to reduced survival. Interestingly, although the cause of mortality is

unknown, all three western gray whale strandings on the east coast of Japan reported from 1990 to the present were of young whales less than 9.5m in length (see Yamada *et al.*, 2002 for review).

As survival probability is only a measure of ‘apparent’ survival (i.e., the probability a whale remains alive and available for recapture), an alternative explanation for low calf survival is that whales permanently emigrate from the Piltun feeding area after their first year. Yet, as stated previously, some juvenile whales initially sighted as calves have exhibited pronounced seasonal site fidelity to the study area (Weller *et al.*, 1999, 2000, 2001, 2003a, 2003b; Würsig *et al.*, 1999, 2000). Additionally, aerial and ship-based surveys of the Okhotsk Sea between 1979 and 1989 found concentrations of gray whales only off the northeastern coast of Sakhalin Island near Piltun Lagoon (Blokhin *et al.*, 1985; Berzin *et al.*, 1988, 1990, 1991; Berzin, 1990; Blokhin, 1996). The distribution of these sightings encompassed some area outside the boundary of typical photo-identification survey coverage. However, whales in the Piltun study area have been noted to travel more than 50 km in less than 24 hours (Burdin *et al.*, 2002). This observation indicates that whales could occur within the distribution documented by previous aerial and ship-based surveys and still be encountered in the study area at some point during any given field season. Furthermore, usable photographic sightings of whales in other parts of the Okhotsk Sea have been matched to whales that regularly use the Piltun feeding ground, and have not yet included any whales first sighted as calves that were not resighted in the study area (Burdin *et al.*, 2002; Weller *et al.*, 2002a).

Therefore, the study area is regarded as the only known location where western gray whales consistently aggregate to feed (Weller *et al.*, 1999).

The present non-calf survival point estimate is somewhat higher than the estimate calculated prior to the 2002 field season (Bradford *et al.*, 2002). However, the new estimate is within the 95% confidence interval of the former estimate. Conversely, the current calf point estimate is nearly twice as high, but exceeds the upper limit of the 95% confidence interval of the previous estimate. Contrasting results from the temporal addition of data are not unexpected for a small population of long-lived animals with demographic variation, highlighting the importance of continuing the long-term western gray whale study. Future data will also facilitate the refined estimation and additional hypothesis testing of temporary emigration probabilities for younger and older whales. Such clarification is important, given the strong influence the various models of temporary emigration had on corresponding estimates of survival in the present analysis. That is, within each case of capture probability, the different models of temporary emigration lead to the broad range of resultant survival estimates (Tables 2.3-2.4). Consequently, if higher temporary emigration probabilities are not really a significant part of the life history of younger whales, then calf survival is actually lower than the model-averaged estimate presented here (Table 2.4).

Estimation of survival probability may give one of the best indications of underlying causes of population declines (Eberhardt and Siniff, 1977). Indications are more likely to come from juvenile survival estimates (Eberhardt and Siniff, 1977), as adult survival is less affected by density dependence in large, long-lived animals

(Goodman, 1981). Continued estimation and temporal evaluation of western gray whale calf survival are needed to make inferences about the status of the population. Similarly, more data are needed to further refine the non-calf estimates. In population modeling of long-lived species, population growth rate is most sensitive to non-calf survival (Goodman, 1981; Taylor and DeMaster, 1993), emphasizing the need for an accurate and precise estimate.

While the survival estimates reported here do not quantitatively determine the status of western gray whales (i.e., degree of depletion and whether the population is growing or declining), they can be used in population modeling that is needed for such an assessment (e.g., Chapter 3). Undoubtedly, a complete assessment should be made before drawing conclusions from these estimates. However, the low calf survival estimate in conjunction with the small population size (Wade *et al.*, 2003), small number of reproductive females identified ($n=17$), and the predominance of a three-year calving interval (Chapter 3; Brownell and Weller, 2002; Weller *et al.*, 2003b) already raises questions about the potential for western gray whale recovery.

Table 2.1. Model comparisons ($n=72$) from Program MARK. Delta AICc is the difference in the AICc of a model from the minimum AICc model, AICc Weight is the Akaike Weight (see Burnham and Anderson, 2002 for description), and Deviance is the difference in $-2\log(\text{Likelihood})$ of the current model and $-2\log(\text{Likelihood})$ of the saturated model. See text for details of parameters and model notation.

CHAPTER 3

CURRENT POPULATION GROWTH RATE AND TWENTIETH CENTURY POPULATION DYNAMICS OF WESTERN GRAY WHALES

INTRODUCTION

Similar to other populations of wildlife, determining the status of a whale population requires comparing the current population size with an accepted reference level, usually the current carrying capacity (i.e., equilibrium population size under conditions of no harvest). For whale populations that are presently depleted as a result of historical whaling, current carrying capacity is often unknown and must be estimated. Commonly, historical population levels are used as estimates of current carrying capacity (Fowler and Siniff, 1992), given that the historical population was at equilibrium and that the environment has not changed significantly since that time (Gerrodette and DeMaster, 1990). However, selecting a point in a population's history to reflect carrying capacity can be difficult (e.g., Reilly, 1992). For whale populations with long histories of aboriginal harvests prior to commercial exploitation, the task is confounded by a lack of information on aboriginal harvest levels and by the inherent ambiguity in the definition of carrying capacity (see Hartvigsen, 2001 for a recent overview of the carrying capacity concept). For example, Fowler and Siniff (1992) present carrying capacity as "...the mean naturally occurring population (i.e., in the absence of perturbations by other than aboriginal human activities) level." If aboriginal activity levels varied historically, or if they contrast with present aboriginal use of the population, which historical equilibrium population size, if any, should be regarded as current carrying capacity?

A primary method for estimating carrying capacity of exploited populations is referred to as back calculation (see Gerrodette and DeMaster, 1990 for an overview). Back calculation fits a population dynamics model to a current abundance estimate (or a series of estimates) and historical catch data, back to a point in time before commercial exploitation. That pre-exploitation population size is considered carrying capacity if it meets the aforementioned assumptions described in Gerrodette and DeMaster (1990).

The population dynamics model used in the back calculation can vary, but the model must include the specification of a density-dependent function (Gerrodette and DeMaster, 1990). General forms of commonly used age-independent and age-structured models are referred to as the generalized logistic equation (e.g., Pella and Tomlinson, 1969) and the Leslie matrix (Leslie, 1945, 1948), respectively, although the Leslie matrix should be combined with a density dependent function. Both model forms have been applied to back calculations performed on cetacean populations. Smith (1983) employed the generalized logistic equation to calculate carrying capacity for three dolphin populations in the eastern tropical Pacific. Breiwick *et al.* (1984) used a density-dependent Leslie-type matrix in a back calculation for western Arctic bowhead whales.

In addition to uncertainty involved in the modeling process (e.g., reliability of input parameters; Smith and Polacheck, 1979), problems can arise when interpreting the selected historical reference level (i.e., pre-exploitation population size) as carrying capacity. Most early attempts to back calculate the eastern gray whale population failed to reconcile the available catch records with the degree of observed late 19th century depletion, the current increase in abundance, and standard density-dependent population

models (Ohsumi, 1976; Reilly, 1981; Cooke, 1986; Lankester and Beddington, 1986). Punt and Butterworth (2002) more recently confirmed these results. Population projections in these efforts all begin prior to 1846, the onset of commercial eastern gray whaling (Scammon, 1874), when the population was harvested only by aborigines (Mitchell, 1979) and assumed to be at a pre-exploitation equilibrium. Butterworth *et al.* (2002) found that carrying capacity estimates producing reasonable trajectories through the current abundance estimates involved making untestable assumptions regarding the temporal consistency of carrying capacity or about the levels of aboriginal or early commercial catches. In order to avoid these problems, Wade (1997, 2002) relied on the richness of the current abundance data and assessed the population using projections beginning in 1900 and 1967, respectively. These analyses did not make any assumptions about where the starting population levels of the projections were relative to carrying capacity.

Estimating carrying capacity in an assessment of western gray whale status could prove equally, if not more, problematic than attempts for the eastern population. Fewer abundance and vital rate data exist, and a reference population level is not as easily determined. Modern commercial western gray whaling began in 1891 (Kato and Kasuya, 2002), but not all previous harvests were aboriginal (Table 1.1). Further, records of takes prior to the modern commercial whaling period are insufficient. For example, the 200-year history of Japanese net whaling is poorly known (Omura, 1984). Even if adequate records did exist, Gerrodette and DeMaster (1990) caution that back calculation is less useful if the pre-exploitation population level is very far back in time, as the carrying

capacity estimate then becomes heavily dependent on the input vital rates. Thus, a variation of the back calculation, such as the method used by Wade (1997) for eastern gray whales, is a more suitable alternative. In that analysis, the initial year of population projections (1900) was after the onset of commercial exploitation, but still far enough back in time to reflect the contrast (i.e., periods of high and low abundance) in the population's history.

The year 1900 is also a suitable year to begin a back calculation of the western gray whale population. The time series of modern whaling catch records begins in this year (Figure 1.1; Appendix A). Moreover, population projections will encompass the concerted Japanese modern whaling operation off the Korean peninsula (Kasahara, 1950; Kato and Kasuya, 2002). Western gray whale population size *circa* 1900 and an apparent estimate of carrying capacity do exist in the scientific literature. Berzin and Vladimirov (1981) suggested that the western gray whale population numbered 1,000-1,500 individuals by 1910, although details of the estimation process were not provided. Yablokov and Bogoslovskaya (1984) speculated that the population might have numbered between 1,500-10,000 whales prior to the onset of the 'whaling industry.' How this range was determined, and to what specific time period it applies, is unclear.

Increased international protection, conservation, and management planning for western gray whales are needed to facilitate the potential recovery of this population. In several predominant national and international contexts, marine mammal conservation currently functions by protecting populations based on the degree to which they are reduced (e.g., Fowler and Siniff, 1992; IWC, 1995; Wade, 1998). Thus, a back

calculation adhering to the previously outlined framework was performed to quantitatively demonstrate the degree to which the western gray whale population was depleted during the 20th century, and possibly historically. Along with 20th century catch data (Figure 1.1; Appendix A), mark-recapture estimates of the number of western gray whales associated with the Piltun feeding ground (Figure 1.2; Wade *et al.*, 2003) were available for fitting of the population dynamics model. However, as the increase in these estimates only verifies an increase in the number of whales using the Piltun study area, the trend in these values is regarded as an overestimate of the present population growth rate (Wade *et al.*, 2003). Thus, fitting the population dynamics model to these estimates would have lead to a biased estimation of model parameters. Therefore, an alternative population characteristic was needed, such as the current population growth rate. Given the survival estimates presented in Chapter 2 and some basic life history information (see below), the current western gray whale population growth rate was estimated accounting for uncertainty in these data. The population dynamics model was then fitted to the calculated growth rate. Results of the growth rate estimation and the ensuing analysis of 20th century western gray whale population dynamics are presented here.

METHODS

Growth Rate Estimation

Population Dynamics Model

According to Lotka's equation of unity (Lotka, 1907; Cole, 1954), any given set of age-specific survival and reproductive parameters can be characterized by a unique

population growth rate. The form of the Lotka equation allowing for a discrete time (in this case, annual) life history representation (e.g., Goodman, 1982) was used to estimate the population growth rate of western gray whales from 1997 to 2002:

$$1 = \sum_{x=1}^w l^{-x} l_x m_x \quad (\text{Equation 3.1})$$

where	x	=	age class
	w	=	maximum age class
	l	=	finite population growth rate
	l_x	=	survival to age class x
	m_x	=	fecundity of age class x .

When implementing the Lotka equation, the first age class (i.e., age class 1) generally relates to young of the year at the time of birthing (i.e., age 0 individuals), such that $l_1=1$. As the western gray whale growth rate estimation is based predominantly on information gleaned from the Piltun feeding ground (i.e., between birthing seasons), age class 1 actually corresponds to young of the year (i.e., calves) that are approximately 6-8 months of age (see Weller *et al.*, 1999 for a discussion of likely ages of calves in the Piltun study area relative to eastern gray whale estimates summarized by Rice and Wolman (1971)). The fact that l_1 is technically unknown in this case is offset by the incorporation of apparent fecundity into the growth rate estimate. That is, the measure of fecundity is also based on observations made during the feeding season. Therefore, fecundity estimates will reflect any loss of calves between the breeding and feeding grounds, making $l_1=1$ an appropriate assumption for the present analysis. The specific life history parameters used in the western gray whale growth rate estimation are detailed below.

The average longevity of western gray whales is unknown, and can only be speculated for eastern gray whales (Rice and Wolman, 1971). However, the maximum age class (w) incorporated into the Lotka equation does not necessarily characterize the longevity of individuals in the population, and can in fact be much larger. When average survival probabilities representing an unknown demographic are used to calculate the l_x schedule, w should be fixed at a value large enough to allow l_w to approach zero. As an average non-calf survival probability was utilized in the western gray whale growth rate estimation (see below and Chapter 2), the maximum age class was set at 150. To illustrate the principle of this concept, summing the Lotka equation to $w=1,000$ would not have changed the results of the growth rate estimation. Further, in the older scientific literature (e.g., Cole, 1954), w was often alternatively represented by ∞ .

The intrinsic growth rate of a population (r) is another measure of population increase often represented in population dynamics modeling. In discrete forms of population dynamics models, the finite population growth rate (?) estimated by the Lotka equation corresponds to r according to the relationship:

$$I = 1 + r \quad \text{(Equation 3.2)}$$

As a form of r was a parameter in the back calculation population dynamics model (see below), consistency and comparability of reported growth rates were needed. Therefore, results of the growth rate estimation are described in terms of $I - 1$ when associated with the Lotka equation, and by the r nomenclature when incorporated into the back calculation.

Life History Parameters

Four life history parameters were required for the western gray whale growth rate estimation: 1) calf survival; 2) non-calf survival; 3) calving interval (i.e., time in years between births of consecutive calves); and 4) age at sexual maturity (ASM). The mark-recapture calf and non-calf survival estimates (f) presented in Chapter 2 were utilized to construct the l_x schedule of the Lotka equation for age class 2 (recall that $l_1=1$) to age class w , where:

$$l_x = f_{x-1} l_{x-1} \quad (\text{Equation 3.3})$$

Thus, the calf survival estimate became f_1 , and the non-calf estimate $f_{2 \rightarrow w-1}$. Calf and non-calf survival values were selected from a beta distribution (i.e., between 0 and 1) with a mean of 0.709 (SE=0.1178) and 0.952 (SE=0.0151), respectively (Chapter 2).

Fecundity (m_x) is the average rate at which female young are produced each year by females, and can be calculated as:

$$m_x = \frac{1}{CI} SR f_x \quad (\text{Equation 3.4})$$

where CI = calving interval
 SR = population sex ratio (assumed to be 0.5).

The western gray whale calving interval was determined from photo-identification records of females with calves on the Piltun feeding ground (Table 3.1; Brownell and Weller, 2002; Weller *et al.*, 2003b), following the estimation method of Jones (1990) for eastern gray whales. As in Jones (1990), only females with one or more observed calving intervals contributed to the estimation. In addition to photographic sightings collected by

TAMU, NMFS, and KIENM between 1997 and 2002, photo-identification records from the 1995 pilot study (Brownell *et al.*, 1997) were included in the calculation, as these data added one observed calving interval each to the encounter histories of two females (Table 3.1).

Averaging the 10 observed calving intervals (3-year *CI*: $n=7$; 4-year *CI*: $n=2$; 2-year *CI*: $n=1$) highlighted in Table 3.1 would lead to a measure of apparent fecundity. However, this measure could potentially be confounded by the capture probability of one or more of the represented females. That is, a female who might have been associated with a calf during any given feeding season could have been sighted only after her calf was weaned, or potentially not observed at all, such that an observed calving interval might actually represent two separate intervals. In general, such a scenario was assumed atypical given the marked seasonal site fidelity to the study area exhibited by females and their calves (Weller *et al.*, 1999, 2000, 2001, 2003a, 2003b; Würsig *et al.* 1999, 2000), and the infrequency of first sighting calves during a field season after weaning has occurred ($n=4$ of 22 calves identified between 1997 and 2002; Brownell and Weller, 2002; Weller *et al.*, 2003b). Further, suggesting that the observed calving interval represents two intervals would have introduced one-year calving intervals in eight of the 10 cases, and annual breeding is considered rare for this species (Jones, 1990).

The remaining two cases are the observed four-year calving intervals of whales No. 005 and No. 015 (Table 3.1). These females both had calves in 1998 and 2002, but it is biologically plausible that one or both of them produced a calf in 2000 that survived until the feeding season. Although whales No. 005 and No. 015 were sighted in 2000,

they were first observed on 12 August and 30 July, respectively (Weller *et al.*, 2001).

Both dates are within the range of known weaning times for western gray whales (Weller *et al.*, 1999, 2000, 2001, 2003a, 2003b; Würsig *et al.* 1999, 2000). Further, one of the three calves identified in 2000 was first sighted post-weaning (Weller *et al.*, 2001), so its mother was unaccounted for (although planned genetic testing could clarify this issue; Brownell and Weller, 2002). Therefore, suggesting that the observed four-year calving intervals could represent two two-year intervals is not an unreasonable assumption.

The goal of calculating the average western gray whale calving interval is to estimate apparent fecundity, and subsequently the current growth rate. While averaging the 10 observed intervals might underestimate apparent fecundity because of a possible capture probability influence, assuming that the observed four-year calving intervals represent two two-year intervals could overestimate apparent fecundity. That is, if whale No. 005 or whale No. 015 produced a calf in 2000 that did not survive until the feeding season, an overestimate of apparent fecundity (and the violation of the aforementioned $l_1=1$ assumption) would result. Therefore, the preferred approach was to bracket a likely range of fecundity values, and thus growth rate estimates. Consequently, a low, medium, and high estimate of calving interval was incorporated into a separate fecundity and growth rate estimation. The low calving interval estimate was the average of the 10 observed intervals; the high estimate was the average with both of the observed four-year intervals representing two two-year intervals ($n=12$). The medium calving interval estimate attributed two two-year calving intervals to either whale No. 005 or whale No. 015 ($n=11$). The low, medium, and high calving interval values were selected from a

normal distribution with a mean of 3.1 (SE=0.18), 2.8 (SE=0.18), and 2.6 (SE=0.15), respectively.

The ASM indicates the first age class with non-zero fecundity in the m_x schedule. As the first age class in the Lotka equation is usually composed of age 0 individuals, m_{ASM+1} is generally the first non-zero value. However, given the previously described 6-8 month offset in the age classes, the first non-zero fecundity value was set at age class ASM. The ASM of western gray whales is unknown, but a median value of 6 years (range 5-9 years) has been estimated for eastern gray whales (see Reilly, 1992 for a summary of eastern gray whale biological parameters). Assuming that eastern and western gray whales share similar reproductive capabilities, values for western gray whale ASM were selected from a discrete uniform distribution of 5-9 years.

According to Equation 3.4, non-zero values of m_x are conditional on the survival of mature females. Given that the f_x used to calculate these values was a non-calf estimate (i.e., based on observations of juvenile and adult whales), and that juvenile survival rates are likely lower than those of adults (Caughley, 1966), there was an inherent negative bias in the fecundity estimates that could not be avoided given the available data. However, population growth rates of long-lived animals are least sensitive to changes in fecundity rates (Goodman, 1981; Taylor and DeMaster, 1993). Hence, the impact of the negatively biased fecundity values on the resulting growth rate estimates was presumed to be minimal.

Statistical Methods

In order to account for the uncertainty of the input life history parameters, the 1997-2002 western gray whale population growth rate was estimated using a Monte Carlo simulation method (e.g., Cox and Baybutt, 1981). Values of the life history parameters were randomly selected from their associated distributions and incorporated into the Lotka equation, and a growth rate specific to that set of parameters was determined. This process was conducted a large number of times ($n=10,000$), producing a growth rate estimate in the form of a distribution. The simulation routine was performed employing the low, medium, and high estimates of calving interval, generating a *conservative*, *intermediate*, and *liberal* growth rate estimate, respectively. Pseudocode for the growth rate estimation procedure is provided in Appendix C.

Back Calculation

Population Dynamics Model

Complex models with more parameters usually provide better fits to data than simpler models. However, simpler models often offer more insight into the modeled system than accurate numerical fits (Hilborn and Mangel, 1997). Thus, the population dynamics model used in the first quantitative western gray whale back calculation was the age-independent generalized logistic equation (e.g., Pella and Tomlinson, 1969), altered for discrete (in this case, year-to-year) growth:

$$N_{t+1} = N_t + N_t r_{MAX} \left[1 - \left(\frac{N_t}{K} \right)^z \right] - C_t \quad (\text{Equation 3.5})$$

where t = time in integer years from 1900 to 2002

N_{t+1}	=	population size at time $t+1$
N_t	=	population size at time t
r_{MAX}	=	maximum net recruitment rate
K	=	carrying capacity
z	=	shape parameter
C_t	=	catch at time t .

The shape parameter (z) controls the amount of non-linearity in the density-dependent function, which sets the maximum net productivity level (MNPL) (Taylor and DeMaster, 1993; Wade, 1998), according to the relationship (e.g., Smith, 1983):

$$MNPL = \frac{K}{(1+z)^{1/z}} \quad (\text{Equation 3.6})$$

Marine mammal populations are thought to exhibit concave non-linear density dependence, such that $MNPL > 0.5K$ making $z > 1.0$ (Eberhardt and Siniff, 1977; Taylor and DeMaster, 1993; Fowler, 1994). However, available data make it difficult to estimate MNPL for any marine mammal population. Allowing $MNPL > 0.5K$ for marine mammals is viewed by Eberhardt and Siniff (1977) as a conservative management policy. Therefore, MNPL was assumed to occur at $0.6K$ (i.e., $z=2.39$) in the present analysis.

As the projection began in 1900, N_{1900} became an additional parameter in the model. Thus, the set of parameters (\mathbf{q}) specified by the model were r_{MAX} , K , and N_{1900} . Two status indices (\hat{N}_{2002}/K and \hat{N}_{2002}/N_{1900}) were also calculated using a model output (\hat{N}_{2002}) and two model parameters (N_{1900} and K). Assumptions of the generalized logistic equation are: 1) growth of the population is dependent on population size (i.e., density dependence); 2) the population was initially at a stable age distribution; 3) K is constant; 4) catch values are known, and 5) catch rates are proportional to the size of each

age class. Information is sparse regarding both the age-specific selectivity of whalers before and after 1900 and the general uncertainty (e.g., under-reporting and whales struck, but lost) in the post-1900 catch data. Consequently, assumptions 2, 4, and 5 were possibly violated by using this model to characterize western gray whale population dynamics. Examining the validity of model assumptions was not an objective of the present analysis, but should be considered in future assessments.

Realistically, the main status determination objective of the back calculation was to estimate N_{1900} . Although K was technically an estimated parameter, the lack of contrasting observed growth rate estimates (i.e., from periods of both low and high abundance) was expected to provide little information about this parameter. Hilborn and Mangel (1997) illustrate a case where the generalized logistic model was fitted to a series of abundance estimates for Serengeti wildebeest (*Conochaetes taurinus*). Although there was excellent agreement between the model predictions and the observed data, the abundance estimates were uninformative in determining carrying capacity (i.e., K was completely undefined). The abundance estimates merely indicated that K could be any value large enough to account for the increasing population size observed during the study period.

Statistical Methods

A Bayesian statistical method (e.g., Press, 1989; Gelman *et al.*, 1995) was used to estimate the model parameters and the status indices. The likelihood function for the parameters calculated the likelihood of the model predicted 1997-2002 growth rate

($r_{1997-2002}^{\text{model}}$) given the observed estimate of 1997-2002 growth rate from the life history

data ($r_{1997-2002}^{\text{LH data}}$), where:

$$r_{1997-2002}^{\text{model}} = \frac{\sum_{t=1997}^{2001} \left(\frac{N_{t+1}}{N_t} - 1 \right)}{5} \quad (\text{Equation 3.7})$$

Assuming the observed 1997-2002 growth rate estimate was normally distributed with standard deviation (\mathbf{s}_r), the likelihood function was:

$$L(\mathbf{q} | r_{1997-2002}^{\text{LH data}}, \mathbf{s}_r) = \frac{1}{\sqrt{2\pi}\mathbf{s}_r} e^{-\frac{1}{2} \left(\frac{r_{1997-2002}^{\text{LH data}} - r_{1997-2002}^{\text{model}}}{\mathbf{s}_r} \right)^2} \quad (\text{Equation 3.8})$$

In order to integrate the product of the prior distributions of the parameters and the likelihood function, the Sample-Importance-Resample (SIR) algorithm (Rubin, 1988; Smith and Gelfand, 1992) was used. SIR requires randomly selecting values of the parameters from their joint prior distributions to form a sample set \mathbf{q}_i , of which the associated likelihood is calculated and stored. The process is repeated until an initial sample of n_1 \mathbf{q}_i s and likelihoods is generated. The n_1 \mathbf{q}_i s are then resampled with replacement n_2 times, with probability equal to weight q_i , where:

$$q_i = \frac{L(\mathbf{q}_i | r_{1997-2002}^{\text{LH data}}, \mathbf{s}_r)}{\sum_{j=1}^{n_1} L(\mathbf{q}_j | r_{1997-2002}^{\text{LH data}}, \mathbf{s}_r)} \quad (\text{Equation 3.9})$$

The resample serves as a random sample of size n_2 from the joint posterior distributions of the parameters (Rubin, 1988).

In the present analysis, a large value of n_1 was established ($n_1=2,000,000$) to ensure convergence of the integration by avoiding potentially overly influencing the resample with repetitive values. However, to confirm that the initial sample was large enough, the maximum number of times a single \mathbf{q}_i appeared in the resample and the number of unique \mathbf{q}_i s in the resample were enumerated. The value of n_2 was set to 5,000 in order to yield sufficiently smooth posterior distributions. The entire back calculation was repeated three times, fitting the population dynamics model to the *conservative*, *intermediate*, and *liberal* 1997-2002 growth rate estimate, respectively. Pseudocode for the back calculation routine is shown in Appendix D.

Prior Distributions

The prior distribution for r_{MAX} was a uniform distribution (U) from 0.00 to 0.10, which was more restrictive than the prior distribution of U(0.01, 0.13) used in the population assessment of eastern gray whales by Wade (2002). However, given the small present population size, the posterior distribution of r_{MAX} was expected to closely approximate the distribution of the specified $r_{1997-2002}^{LH\ data}$ and associated standard deviation. The 95th percentiles of the three 1997-2002 growth rate estimates were all well below 0.10 (Table 3.2). Although the 5th percentiles of the *conservative* and *intermediate* 1997-2002 growth rate estimates were both less than 0.00 (Table 3.2), a maximum net recruitment rate below zero was considered biologically implausible.

The prior distribution for K was U(1,500, 20,000). While Yablokov and Bogoslovskaya (1984) hypothesized that the western gray whale population might have

previously numbered between 1,500-10,000 whales, there is no quantitative basis for this estimate. Yet, given the over 400-year history of western gray whaling, a value of K less than 1,500 whales was considered highly improbable. Previous speculation (Yablokov and Bogoslovskaya, 1984) and genetic inference (LeDuc *et al.*, 2002) suggest that the western gray whale population was never as large as that of the eastern population. Recent point estimates of eastern gray whale carrying capacity range from approximately 25,000 to 32,000 whales (Wade, 2002). Thus, a range of upper bounds for the prior distribution of K between 10,000 and 40,000 was explored for use in the western gray whale back calculation. These preliminary analyses demonstrated that any value within this range could be utilized as an upper prior bound without influencing the general results of the back calculation. Therefore, to avoid potentially increasing the number of initial samples and resamples (which would require more computation time), an upper bound for K of 20,000 was established, with the recognition that this value is somewhat arbitrary. However, to demonstrate the minimal effect a different upper bound for K within the aforementioned range would have on the back calculation results, an additional back calculation was performed. This analysis duplicated the back calculation incorporating the *intermediate* estimate of $r_{1997-2002}^{\text{LH data}}$, with the exception of a prior distribution for K of $U(1,500, 10,000)$.

The prior distribution for N_{1900} was initially set as $U(500, 20,000)$. Given that the population sustained a harvest of at least 1,100 whales between 1900 and 1915 (Figure 1.1; Appendix A), a value of N_{1900} less than 500 whales was regarded as unlikely. For

each draw of N_{1900} , the upper bound of the prior was constrained to be less than the value of K selected in that sample. However, preliminary analyses revealed that forward projections from most N_{1900} values selected from the upper portion of the prior distribution could not produce a depleted population in 2002. Given that the likelihood function was based on the observed 1997-2002 growth rate, a mechanism to penalize such trajectories was not in place. Thus, the *backwards* method described by Butterworth and Punt (1995) was implemented. In this approach, a current estimate of absolute abundance is treated as a model input along with the other model parameters, with the exception of the projection starting population size parameter. For each sample, these model inputs are selected from their prior distributions, and then used to calculate the initial population level corresponding to those values. That is, the population is projected *backwards* from the current abundance estimate to the starting population level. Therefore, the prior for initial population size is implicitly determined by the priors for the other parameters (Butterworth and Punt, 1995).

The mark-recapture estimate of the number of western gray whales associated with the Piltun study area in 2002, which is considered to closely approximate current population size (Figure 1.2; Wade *et al.*, 2003), was utilized as a model input (N_{2002}) in the western gray whale back calculation. The prior distribution for N_{2002} was normally distributed with mean 98 and standard error 5 (Figure 1.2; Wade *et al.*, 2003). During each initial sample, the randomly selected values from the priors for r_{MAX} , K , and N_{2002} were used to calculate a corresponding N_{1900} within the aforementioned prior distribution

for this parameter. Specifically, this process was accomplished by using a bisection approach to find the value of N_{1900} between 500 and K , given the prior draws of r_{MAX} , K , and N_{2002} , that would minimize the difference (i.e., residual) between \hat{N}_{2002} and N_{2002} . That is, N_{1900} was initialized at a value halfway between 500 and K , only to become the new upper or lower bound of possible N_{1900} values if the \hat{N}_{2002} and N_{2002} residual was positive or negative, respectively. A value of N_{1900} halfway between the boundaries of the redefined interval was examined, and the bisection routine continued until \hat{N}_{2002} was very close to (arbitrarily defined to mean within five whales of) N_{2002} . At that point, the exact value of N_{1900} was solved for that would minimize the squared residual of \hat{N}_{2002} and N_{2002} , which finally completed the \mathbf{q}_i for that initial sample. Thus, although the resultant N_{1900} was always within the initially designated prior distribution, the actual prior for N_{1900} was a non-uniform distribution dictated by r_{MAX} , K , and N_{2002} .

Preliminary analyses revealed that not all combinations of r_{MAX} and K (particularly with high values of r_{MAX}) could produce an estimate of \hat{N}_{2002} that closely approximated N_{2002} , regardless of the value of N_{1900} (i.e., the bisection routine could not find an N_{1900} ‘solution’). Since the likelihood function was based solely on the observed and predicted 1997-2002 growth rate estimates, a diagnostic was implemented to identify and penalize such parameter sets. That is, before the bisection procedure was initiated with the selected \mathbf{q}_i , N_{1900} was set at both 500 and K . If the resulting trajectories did not bracket

N_{2002} (i.e., the \hat{N}_{2002} and N_{2002} residuals were either both positive or both negative), then that \mathbf{q}_i was assigned a likelihood of zero.

As the $r_{1997-2002}^{\text{LH data}}$ utilized in the likelihood function had some basis in the mark-recapture analyses of the western gray whale photographic dataset (i.e., through the survival estimates), concern may be expressed about the lack of independence between $r_{1997-2002}^{\text{LH data}}$ and the mark-recapture estimate used to generate N_{2002} . However, the only data that are shared between these two estimates are the monthly sightings used to estimate capture probability in 2002. Further, a lack of covariance was found between capture probability in 2002 and the non-calf and calf survival estimates. Therefore, the estimates of $r_{1997-2002}^{\text{LH data}}$ and N_{2002} were treated as independent values.

RESULTS

Growth Rate Estimation

Estimates of the *conservative*, *intermediate*, and *liberal* 1997-2002 population growth rates are displayed in Table 3.2. As expected, the sequence of these estimates reflects the incorporation of the low, medium, and high fecundity values, respectively, with higher fecundity estimates resulting in increased growth rates. The growth rate estimates suggest that the western gray whale population was increasing during the observation period (Table 3.2, Figure 3.1). However, in each case, the left tails of the distribution indicate that some combinations of the life history parameters produced a negative growth rate (Figure 3.1).

Back Calculation

The maximum number of times a single q_i appeared in the resample of each of the three back calculations was two, and the number of unique q_i s in each of the three resamples was greater than 4,950. Given the small number and reduced extent of repetitive parameter sets in the resample of each version of the back calculations, the size of each initial sample ($n_1=2,000,000$) was considered adequate for integration convergence. A summary of the back calculation model parameters and status indices according to the *conservative*, *intermediate*, and *liberal* 1997-2002 population growth rate scenarios is shown in Table 3.3.

As expected, the point estimate and posterior distribution for r_{MAX} in each of the three back calculations closely resembled the value and distribution for $r_{1997-2002}^{LH\ data}$ used in model fitting (Tables 3.2-3.3, Figures 3.1-3.2). That is, given the model of population dynamics and the small present population size, the western gray whale population is essentially currently growing at its maximum net recruitment rate. However, the left tails of each r_{MAX} posterior distribution (Figure 3.2) and corresponding $r_{1997-2002}^{LH\ data}$ distribution (Figure 3.1) differed, as the prior distribution for r_{MAX} prevented negative values of this parameter.

As anticipated, the point estimate and posterior distribution for K in each of the three back calculations reproduced the prior distribution for this parameter (Table 3.3, Figure 3.3). That is, any value of K within the prior distribution could support likely combinations of the other parameters. In other words, the carrying capacity of western

gray whales is undefined. The same situation resulted in the additional *intermediate* $r_{1997-2002}^{\text{LH data}}$ scenario back calculation utilizing the prior distribution of $U(1,500, 10,000)$ for K (Figure 3.4A). The posterior distributions and point estimates for the other model parameters and status indices in this analysis duplicated those resulting from the initial *intermediate* back calculation (Table 3.3), with the exception of \hat{N}_{2002} / K (see below).

The point estimate and posterior distribution for N_{1900} in each of the three back calculations indicate that only values within the lower range of the investigated prior distribution were able to produce a depleted population in 2002 using the *backwards* method and the likelihood function (Table 3.3, Figure 3.5). The resulting N_{1900} posterior distributions were negatively correlated with the observed 1997-2002 population growth rate estimates incorporated in the back calculations (Figure 3.5). That is, as the value of $r_{1997-2002}^{\text{LH data}}$ increased, the value of N_{1900} that was required to minimize the residual between \hat{N}_{2002} and N_{2002} decreased.

The point estimate and posterior distribution for the status index \hat{N}_{2002} / K were essentially the same between each version of the back calculation (Table 3.3, Figure 3.6), reflecting the similarity between each posterior distribution for K (Figure 3.3). Although the back calculation procedure did not define a value of western gray whale carrying capacity, the resulting \hat{N}_{2002} / K suggests that the population is currently less than one percent of its original size (Figure 3.6). However, the posterior distribution for \hat{N}_{2002} / K is the one model output dictated by the selected upper bound of the prior distribution for

K . That is, the \hat{N}_{2002} / K distribution would shift to the left or right if the upper bound was increased or decreased, respectively. A slight rightward shift is evident in the posterior distribution for \hat{N}_{2002} / K resulting from the back calculation using the *intermediate* 1997-2002 growth rate estimate and the prior distribution of $U(1,500, 10,000)$ for K (Figure 3.4B; Median=0.017, 5th-95th Percentiles=0.010-0.049).

Yet, the posterior distribution for \hat{N}_{2002} / K would never shift farther to the right than the posterior distribution for the status index $\hat{N}_{2002} / N_{1900}$, as N_{1900} can only be less than or equal to K in the back calculation (although the over 300-year history of western gray whaling prior to 1900 implies that the population size was already reduced by that year; Omura, 1984). Thus, the resulting $\hat{N}_{2002} / N_{1900}$ values can be interpreted as a maximum estimate of current population size relative to K . The three back calculation point estimates and posterior distributions for $\hat{N}_{2002} / N_{1900}$ suggest that the western gray whale population is currently *at most* between 8-9% of its original size (Table 3.3, Figure 3.7). The $\hat{N}_{2002} / N_{1900}$ posterior distributions were positively correlated with the value of $r_{1997-2002}^{LH data}$ used in model fitting (Figure 3.7). That is, values of $\hat{N}_{2002} / N_{1900}$ were smaller for the lower estimates of $r_{1997-2002}^{LH data}$, meaning that the population is most depleted according to the *conservative* back calculation scenario.

Results of the three back calculations reveal that the western gray whale population is presently highly depleted (Figure 3.7). Interestingly, findings from each of the three back calculations also indicate that the population has been highly depleted (i.e.,

less than 10% of its size in 1900) for over 70 years (Figure 3.8). In other words, the western gray whale population spent over half of the 20th century at extremely low population densities.

DISCUSSION

Growth Rate Estimation

Although variations have been documented, biological and observational data collected when eastern gray whales were recovering have indicated that the population has predominantly adhered to a two-year calving interval (e.g., Rice and Wolman, 1971; Blokhin, 1984; Jones, 1990). Evidence exists that, at least during the late 1980's, pregnancy rates of eastern gray whales have declined (Reilly, 1992). Density dependent mechanisms would suggest that lower pregnancy rates (i.e., increased calving intervals) would be attributed to the population reaching higher densities (e.g., Fowler, 1981). If the reproductive potentials of eastern and western gray whales are comparable, then a maximized reproductive output based on a two-year calving interval would be expected for the low-density western gray whale population. However, the low, medium, and high western gray whale fecundity values used in the growth rate estimation were all based primarily on three-year calving intervals (see Brownell and Weller, 2002 for a potential explanation of the three-year calving interval phenomenon).

Despite the estimates of longer calving interval and reduced calf survival (Chapter 2), the 1997-2002 population growth rate estimates imply that the population was increasing during that time (Table 3.2, Figure 3.1). However, the calculated growth rates

are relatively low compared to estimates from other depleted populations of baleen whales. Best (1993) summarized the growth rates of 10 severely depleted baleen whale populations (i.e., estimated to be less than 10% of their original population size at one time), including one bowhead, four right, one gray (eastern), one blue, and three humpback whale populations. These growth rate estimates ranged from 0.031 to 0.144, but were not necessarily measured when the populations were at their lowest levels. Depletion levels were known for five of the 10 populations, and demonstrated that higher growth rates corresponded to more depleted populations (Best, 1993). Yet, the 1997-2002 growth rates calculated for the severely depleted western gray whale population (i.e., at most between 8-9% of its original size; Figures 3.6-3.7) are markedly lower than the growth rate estimates of the three most depleted populations (i.e., ~3-20% of their initial population level during the observation period) discussed in Best (1993). However, drawing conclusions from this contrast is imprudent, as the growth rate values of these three populations (i.e., one right and two humpback whale populations) have large (or unknown) associated errors (Best, 1993).

A potentially more meaningful comparison can be made between the two gray whale populations. The trajectory of abundance estimates for eastern gray whales showed an annual rate of increase of 0.032 (SE=0.0055) during the period when the population doubled from about 10,000 to 20,000 whales, while maintaining an aboriginal harvest averaging approximately 175 whales per year (Reilly, 1992). Thus, estimates of their maximum net recruitment have ranged from 0.05-0.08 in stock assessments (e.g., Wade, 2002; Wade and Perryman, 2002). The small size of the western gray whale

population implies that they are likely currently growing at their maximum net recruitment rate. Results of the back calculation support this suggestion (Figure 3.2). Yet, the current western gray whale population growth rate estimates (Figure 3.1) are essentially half in value of the range of maximum net recruitment rates attributed to eastern gray whales. This difference in estimated maximum growth rates between the two populations is likely due to varying natural and anthropogenic influences (e.g., prey availability and human-caused mortality, respectively) on individual life history parameters, although the specific causes are unclear. However, given that the 1997-2002 western gray whale population growth rate estimates do include the effect of possible human-caused mortality (e.g., direct catching, entanglement in fishing gear), these values (and thus estimates of r_{MAX}) may be lower than the actual biological maximum growth rate of the population.

Interestingly, genetic evidence predicted that the rate of population increase of western gray whales could be comparatively low. LeDuc *et al.* (2002) detected the presence of 10 haplotypes in biopsy samples of western gray whales, which was higher than expected. In contrast, only five haplotypes have been identified for western North Atlantic right whales, a population estimated to consist of approximately 300 individuals (Malik *et al.*, 2000). A possible explanation for the high retention of haplotypes in western gray whales is that the depleted population has grown much more slowly since 1966 (the last year of reported modern commercial western gray whaling; Brownell and Chun, 1977; Kato and Kasuya, 2002) than recovering eastern gray whales (LeDuc *et al.*, 2002). If the population growth rate of western gray whales had been higher than the

eastern gray whale rate of 0.032, then the western gray whale populations would have been too low in 1996 to have included enough females to maintain 10 haplotypes (LeDuc *et al.*, 2002).

Accounting for uncertainty in the western gray whale life history parameters revealed that some combinations of these values resulted in a negative growth rate (Figure 3.1). A population exhibiting a negative population growth rate is doomed to extinction, unless anthropogenic factors contributing to the population decline (e.g., human-caused mortality, habitat degradation) can be identified and mitigated. Thus, conservation plans for western gray whales should reflect not only the depleted status of the population, but also the possibility that the population is currently declining. Future monitoring will allow for the refined estimation of the life history parameters, which is needed to further investigate the possibility that the population growth rate is not at a replacement level.

Back Calculation

The posterior distributions for r_{MAX} and K resulting from the three western gray whale back calculations were not surprising. As aforementioned, the small population size in conjunction with the model of population dynamics employed was expected to produce a distribution of r_{MAX} similar to the distribution of $r_{1997-2002}^{LH\ data}$ used in the likelihood function of each back calculation scenario (Figures 3.1-3.2). Carrying capacity was expected to be undefined, as the data (i.e., $r_{1997-2002}^{LH\ data}$) used to fit the population dynamics model were measured only when the population was at low densities. Data characterizing the western gray whale population at higher densities are necessary to

make inferences about its carrying capacity. Alternatively, a back calculation in which the initial population size of the projection was assumed to be at a pre-exploitation equilibrium could be attempted. However, for reasons discussed above (e.g., the lack of required historical catch records), this task would currently be unfeasible without making numerous untestable assumptions.

Preliminary analyses exploring the full range of the initial prior distribution for N_{1900} demonstrated that forward projections from higher values could not generate a depleted population in 2002. Increasing the size of the initial samples to ensure that enough reasonable trajectories existed for integration convergence might have mitigated this problem, except that the $r_{1997-2002}$ -based likelihood would not have penalized the unrealistic trajectories. Thus, these trajectories could have still appeared in the resample. Instead, allowing r_{MAX} , K , and N_{2002} to implicitly determine the prior distribution of N_{1900} via the *backwards* method (Butterworth and Punt, 1995) was a more appropriate and successful solution. An examination of the posterior distributions for N_{1900} illustrates the utility of the *backwards* method. That is, only a small range of values within the lower portion of the original N_{1900} prior distribution were able to produce a depleted 2002 population in conjunction with the incorporated values of $r_{1997-2002}^{LHdata}$ (Figure 3.5).

The posterior distributions for N_{1900} indicate that the western gray whale population likely numbered around 1,000-1,200 individuals in 1900, when intensive modern commercial whaling for gray whales began (Kasahara, 1950; Kato and Kasuya, 2002). Omura (1984) proposed that the population at this time was already substantially

reduced from its original size after sustaining centuries of pre-modern whaling harvests. However, as previously indicated, findings from the back calculations are not able to clarify the degree to which the population in 1900 was depleted from its pre-exploitation level. The estimates of N_{1900} are still important in determining the current status of western gray whales, as associated values of $\hat{N}_{2002} / N_{1900}$ can be regarded as a maximum estimate of current population size relative to K . The posterior distributions for $\hat{N}_{2002} / N_{1900}$ imply that the western gray whale is presently *at most* between 8-9% of its initial population size (Figure 3.7). Note that if the 20th century catches were actually higher than the minimum numbers used in the western gray whale back calculations, then a higher and lower value of N_{1900} and $\hat{N}_{2002} / N_{1900}$, respectively, would have been estimated by the analysis. Additionally, the possibility that the population is even further depleted, potentially down to a size below 1% of its original level, should not be disregarded (Figures 3.4B and 3.6).

Significance

Perhaps the most significant result of the western gray whale back calculation analysis is the implication that the population spent a majority of the 20th century at extremely low population densities (Figure 3.8). The long-term depleted status of western gray whales raises concerns about the negative effects of the population remaining at low densities. Populations at low densities are subject to increased risk of extinction by threatening factors, such as environmental and anthropogenic catastrophes (Gilpin, 1987).

This extinction risk can be compounded by depensation (i.e., the Allee effect; Allee *et al.*, 1949; Dennis, 1989). In depensation, the population growth rate decreases with decreasing population density (see Fowler and Baker, 1991 for a review of population dynamics at low densities). Severe depensation implies the existence of a critical population density, below which the population will go extinct (Courchamp *et al.*, 1999). Factors such as inbreeding depression, demographic stochasticity (e.g., sex-ratio fluctuations), and reduced cooperative interactions (e.g., reproduction, resulting from the inability to find a mate) can lead to depensation (Fowler and Baker, 1991; Courchamp *et al.*, 1999).

Although empirical evidence supports the occurrence of such negative factors associated with low population densities (see Petersen and Levitan, 2001 for a recent review), little evidence of actual depensation exists in the scientific literature. Further, the role of depensation, if any, in the population dynamics of whales is unknown. However, issues relating to depensation should not be ignored, as the associated low-density effects could be enough to slow the recovery of a population, making it more vulnerable to extinction risk (Petersen and Levitan, 2001). Current threats to western gray whales could also inhibit the recovery of the population, increasing its susceptibility to all of the aforementioned low-density population effects (see Chapter 2 and Weller *et al.*, 2002c for discussions of current threats). Disturbances associated with the intensive multinational oil and gas development off the northeastern shelf of Sakhalin Island are of particular concern (Würsig *et al.*, 1999, 2000; Weller *et al.*, 2002c, 2002d).

Using findings of the back calculations to suggest a magnitude to which the recovery of western gray whales is threatened by current threats and low-density factors would be premature. However, the western gray whale back calculation population dynamics model and resulting parameter estimates could provide a framework for a population viability analysis (PVA) (Gilpin and Soulé, 1986), which could be used to compare estimates of the probability of western gray whale extinction. Results of a PVA could be interpreted through the use of a decision analysis, where probabilities of extinction would be presented relative to both alternative states of nature (e.g., r_{MAX}) and alternative anthropogenic actions (e.g., human-caused mortality).

In conclusion, the western gray whale population is small, highly depleted, and has a low population growth rate. Western gray whales are at risk from factors threatening low-density populations, and current threats could compound these risks. These points highlight the timely need for the increased protection, conservation, and management planning of this critically endangered population.

Table 3.1. Annual records of known reproductive western gray whale females photographically identified in the Piltun study area between 1995 and 2002 (no data were collected in 1996). 1 = photographically identified. XX = photographically identified with a calf. 0 = not photographically identified. *n* = the number of calving intervals (highlighted) observed for each female. Records compiled from Brownell and Weller (2002) and Weller *et al.* (2003b).

**n*=2 when observed interval was assumed to represent two intervals.

Table 3.2. Summary of 1997-2002 western gray whale population growth rates (λ -1) resulting from a Monte Carlo simulation of 10,000 trials sampling from associated distributions for life history parameters, including a low (*conservative*), medium (*intermediate*), and high (*liberal*) estimate of calving interval (*CI*).

<i>CI</i>	λ -1	Median	Standard Deviation	5 th -95 th Percentiles
3.1 (SE=0.18)	<i>conservative</i>	0.026	0.0190	-0.008-0.054
2.8 (SE=0.18)	<i>intermediate</i>	0.031	0.0194	-0.003-0.061
2.6 (SE=0.15)	<i>liberal</i>	0.036	0.0198	0.001-0.066

Table 3.3. Summary of model parameters (r_{MAX} , K , and N_{1900}) and status indices (\hat{N}_{2002} / K and $\hat{N}_{2002} / N_{1900}$) resulting from Bayesian back calculations of western gray whales using the SIR algorithm ($n_1=2,000,000$; $n_2=5,000$), incorporating the *conservative*, *intermediate*, and *liberal* estimates of 1997-2002 population growth rate ($r_{1997-2002}^{LH \text{ data}}$) into the likelihood function.

$r_{1997-2002}^{LH \text{ data}}$	Scenario	Parameter	Posterior Median	5 th -95 th Percentiles
0.026 (SD=0.0190)	<i>conservative</i>	r_{MAX}	0.028	0.005-0.058
		K	10,789	2,548-19,093
		N_{1900}	1,216	799-1,769
		\hat{N}_{2002} / K	0.009	0.005-0.038
		$\hat{N}_{2002} / N_{1900}$	0.080	0.054-0.123
0.031 (SD=0.0194)	<i>intermediate</i>	r_{MAX}	0.033	0.006-0.064
		K	10,919	2,487-19,089
		N_{1900}	1,137	744-1,739
		\hat{N}_{2002} / K	0.009	0.005-0.039
		$\hat{N}_{2002} / N_{1900}$	0.086	0.056-0.133
0.036 (SD=0.0198)	<i>liberal</i>	r_{MAX}	0.037	0.009-0.069
		K	10,953	2,541-19,031
		N_{1900}	1,071	693-1,666
		\hat{N}_{2002} / K	0.009	0.005-0.039
		$\hat{N}_{2002} / N_{1900}$	0.091	0.058-0.142

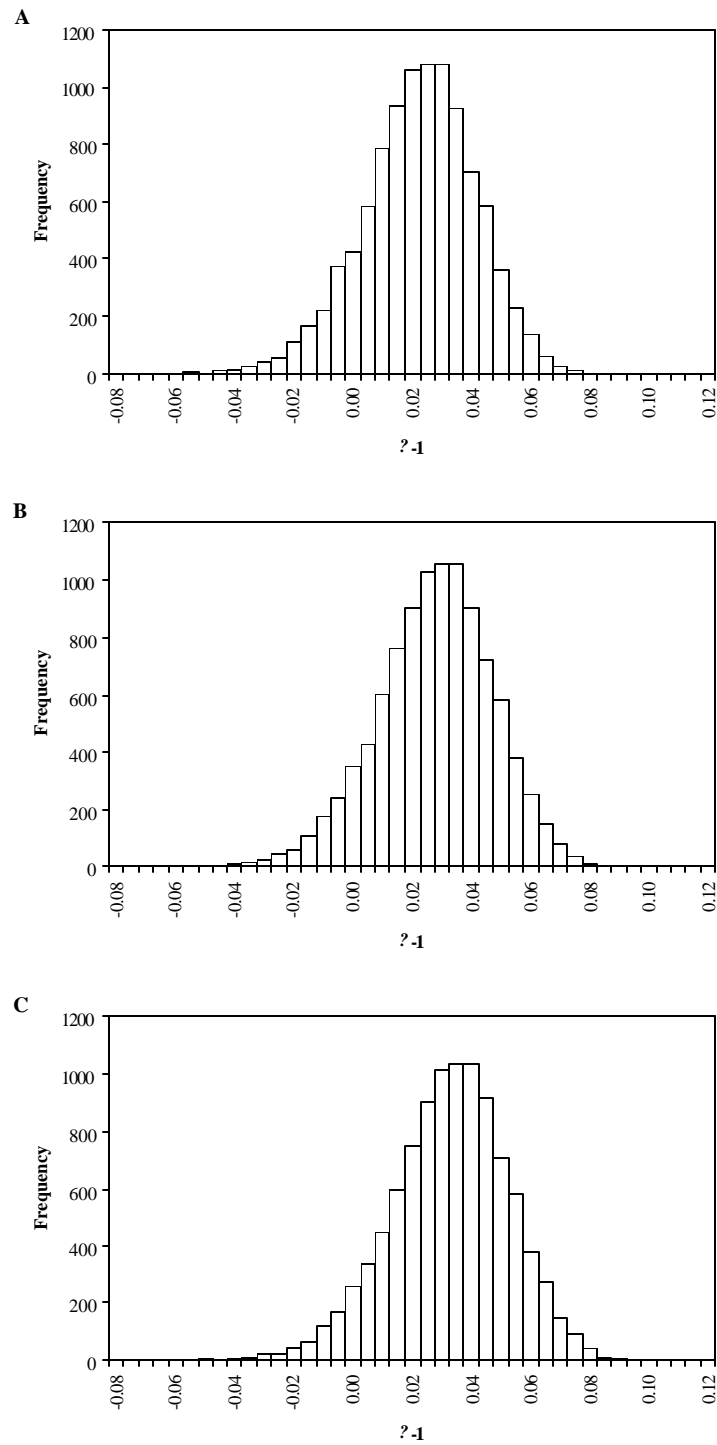

Figure 3.1. Histogram of values for the *conservative* (A), *intermediate* (B), and *liberal* (C) estimates of 1997-2002 population growth rate ($\lambda-1$).

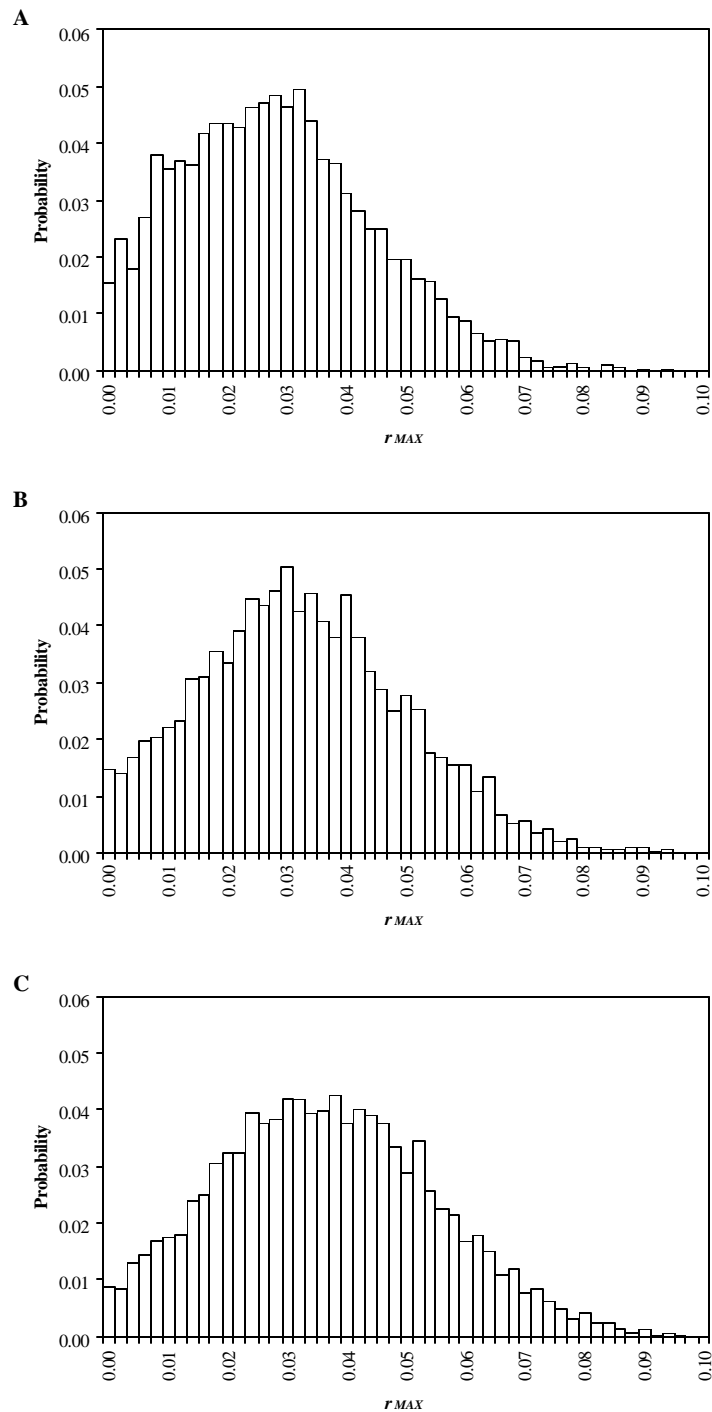

Figure 3.2. Posterior probability distributions for maximum net recruitment rate (r_{MAX}) resulting from back calculations using the *conservative* (A), *intermediate* (B), and *liberal* (C) estimates of 1997-2002 population growth rate.

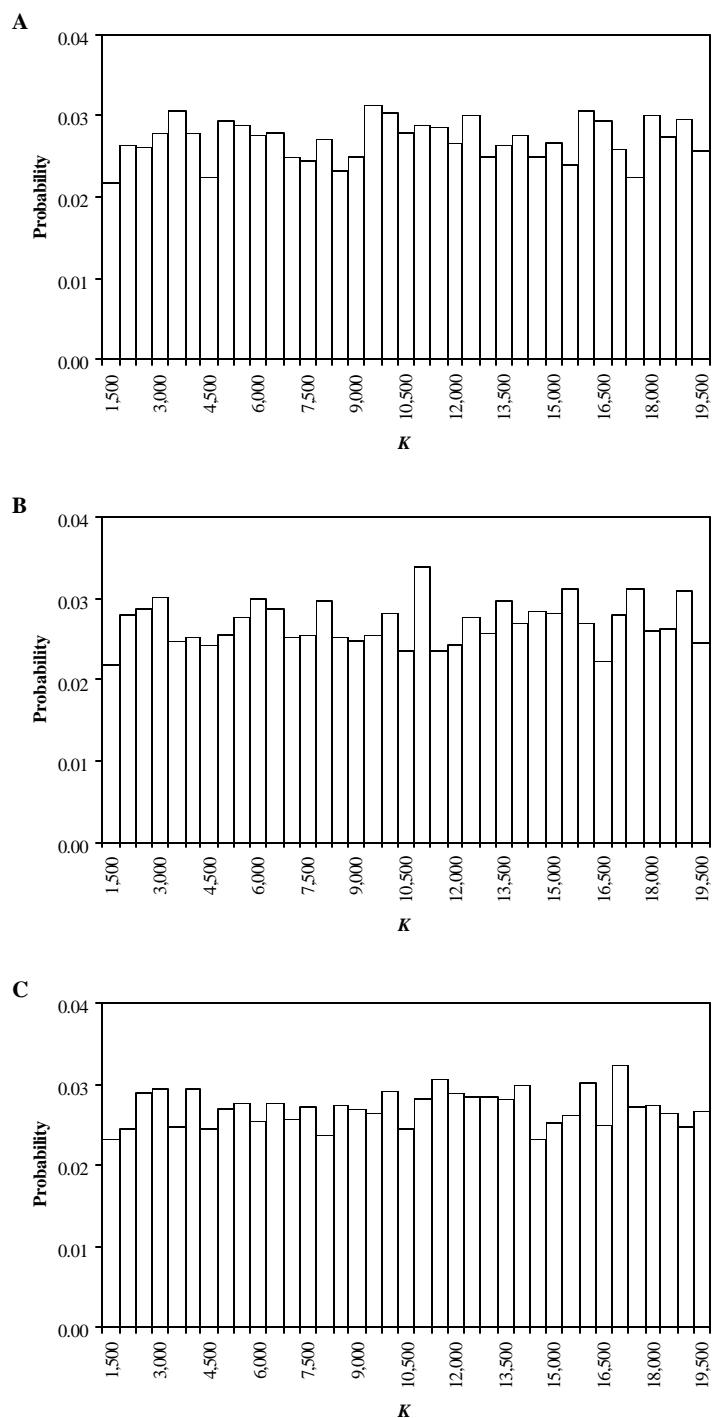

Figure 3.3. Posterior probability distributions for carrying capacity (K) resulting from back calculations using the *conservative* (A), *intermediate* (B), and *liberal* (C) estimates of 1997-2002 population growth rate.

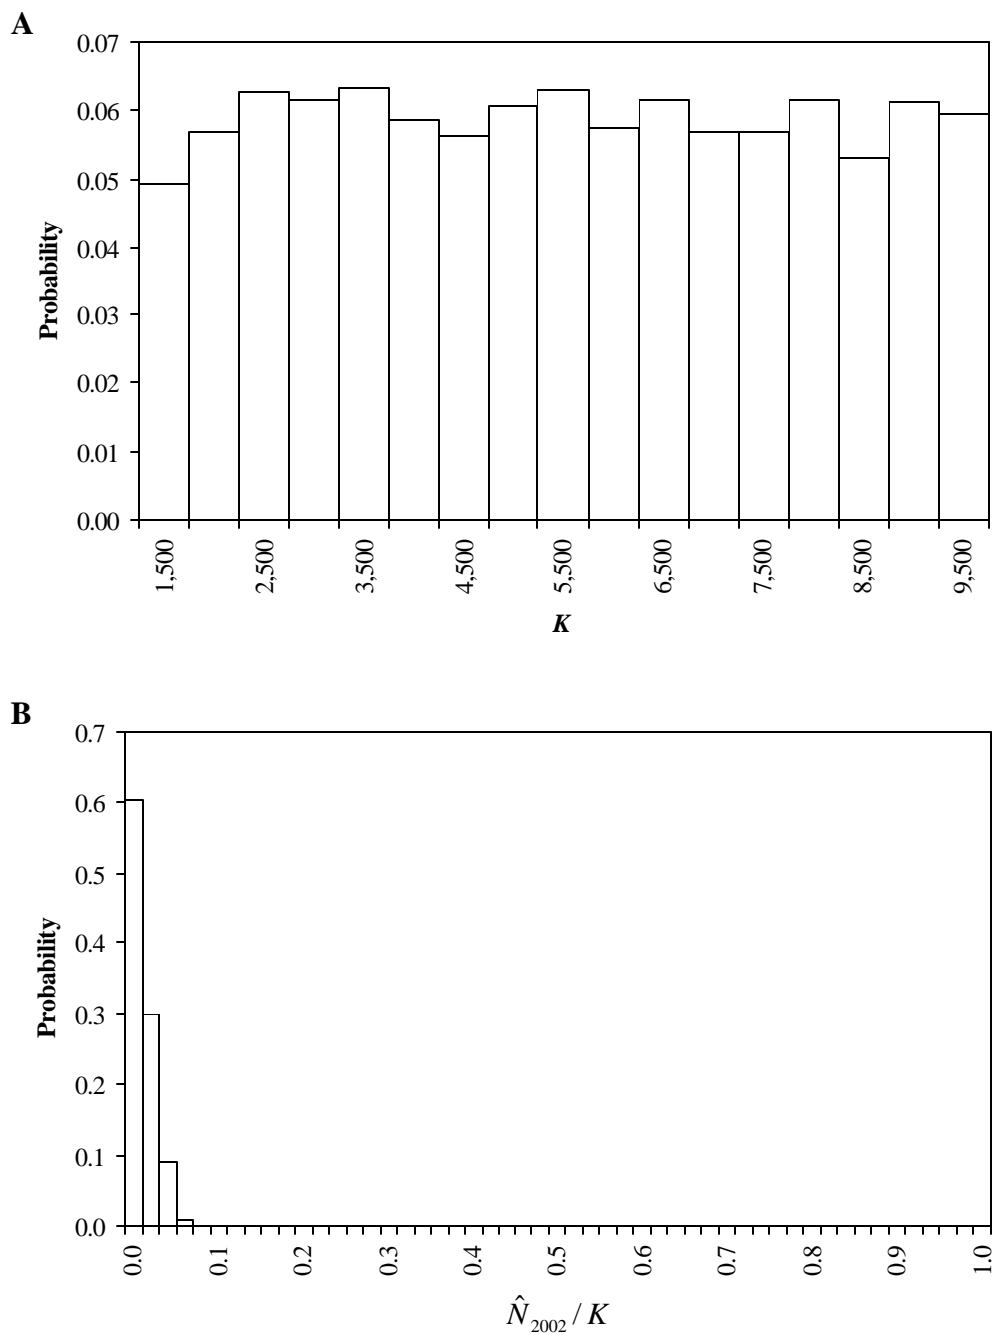

Figure 3.4. Posterior probability distributions for carrying capacity (K) (A) and a status index (\hat{N}_{2002} / K) (B) resulting from a back calculation using a prior distribution for K of $U(1,500, 10,000)$ and the *intermediate* estimate of 1997-2002 population growth rate.

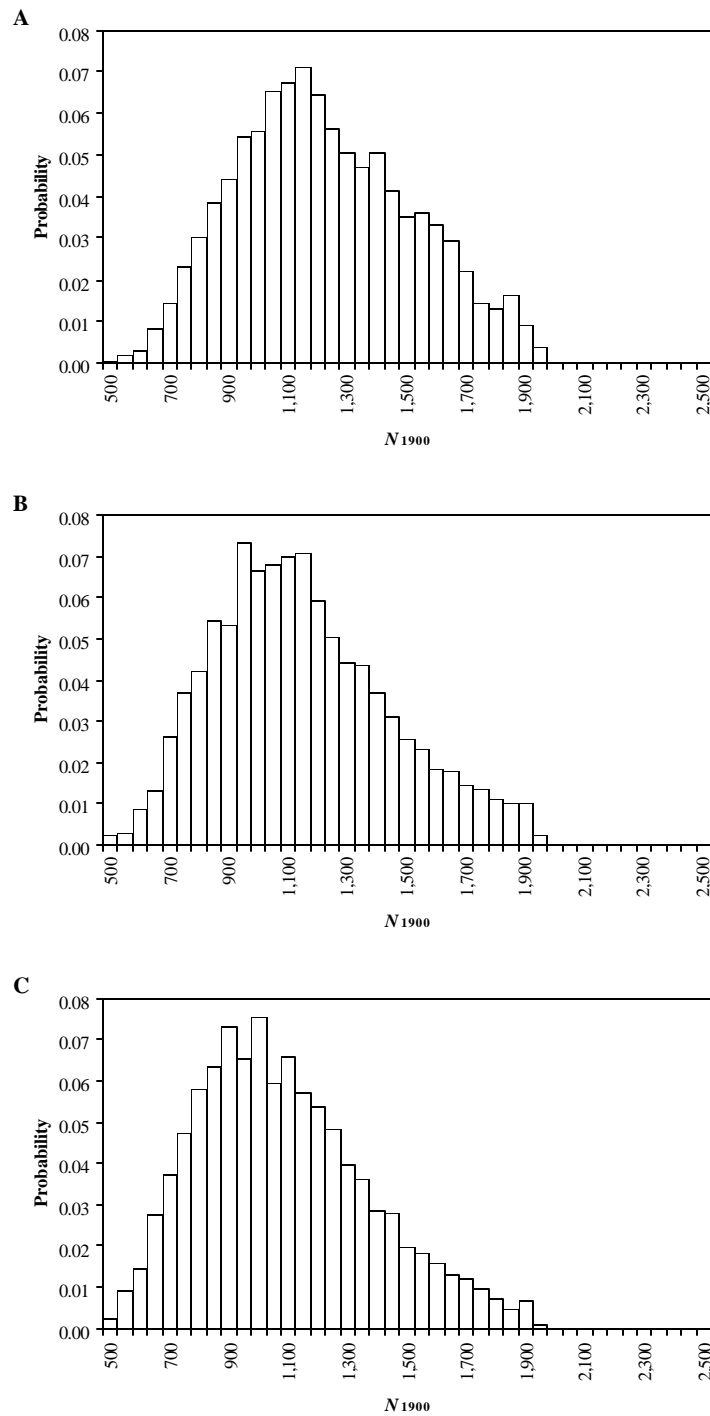

Figure 3.5. Posterior probability distributions for population size in 1900 (N_{1900}) resulting from back calculations using the *conservative* (A), *intermediate* (B), and *liberal* (C) estimates of 1997-2002 population growth rate.

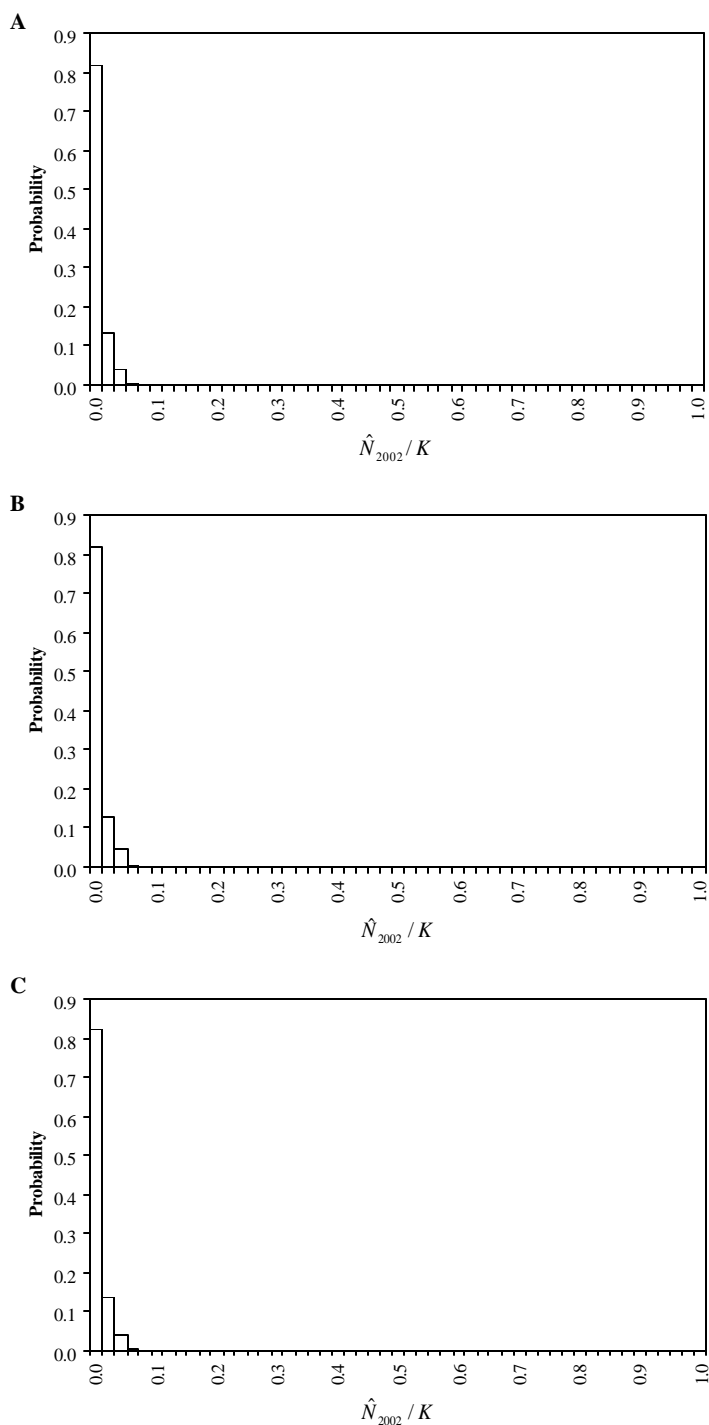

Figure 3.6. Posterior probability distributions for a status index (\hat{N}_{2002} / K) resulting from back calculations using the *conservative* (A), *intermediate* (B), and *liberal* (C) estimates of 1997-2002 population growth rate.

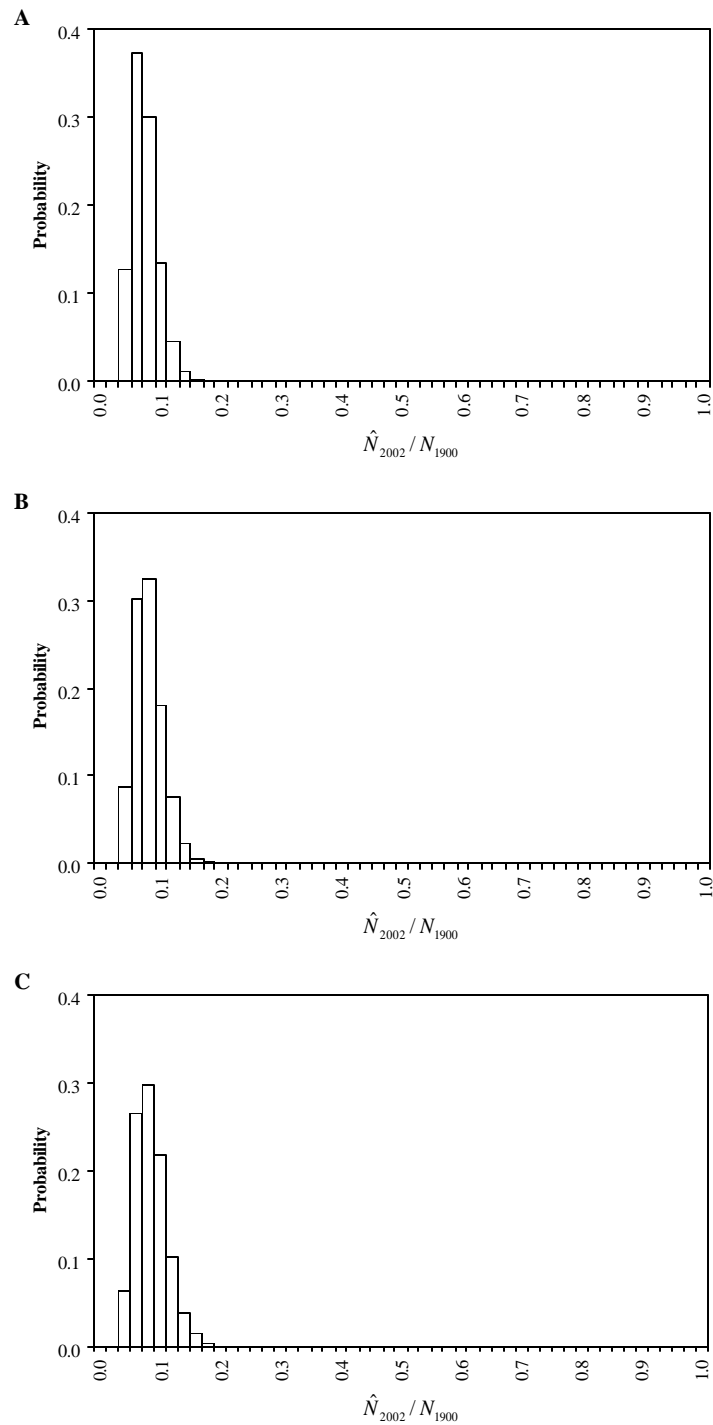

Figure 3.7. Posterior probability distributions for a status index ($\hat{N}_{2002} / N_{1900}$) resulting from back calculations using the *conservative* (A), *intermediate* (B), and *liberal* (C) estimates of 1997-2002 population growth rate.

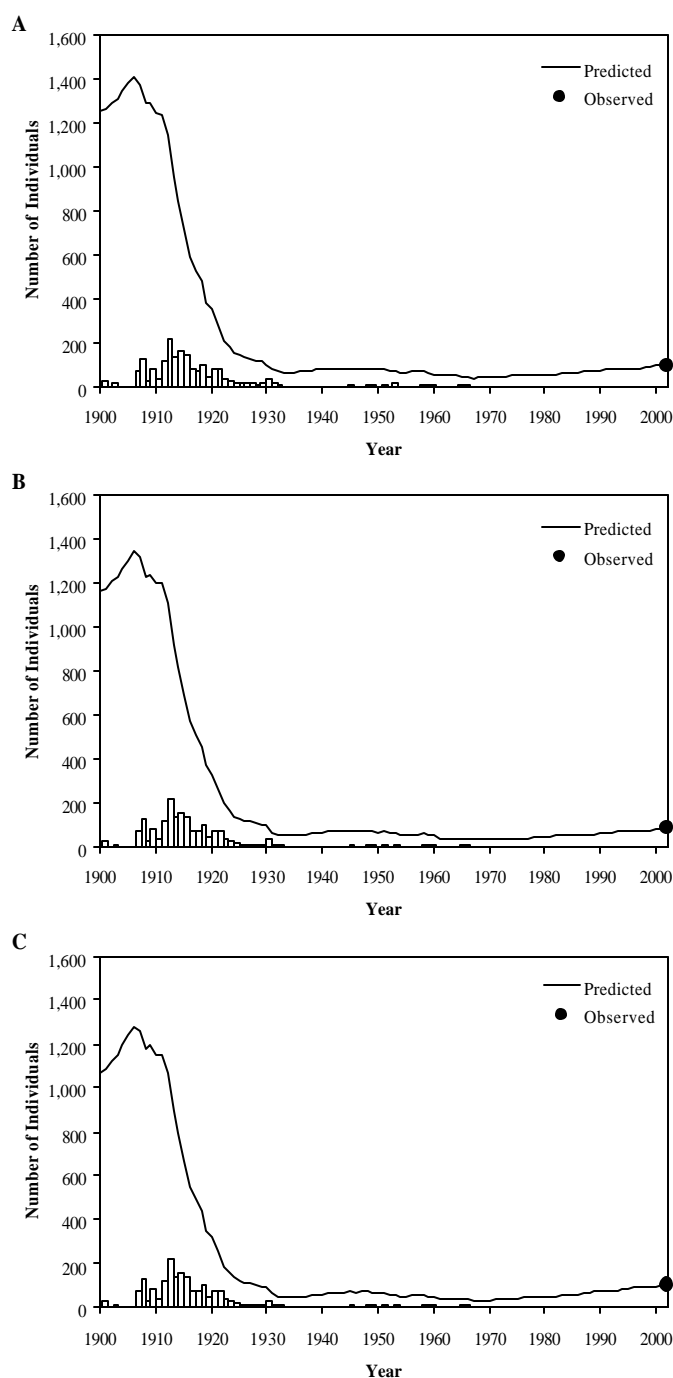

Figure 3.8. Twentieth century population projections resulting from back calculations using the *conservative* (A), *intermediate* (B), and *liberal* (C) estimates of 1997-2002 population growth rate. Predicted = the population dynamics model trajectory with the highest likelihood in the resample. Observed = the 2002 population size used in the *backwards* method. Bars = the minimum numbers of whales caught during the 20th century.

Appendix B Monthly encounter histories of western gray whales photographically identified from 1997 to 2002 off Piltun Lagoon, Sakhalin Island, Russia. 1 = photographically identified. 0 = not photographically identified. Whale identification (ID) numbers of whales first identified as calves are italicized. *n* = the number of monthly photo-identification surveys. Encounter histories compiled from Weller *et al.* (1999, 2000, 2001, 2003a, 2003b) and Würsig *et al.* (1999, 2000).

Appendix C. Pseudocode outlining the Monte Carlo simulation procedure used for the western gray whale 1997-2002 population growth rate estimation.

- 1) Specify the distributions for the life history parameters (f_{calf} , $f_{non-calf}$, CI , and ASM), the maximum age class (w), and the number of samples in the simulation (n).
- 2) Draw values of f_{calf} and $f_{non-calf}$ from their distributions, and determine the l_x schedule (Equation 3.3).
- 3) Select values from the distribution of CI and ASM , and compute the m_x schedule (Equation 3.4).
- 4) Use Equation 3.1 to find the population growth rate (?) that characterizes the selected life history parameters.
- 5) Store the set of life history parameters and the resulting growth rate estimate.
- 6) Repeat Steps 2-5 until a sample size of n is generated.

Appendix D. Pseudocode outlining the Bayesian statistical method used for the 20th century western gray whale back calculation.

- 1) Specify the data ($r_{1997-2002}^{\text{LH data}}$), the prior distributions for the model parameters (r_{MAX} , K , and N_{1900}) and the 2002 abundance estimate (N_{2002}), and the number of initial samples (n_1) and resamples (n_2).
- 2) Draw a value of r_{MAX} , K , and, N_{2002} from their joint prior distributions.
- 3) Given these parameters, determine if a value of N_{1900} exists within its prior distribution that would produce a reasonable \hat{N}_{2002} . If so, implement the *backwards* method by using a bisection approach to find the value of N_{1900} such that \hat{N}_{2002} is as close as possible to N_{2002} . If not, penalize the parameter set and proceed to the next sample (Step 2).
- 4) Use Equation 3.5 to project the population from 1900 to 2002 according to the selected parameters.
- 5) Estimate $r_{1997-2002}^{\text{model}}$ (Equation 3.7) and the two status indices (\hat{N}_{2002}/K and \hat{N}_{2002}/N_{1900}).
- 6) Calculate the likelihood of the parameters using the likelihood function (Equation 3.8).
- 7) Store the set of parameters, status indices, and associated likelihood.
- 8) Repeat Steps 2-7 until an initial sample of size n_1 is generated.
- 9) With probability equal to weight q_i , resample the initial sample with replacement n_2 times, thus approximating the joint posterior distributions of the parameters and status indices.

previously suspected. This species may then be expected to be found (at least in canyon bottoms) at 1770 m and above throughout the entire area of the Animas Mountains but further collecting will be necessary to demonstrate validity of this expectation. It is further suggested that *T. umbrinus* may occur in New Mexico above 1770 m (5800 ft) south of San Luis Pass in the San Luis Mountains, and from there south into the state of Chihuahua, Mexico.

We are grateful to the New Mexico Department of Game and Fish for granting us permission to collect *Thomomys umbrinus* (permit no. 1055S); to Mr. Robert Burris, Manager of the Gray Ranch, for granting us permission to enter the Animas Mountains; to Mr. Wes Bonsell, U. S. Fish & Wildlife Service for assisting us in obtaining permission to enter this area; and to Mr. Bret Thaeler for field assistance. The Department of Biology, New Mexico State University, provided support for this work.

PROBABLE EXISTENCE OF THE KOREAN STOCK OF THE GRAY WHALE (*ESCHRICHTIUS ROBUSTUS*)

Two geographically isolated populations of gray whales, *Eschrichtius robustus*, are known in the North Pacific—the eastern Pacific or California stock, and the western Pacific or Korean stock (Rice and Wolman, 1971; Tomilin, 1967). The range of the Korean stock is from the Sea of Okhotsk to the southern shores of the Republic of Korea (Tomilin, 1967; Andrews, 1914). Rice and Wolman (1971) reviewed the history of commercial exploitation of the Korean stock. Mizue (1951) reported that the last catch from this stock was a single whale taken in 1933 off the eastern coast of Korea, and concluded that the stock was extinct. Bowen (1974) summarized his recent negative findings and also concluded that the stock was probably extinct. The purpose of this note is to review and report recent catches and observations on western Pacific gray whales.

Chun examined six gray whales landed at Ulsan, Korea in 1948. The date of capture, size, and sex of these were as follows: 1 January, 37 feet (ft) (11.3 meters, m), female; 3 January, 33 ft (10.1 m), female, and 42 ft (12.8 m), male; 5 January, 40 ft (12.2 m), male; 8 January, 42 ft (12.8 m), male; and 11 January, 40 ft (12.2 m), male.

Gray whales landed at Ulsan and reported to Chun were the following: 1945–1947, 0; 1948, 9; 1949, 4; 1950, 0; 1951, 7; 1952, 1; 1953, 7; 1954–1957, ?; 1958, 7; 1959, 7; 1960, 8; 1961, 3; 1962, 0; 1963, 2; 1964, 3; 1965, 4; 1966, 5; 1967–1975, 0. Between 1948 and 1966 at least 67 gray whales were taken in South Korean waters. However, the absence of catch reports between 1967 and 1975 does not necessarily indicate that no gray whales were taken.

The last sighting of this species in Korean waters was a female with a calf near Yokji Island (34°40'N, 128°15'E) in May 1968. This observation was reported to Chun by a Korean whaler. During recent research cruises in the Sea of Okhotsk, four gray whales were observed in Tugursk Gulf in June 1967 (Berzin, 1974), but in August 1974 only a single gray whale was observed (Berzin and Kuz'min, 1975; Kuz'min and Berzin, 1975).

Bowen (1974) considered that three gray whales recorded in the western Pacific should be regarded as strays from the California stock and not survivors of the Korean stock. These records are as follows: one taken off Otomae (Shiashkotan Island) in the northern Kuril Islands in 1942 (Mizue, 1951); the other two off the southeast coast of Honshu, Japan at 33°29'N, 135°55'E and 33°43'N, 136°02'E in 1959 and 1968, respectively (Nishiwaki and Kasuya, 1970). Nishiwaki and Kasuya (1970) reported that their 1968 specimen had nasal bones that were fused and similar in shape to a skull from California illustrated by Andrews (1914). However, nothing is known about individual variation in either stock and they noted that more specimens need to be examined before any conclusion can be reached.

A consideration of older Japanese records suggests that the whales noted by Bowen (1974) were not outside the normal migratory path and thus probably belong to the Korean stock. Mizue (1951) reported that four gray whales were killed in 1914 along the northern Pacific coast of Japan, one off Nemuro, eastern Hokkaido, and three off Ayukawa, Miyagi Prefecture, Honshu. Omura (1974) has summarized records from the coasts of Wakayama, Kochi (Shikoku), Yamaguchi, and Kyushu, and hypothesized that the Seto Inland Sea was a calving ground for the Japanese substock of western Pacific gray whales. The migration route to and from the Seto Inland Sea was probably along the east coast of Japan from the Kuril Islands (Nishiwaki and Kasuya, 1970; Omura, 1974). Japanese gray whales were nearly exterminated by the end of the 19th century (Nishiwaki and Kasuya, 1970) and/or driven out of the Seto Inland Sea because of increased industrial development and ship traffic (Omura, 1974).

We believe, because of the above reports and observations, there is no reason to think that any of the recent gray whales from the western Pacific should be regarded as vagrants from the California stock. The Korean stock of gray whales probably still exists in small numbers. Whether this stock is below its "critical population size" is unknown, but the continued small catches during this century have probably prevented any recovery. The western Pacific stock is not accorded complete protection by the regulations of the International Whaling Commission because several nations which may exploit it (People's Republic of China, Democratic People's Republic of Korea, and the Republic of Korea) are not signatories to the International Convention for the Regulation of Whaling, 1946. Even under the Convention the taking of gray whales is permitted by aborigines of the Contracting Governments when the meat and products of such whales are to be used exclusively for local consumption. Therefore, we believe the western Pacific stock of gray whales will become extinct in the near future unless meaningful international protection is achieved.

Acknowledgments.—We are especially grateful to Drs. T. Kasuya, K. Mizue, M. Nishiwaki, S. Ohsumi, H. Omura, and D. W. Rice for their discussions with us on western Pacific gray whales. We also wish to thank Dr. R. S. Hoffmann for translating various Russian papers for us.

BURROWING IN WILD AND DOMESTIC NORWAY RATS

The burrowing behavior of the wild Norway rat has been studied by Pisano and Storer (J. Mamm., 29:374-383, 1948) and Calhoun (Ecology and Sociology of the Norway Rat, pp. 15-54, 1962). This behavior is of obvious importance to animals living in nature but of little consequence to Norway rats maintained in captivity. The following study tests the hypothesis that the propensity of the Norway rat to burrow has been significantly reduced during the process of domestication.

A total of 35 wild and 26 domestic Norway rats were used in the present study. Ten male and 16 female wild rats were born and reared in captivity by 21 pairs of field-trapped parents. In addition, nine adult males trapped in two different locations in the Syracuse, New York, area were tested after being in captivity a minimum of 24 days (range = 24-163 days). Ten male and 13 female domestic subjects were of Long Evans hooded stock representing the offspring of 10 breeding pairs. The remaining three females were Sprague-Dawley albino subjects. All subjects (except for field-trapped rats) were reared and maintained in 35.6 by 35.6 by 17.8 centimeter (cm) wire-bottom cages prior to testing, precluding early digging experience. All animals were fed "Charles River Rat and Mouse Diet" and water *ad libitum*. Ages and weights of the subjects at the start of testing are presented in Table 1.

Subjects were individually placed in burrowing chambers with 91.4 by 76.2 by 0.64 cm plate glass sides held 21.6 cm apart by plywood ends and base. Chambers were filled with commercial ("Sunshine"), fumigated organic topsoil to a depth of about 50 cm. A wire mesh lid prevented the animals from escaping and removable black polyethylene plastic sheets covered the plate glass sides. Food and water were provided *ad libitum*. Temperature in the experimental room varied from 20 to 22°C and an artificial light:dark cycle of 14:10 was maintained. Burrowing chambers were checked daily for 4 consecutive days between 1500 and 1700 hours. Because rats usually tunneled along the plate glass wall, removal of the black plastic sheets revealed the nature of the burrows constructed. Side and top views of the burrow system were recorded daily using a grid painted on the glass as a reference. Existing tunnels were destroyed only after the 4-day test period was terminated. The topsoil in each apparatus was changed after every third animal had been tested.

Significantly more wild rats dug burrows than domestic rats (Table 1) during the 4-day test period ($\chi^2 = 10.5$, $df = 1$, $P < .001$). Although wild females exhibited more burrowing activity than domestic females ($\chi^2 = 6.12$, $df = 1$, $P < .02$) laboratory-reared wild males did not differ significantly from their domestic male counterparts (Fisher Exact Probability Test; Siegel, Non-Parametric Statistics, pp. 96-104, 1956). However, because field-trapped males tended to burrow more than laboratory-reared wild males and domestic males did not burrow at all, a Chi-square test including all three male groups proved significant ($\chi^2 = 9.8$, $df = 2$, $P < .01$).

Laboratory-reared female wild rats dug more burrows than their lab-reared male counterparts (Fisher Exact Probability Test, $P < .05$) but male and female domestic stocks did not differ significantly (F.E.P. Test) even though females were the only domestic rats to burrow.

The western gray whale population is distinct: a response to SC/61/BRG22

Brownell, R.L., Jr.¹, Lang, A.R.¹, Burdin, A.M.^{2,3}, Bradford, A.B.⁴ and Weller, D.W.¹

³ Alaska Sealife Center, Seward, Alaska, USA

⁴ School of Aquatic and Fishery Sciences, University of Washington, Seattle, Washington, USA

The western gray whale population was depleted to such low levels by commercial whaling that some considered it extinct (Mizue, 1951; Bowen, 1974). As such, gray whales sighted in the western Pacific after the 1930s were, for a period of time, considered to be strays or vagrants from the eastern stock (Nishiwaki and Kasuya, 1970). The publication of reports of catches off the coast of Korea through the first half of the 1960s (Brownell and Chun, 1977), as well as an increased number of sightings off Russia and Japan after that time (Nishiwaki and Kasuya, 1970; Berzin, 1974), eventually caused this hypothesis to be re-evaluated and replaced by the suggestion that a small remnant population of western gray whales remained throughout the 20th century.

Most of what is known today about western gray whales comes from ongoing studies since 1995 of feeding animals off the northeastern shelf of Sakhalin Island, Russia. These studies show that whales photographically identified off Sakhalin have strong site fidelity and return annually to this area; this is particularly true of females with calves (Weller *et al.*, 1999). In addition, information gained via biopsy sampling of individuals off Sakhalin has shown them to be genetically distinct from the eastern population (Lang *et al.*, 2008a). More recent observations of western gray whales in regions potentially visited by animals from both the eastern and western North Pacific (e.g. the waters off eastern Kamchatka), however, have once again raised questions about the degree to which Sakhalin gray whales are from those in the eastern Pacific as illustrated by paper SC/61/BRG22.

SC/61/BRG22 suggests that the current population of western gray whales is derived from eastern gray whales. It is disappointing that the author of this paper does not offer any data or references to support the conclusions drawn nor does the paper take into account the rather substantial body of work comparing eastern and western gray whales using both mtDNA and microsatellite makers (LeDuc *et al.*, 2002; Lang *et al.*, 2008a, 2008b). Similarly, the extensive discussions regarding this topic, as reported in numerous reports of the IWC SC and IUCN have also been ignored.

That being said, the idea that the western gray whale population is derived from the eastern population is not a new idea. Nishiwaki and Kasuya (1970) suggested that a specimen from Japan killed by local fishermen had some similar characteristics to eastern gray whales. Here we provide a partial review of information gained from sightings and genetic data which addresses the question of gray whale population differentiation:

1. The observation offered in SC/61/BRG22 that sightings of gray whales off Sakhalin became more common during a time when the eastern gray whale population was increasing is used to suggest that the feeding ground off Sakhalin was established in part as a result of range expansion of the eastern population.
 - a. The last known catches off Korea continued through the 1960s confirming the existence of the population (Brownell and Chun, 1977). Some records of gray whales off Russia, Japan, and Korea exist for the 1960s and 1970s (reviewed in Brownell and Weller 2008). A few sightings of western gray whales were reported from the western Okhotsk Sea in the 1960s but these observations are not well known because they were reported only in Russian (e.g. Berzin, 1974).

Aerial observations of a small number of whales off the northeastern coast of Sakhalin began in the early 1980s (Blokhin *et al.* 1985, Berzin *et al.* 1990); concerted boat-based studies in that area starting in 1995 have documented continued use of the northeastern Sakhalin area by western gray whales (see Weller *et al.*, 2008a). An increase in the number of reported sightings, strandings, and entanglements of gray whales off Japan also started in the 1980s, and records have become more frequent since then (reviewed in Koya *et al.*, 2008). It therefore seems most likely that sightings of gray whales in the western Pacific during the 1960s and 1970s were representative of a small number of animals that survived extirpation from commercial whaling and that this population has been increasing slowly.

- b. Both mtDNA and bi-parentally inherited microsatellite markers (n=14) have now been used to measure differentiation between eastern and western gray whale populations as well as to compare levels of nuclear genetic diversity retained in each (LeDuc *et al.*, 2002; Lang *et al.*, 2008b). Mean levels of genetic diversity were similar between the eastern and western populations, suggesting that significant amounts of nuclear genetic diversity have not yet been lost in the small western population. Comparison of microsatellite allele frequencies confirmed that eastern and western populations are genetically distinct ($p < 0.001$).
 - c. The whale entrapped in a set net in Yoshihama Bay, Japan in 2007 was photographically matched to an animal first identified as a calf off Sakhalin in 2006, providing a confirmed link between the Sakhalin feeding ground and a migratory corridor off Japan (Weller *et al.*, 2008b). A genetic sample was collected from this whale during the 2006 field season off Sakhalin. Although this whale has a haplotype that is common in both eastern and western sample sets, genetic assignment tests group her (and her mother) with the western cluster of animals. As well, paternity testing assigns this whale a putative father that has been repeatedly identified off Sakhalin; this male is also the putative father of two other calves first identified off Sakhalin. By establishing a connection between the entrapped whale and other whales utilizing Sakhalin, this genetic information adds further support for the link between the feeding ground off Sakhalin and the migratory corridor off the eastern side (Pacific) of Japan.
2. Recent sightings of Sakhalin gray whales in areas potentially utilized by animals from the eastern population (eastern Kamchatka) are used in SC/61/BRG22 to suggest that animals feeding off Sakhalin are part of the eastern population.
- a. The lack of sighting and photo-identification effort off Kamchatka until recent years makes it difficult to assess whether use of this area by Sakhalin gray whales is a new phenomenon or simply was previously undiscovered. If the appearance of Sakhalin whales off eastern Kamchatka represents a recent range expansion of western gray whales (potentially recolonization of areas previously used) it would be consistent with similar shifts in the distribution of feeding eastern gray whales and may be driven by ecological factors. Alternatively, it is also possible that sources of anthropogenic disturbance from oil and gas development activities on or near the Sakhalin feeding ground have displaced whales from, or worse yet, indicates abandonment of what has traditionally been a critical feeding habitat (especially for mother-calf pairs) for the population (Weller *et al.*, 2008a).
 - b. The sample set used in the genetics studies by Lang *et al.* (2008b) includes 12 samples from gray whales taken in the hunt off Chukotka in 1994. The mtDNA haplotypes of these animals are all haplotypes either found only among the eastern samples or found in higher frequencies in the eastern sample set. Assignment tests group all of these animals with the eastern cluster (although one animal's assignment is somewhat equivocal), suggesting that the gray whales using this region are primarily eastern animals.

- c. A genetic sample was collected from a gray whale in August 2004 on the eastern side of the Kamchatka peninsula. This animal was identified as a female and her genotype did not match that of any other sampled animals. The genotype of this sample had a higher probability of belonging to the western population than to the eastern population, supporting photo-identification studies that have shown that some western gray whales use this area during summer months.
- d. Although understanding movements of animals between feeding grounds has important implications for management and conservation, genetic "isolation" is dependent on a lack of interbreeding between groups of animals. As such, even if substantial mixing of eastern and western gray whales occurs in feeding areas, isolation could still be maintained if those animals were returning to different areas to breed (Lang *et al.*, 2008b).

Recommendations for future work to address these issues are:

Satellite tagging – a major gap in our understanding of the western gray whale population and the threats it faces lies in our lack of knowledge about migratory routes and wintering grounds. Satellite tagging may help to address that lack of knowledge and may provide further information on the discreteness of the western gray whale population. The lack of recent sightings in areas south of Japan further supports this need. On this point we agree with SC/61/BRG22.

Photo-identification comparisons of the western gray whale catalogue with those maintained for eastern gray whales might provide an additional line of evidence to further address questions about the isolation of the western population.

Genetic sampling of animals feeding in areas potentially used by both eastern and western animals would be valuable in assessing the stock identity of those individuals.

Genetic analysis of samples obtained from animals entrapped, stranded, or sighted in other areas of the western gray whale's range other than Sakhalin and Kamchatka (e.g. Japan) would provide useful information to determine the relationship of such animals to those identified off Sakhalin. Similarly, if any historic bone or baleen samples from western gray whales exist, genetic analysis could be used to compare genetic diversity between historic and current western gray whales.

Acknowledgments

We would like to thank the numerous people who have provided assistance to the Russia-U.S. team in the field, especially: S. Blokhin, Y. Ivashchenko, H.W. Kim, S. Reeve and G. Tsidulko. And, we gratefully acknowledge the thoughts of Justin Cooke, Toshio Kasuya and Randy Reeves. Support granted to the Russia-U.S. team came from (in alphabetical order): Alaska SeaLife Center, International Fund for Animal Welfare, International Whaling Commission, Ocean Park Conservation Foundation, University of Washington, U.S. Marine Mammal Commission and the U.S. National Marine Fisheries Service. Fieldwork in Russia was conducted as part of the Marine Mammal Project under Area V: Protection of Nature and the Organization of Reserves within the U.S.-Russia Agreement on Cooperation in the Field of Environmental Protection. We also wish to thank R. R. Reeves for providing useful suggestions to a draft of this paper.

Gray whales (*Eschrichtius robustus*) in the Western Pacific are critically endangered, whereas in the Eastern Pacific, they are relatively common. Holocene environmental changes and commercial whaling reduced their numbers, but gray whales in the Eastern Pacific now outnumber their Western counterparts by more than 100-fold. Herein, we investigate the genetic diversity and population structure within the species using a panel of genic single nucleotide polymorphisms. Results indicate the gray whale gene pool is differentiated into two substocks containing similar levels of genetic diversity, and that both our Eastern and Western geographical samples represent mixed-stock aggregations. Ongoing or future gene flow between the stocks may conserve genetic diversity overall, but admixture has implications for conservation of the critically endangered Western gray whale.

1. Background

The gray whale (*Eschrichtius robustus*) is considered to consist of two stocks defined by the location of feeding and breeding grounds [1]. Western gray whales exist along the Asian Pacific coast and the Eastern gray whales populate the North American coastline, each presumably migrating to separate breeding and feeding areas [2]. The Western stock is now listed as *critically endangered*, whereas the Eastern stock is of *least concern* [3]. Both experienced population decline during the mid-Holocene [4] and were extensively harvested during commercial whaling [5,6]. The Eastern stock now numbers approximately 27 000 individuals [6], but the Western stock is approximately 200 individuals [7]. Satellite tagging and photo identification have revealed long-distance movements between the Western and Eastern Pacific [7,8], suggesting that stock structure may be more complex than a simple east–west divide [7,8]. Presumptively neutral genetic markers have shown low differentiation between eastern and western sampling locales [9,10], and given the critically endangered status of the Western stock, such movements and associated gene flow could prove extremely beneficial by counteracting genetic erosion [11].

We genotyped a panel of 95 single nucleotide polymorphisms (SNPs) using skin biopsies of gray whales from the Eastern and Western Pacific to assess genetic diversity and population structure (figure 1). We were particularly

Figure 1. Sampling locations for the gray whales obtained near Sakhalin Island, Russia, and off the coast of Baja, Mexico.

interested in whether the gene pool was geographically partitioned and if there was evidence of admixture. Our results indicate that: (i) two substocks with similar levels of functional genetic diversity exist; (ii) the pronounced differentiation within the gray whale gene pool is not predicted by simple geography; and (iii) genetic signatures indicate that some individuals were admixed.

2. Material and methods

(a) Genetic diversity

Tissue biopsy samples were collected between 2011 and 2016 using a 150 lb draw weight compound crossbow (Barnett RC-150) with 40 mm by 7 mm internal diameter tips arrows [12]; 77 were sampled near Sakhalin Island (Russia) summer feeding grounds and 135 near the Mexican winter breeding grounds (figure 1) [2]. Following DNA extraction, we genotyped samples using SNPs in or near genes of functional importance, including osmoregulation, thermoregulation and oxygen delivery [13]. We removed samples with more than 20% missing data and loci with more than 25% missing data before using Allelematch v. 2.5 [14] to identify potential replicate samples [15].

Observed (H_O) and expected (H_E) heterozygosity and the inbreeding coefficient (F) were quantified in Genodive v. 2.0b [16]. Statistical departures from equilibrium were assessed using 10^3 bootstraps. We used Demerelate [17] to calculate Blouin's genetic similarity measure (M_{xy}) [18], which is independent of population size. Differences in mean M_{xy} were assessed with a Welch two-sample t -test and Fisher's exact test was used to test for heterozygote excess or deficiency.

(b) Population structure

We used four complementary approaches to characterize genetic structure: F_{ST} [19], Jost's D [20], discriminant analysis of principal components (DAPC) [21] and admixture analysis [22,23]. Significant differentiation for the F -statistics was assessed using a log-likelihood ratio test (G) [24]. DAPC was performed in adegenet v. 2.1.0 [24] by transforming SNP data to principal components followed by discriminant analysis. Admixture analysis was conducted with LEA v. 1.6.0 [25] and Structure

v. 2.3.4 [23]; they yielded qualitatively similar results, so only the Lea results are reported. We did not purge putative siblings to avoid bias [26]. We evaluated clusters (K) from 1 to 6 and used the Bayesian information criterion and tested the robustness of our population structure inference by subsampling data (electronic supplementary material, S1) [27]. To assess the potential of hierarchical structure, we also ran the admixture analyses for sampling locations separately.

To infer recent migration rates between the two sampling locations, we used BayesAss v. 3.0 [28]. Migrants and their recent descendants were identified based on transient disequilibrium at individual multi-locus genotypes. A Monte Carlo Markov Chain (MCMC) of length 5×10^6 with sampling every 2×10^3 iteration was used, with the first 10% removed as burn-in. Delta values, which describe the maximum amount that the parameters can change in each iteration, were adjusted for allele frequencies ($a = 0.4$), migration rates ($m = 0.1$) and inbreeding values ($F = 0.7$) to assure an acceptance rate of 20–60% of the total iterations for each parameter. Two different seed values were used, and the MCMCs were checked for mixing and convergence in Tracer v. 1.6.0 (<http://tree.bio.ed.ac.uk/software/tracer/>). We estimated effective population sizes (N_e) based on linkage disequilibrium [29] using NeEstimator v. 2.01 [30].

3. Results

Of the 91 autosomal loci, 84 loci passed our quality-control criteria and Allelematch identified 166 unique genotypes (electronic supplementary material, S2) [15]. On average, each sample was genotyped at 82 loci, and the overall proportion of missing data was low (less than 0.03). Putative duplicate samples were always from the same location (e.g. east/east and west/west); thus, there were no replicate genotypes between the two sampling sites. The overall H_O was 0.30 and we detected no global deviations from equilibrium using the exact test, but H_O was significantly lower ($t = 10.0$; d.f. = 164; $p = 0.0001$) in the Eastern Pacific ($H_O = 0.28$) compared to the Western Pacific ($H_O = 0.32$). There were minor departures from random mating at both sampling sites (electronic supplementary material, S3).

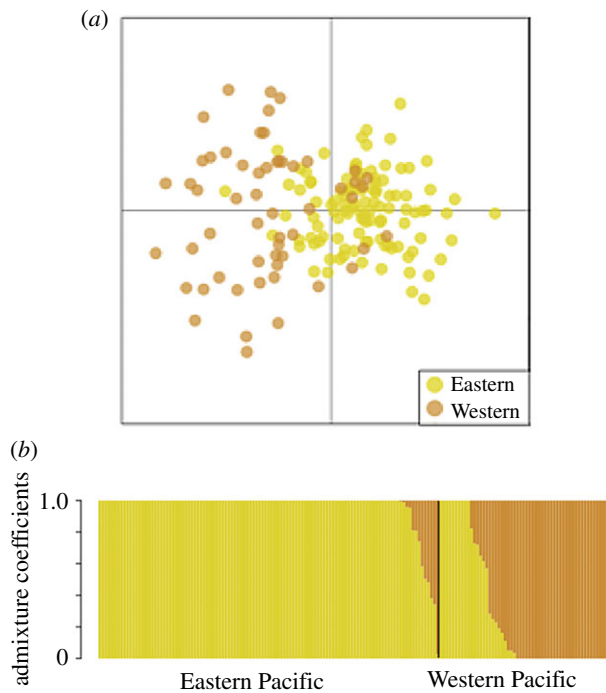

Figure 2. Genetic structure and geographical affiliations of sampled gray whales: (a) DAPC for the two ($K = 2$) geographical clusters; and (b) LEA admixture coefficients for each individual are represented by coloured vertical bars that illustrate proportional genomic ancestry for each individual in two ($K = 2$) geographical clusters. Both analyses suggest that each geographical site harbours mixed-stock aggregations of gray whales. (Online version in colour.)

The degree of genetic differentiation between the two primary geographical sites was small ($F_{ST} = 0.039$; $D = 0.017$) but significant ($p = 0.001$). Discriminant analysis showed that gray whales from the two sites could generally be separated, but there was some overlap in principal components (figure 2a). Similarly, the LEA admixture results divided the gray whales into two clusters (figure 2b; electronic supplementary material, S4); this result was confirmed by subsampling (electronic supplementary material, S5). No substructure was found within either cluster (electronic supplementary material, S6). There were putatively admixed individuals sampled from each primary geographical site, but a larger proportion was sampled from the Western Pacific (figure 2b). The Western Pacific samples had significantly ($p = 2 \times 10^{-16}$) lower genetic similarity index ($M_{xy} = 0.72$; s.d. ± 0.070) than the Eastern Pacific samples ($M_{xy} = 0.75$; s.d. ± 0.039), which indicates that the mixed-stock aggregation in the Western Pacific consists of a more uniform proportion of both substocks (electronic supplementary material, S7 and S8). The Eastern samples had an eightfold larger contemporary N_e (mean = 164; 122–237, 95% confidence interval (CI)) than the Western samples ($N_e = 22$ and 95% CI = 19–25). BayesAss identified an approximately 65-fold difference in absolute migration rates ($m_{w \leftarrow e} = 0.327 \pm 0.006$; $m_{e \leftarrow w} = 0.0051 \pm 0.042$), which mirrors the large difference in estimated census numbers of Eastern versus Western gray whales.

4. Discussion

Gray whales that summer in the Western Pacific are of major conservation concern [2]. Previous studies [4,9] have revealed modest genetic differences between Eastern and Western gray

whales, but no obvious structure within a sampling locale. Our SNP data provide additional resolution showing that each substock is found in both the Eastern and Western Pacific (figure 2a,b), but we identified no further substocks. Despite the 100-fold population size difference, whales sampled from the Eastern Pacific were more homogeneous than those from the Western Pacific (figure 2a,b; electronic supplementary material, S7 and S8). This likely reflects that admixed individuals in the Western Pacific inflate the similarity index more so than in the Eastern Pacific owing to their relative frequencies (i.e. overall population sizes).

Our analyses identified admixed individuals (figure 2b) and some overlap between the two substocks (figure 2a), patterns likely driven by introgression [7,8,31]. Migration was most pronounced into the Western Pacific, where the two substocks were found in a ratio of 2 : 1. The high degree of gene flow ($N_e m \gg 1$) into the Western Pacific stock could be sufficient to prevent loss of genetic diversity but might eventually homogenize the gene pool. The whales from the Eastern Pacific had marginally lower heterozygosities and nominally higher inbreeding than those sampled in the Western Pacific (electronic supplementary material, S2), but these minor statistical deviations may reflect a modest ascertainment bias rather than true biological differences, given that the markers were originally developed from Western Pacific samples [13].

Our SNP data show that despite mid-Holocene population declines [4], commercial whaling [5,6] and a prolonged bottleneck, the critically endangered Western gray whale is still genetically diverse at functionally important loci. These results confirm earlier microsatellite and mitochondrial DNA studies of a few presumptively neutral markers [9,10], but extend those data using genic SNPs that identify admixed individuals and mixed-stock aggregations on both sides of the Pacific. Overall, these data indicate that current population structure is not determined by simple geography and may be in flux owing to migratory dynamics [7,8]. Our findings have conservation implications (e.g. how future IUCN designations are formulated), but also provide a contemporary snapshot into the evolutionary phenomenon of divergence with gene flow that appears to be an integral part of rorqual evolution [31].

Ethics. Russian and Mexican field research was approved by the Ethics Committee of the National Scientific Center of Marine Biology of the Far East Branch of the Russian Academy of Science and by the Subsecretaria de Gestion Para La Protection Ambiental of the Mexican Direccion General de Vida Silvestre, respectively. US research on marine mammal samples collected abroad by foreign colleagues falls under the authority of NOAA and requires a US MMPA permit as well as the proper CITES permits for import and export of the samples. Russian and Mexican collaborators obtained proper research permits, which covered ethical considerations for the collection of samples. Thus, all relevant US and international permits were secured for this research. National Marine Fisheries Service Office of Protected Resources' Marine Mammal Health and Stranding Response Program permit 93-1905-MA-009526. CITES permit 13US082589/9, 13RU00580, MX89451 and MX71396.

Data accessibility. SNP genotypes have been uploaded to the Dryad Digital Repository: <http://dx.doi.org/10.5061/dryad.954ht26> [15].

Authors' contributions. A.B.-O. and J.A.D. conceived the work and planned the research design. J.U.R., V.V.V., C.A.J.G.-C. and J.W.B. initiated the study, conducted/supervised fieldwork and secured permits. A.B.-O. genotyped samples and performed all analyses. The inference of gray whale (*Eschrichtius robustus*) historical population attributes from whole-genome sequences

Anna Brüniche-Olsen^{1*} , Rick Westerman², Zuzanna Kazmierczyk³, Vladimir V. Vertyankin⁴, Celine Godard-Coding⁵, John W. Bickham⁶ and J. Andrew DeWoody¹

Abstract

Background: Commercial whaling caused extensive demographic declines in many great whale species, including gray whales that were extirpated from the Atlantic Ocean and dramatically reduced in the Pacific Ocean. The Eastern Pacific gray whale has recovered since the 1982 ban on commercial whaling, but the Western Pacific gray whale—once considered possibly extinct—consists of only about 200 individuals and is considered critically endangered by some international authorities. Herein, we use whole-genome sequencing to investigate the demographic history of gray whales from the Pacific and use environmental niche modelling to make predictions about future gene flow.

Results: Our sequencing efforts and habitat niche modelling indicate that: i) western gray whale effective population sizes have declined since the last glacial maximum; ii) contemporary gray whale genomes, both eastern and western, harbor less autosomal nucleotide diversity than most other marine mammals and megafauna; iii) the extent of inbreeding, as measured by autozygosity, is greater in the Western Pacific than in the Eastern Pacific populations; and iv) future climate change is expected to open new migratory routes for gray whales.

Conclusion: Our results indicate that gray whale genomes contain low nucleotide diversity and have been subject to both historical and recent inbreeding. Population sizes over the last million years likely peaked about 25,000 years before present and have declined since then. Our niche modelling suggests that novel migratory routes may develop within the next century and if so this could help retain overall genetic diversity, which is essential for adaption and successful recovery in light of global environmental change and past exploitation.

Background

Widespread commercial whaling during the last two centuries unsustainably harvested many whale populations [1]. Whale products such as oil, meat, blubber, and ambergris were commercially important and overharvesting greatly diminished many whale populations [2–5]. In 1982 the International Whaling Commission (IWC) instituted a moratorium on commercial whaling (<https://iwc.int/commercial>), and although some whale populations have since

recovered to near their pre-whaling abundance, others remain compromised. Recent, anthropogenic bottlenecks due to commercial whaling can be contrasted with more ancient, natural bottlenecks often associated with climate and/or ecological change [3].

Great whales are important for marine ecosystems, as they facilitate nutrient transfer in the water column and stabilize ecosystems by increasing biodiversity [6]. Whales are associated with areas of high primary productivity, and their sensitivity to environmental changes make them prime indicators of ecological perturbations [7]. The marine ecosystem is rapidly changing due to anthropogenic impacts [8–10], most of which have unknown

consequences for the future of marine environments and marine mammals [11, 12]. Scientists are just beginning to understand how large marine mammals have responded to past climatic cycles [13–15], and models predict that range and distribution patterns will shift towards the poles in the face of global warming [16].

One species severely affected by commercial whaling is the gray whale (*Eschrichtius robustus*). Gray whales were once common in the Northern hemisphere, but were extirpated from the Atlantic ocean by the early eighteenth century [17], potentially due to environmental change and/or by commercial whaling [2, 18]. Today, gray whales are found in the Eastern Pacific near the coast of North America and the Western Pacific near the coast of Asia (Fig. 1). There is evidence of gene flow between the two “stocks”, but there is also statistically detectable genetic differentiation between them [2, 19]. The eastern gray whale (EGW) population has been extensively studied, and post-whaling estimates based on genetic and ecological data indicate there are ~27,000 individuals [19–21]. In contrast, data on the western population is limited [22, 23]. Commercial whaling

lasted considerably longer in the western Pacific [24], and today the western gray whale (WGW) is thought to be comprised of <200 individuals and is listed as ‘critically endangered’ by the International Union for Conservation of Nature (IUCN) [25, 26].

During the late Pleistocene and Holocene (i.e., within the last ~100,000 years), the Northern hemisphere experienced massive changes to its marine ecosystems [27]. Glacial periods led to ice cap oscillations that repeatedly opened and closed migration corridors [28–30], and fluctuations in water temperature and sea levels likely forced changes to habitats and feeding modes [2, 3]. Gray whale carrying capacities have been modelled based on shifts in feeding habitat during the last 120,000 years, and those data suggest that multiple demographic bottlenecks may have occurred [3]. In addition to the trophic data, DNA sequences suggest that the EGW population has been subject to a genetic bottleneck during the last century [20]. Although population fluctuations have not been investigated in the WGW, microsatellite and mitochondrial data suggest that the two populations have similar levels of neutral

Fig. 1 Environmental niche modelling of (a) current and (b) future (year 2100) suitable habitat for gray whales in the Pacific Ocean. Colours depict the habitat suitability ranging from low (yellow) to high (red). Shapes represent sampling locations for the putative western grey whales (triangle) and eastern grey whales (circle). Feeding grounds are located at higher latitudes, whereas breeding grounds are at lower latitudes

genetic diversity and thus may have similar long-term demographic histories [2, 19].

The ongoing reductions in the extent of sea ice provide gray whales with new potential migration routes and they may be shifting their range farther north in the Arctic [31]. Gray whales have responded to climate changes by shifting the timing of their southbound migration [32]. Because they annually migrate thousands of kilometres from their summer feeding grounds at high latitudes to their winter calving waters at lower latitudes, there may be opportunities for contemporary (i.e., within the last few dozen generations) gene flow between eastern and western Pacific populations (Fig. 1). There are indications of historical (referring to the Pleistocene and early Holocene) gene flow between Atlantic and Pacific gray whales [2], and—more recently—a satellite-tagged WGW has been tracked to an EGW wintering area near the Mexican coast [22]. Furthermore, photographic identification has documented individual gray whales moving between the western Pacific (near Sakhalin Island, Russia) and the eastern Pacific [26]. Collectively, these data suggest that the currently recognized WGW and EGW “populations” of this highly vagile species are not completely independent (i.e., gene flow is possible). Fortunately, population attributes such as historical demography, admixture (i.e., interbreeding between populations that have previously been isolated), and genetic diversity can now be addressed using whole genome sequences [33–35]. The ability to make population inferences from one or a few samples is especially important for rare species, where sampling efforts are often difficult, expensive, and should be minimized because of conservation concerns.

Herein, we employ genomic and computational techniques to infer population attributes of gray whales. The distribution of gray whales is largely disjunct today, but these geographic isolates were demographically and genetically connected in the past (as evidenced by the fact that they are recognized as a single species). Given the recent growth of the EGW population and ongoing climate change, there is reason to suspect that increased gene flow between EGW and WGW may occur in the future. We are interested in the long-term demographic trajectory of gray whales, both from a historical and a future perspective. Given the critically endangered status of the WGW, we were interested in comparing genomes of the WGW and the EGW to investigate levels of genetic diversity as a key component of adaptive potential. We used coalescent-based approaches to retrospectively gauge ancient admixture in gray whale genomes during the Pleistocene, and measures of autozygosity to directly assess inbreeding and search for signals of contemporary differentiation. Our habitat prediction models suggest that novel migratory routes may develop within the next

century, which could influence the overall retention of genetic diversity in the species. This study presents the first genomic comparison of gray whales, and extends our insights into the molecular diversity and demographic history of this enigmatic species while contributing to our understanding of how our ocean's great whales have responded to historical climate change.

Methods

Sampling, sequencing and SNP calling

We used previously published whole genome DNA sequences from DeWoody et al. [36]. These sequences were derived from two gray whales sampled near Sakhalin Island, Russia, designated WGW1 (female) and WGW2 (male), and from one putative Eastern gray whale female (EGW) that was beached near Barrow, Alaska (Fig. 1). There is some uncertainty as to true population affinities of these individual gray whales. For example, WGW1 was biopsied near Sakhalin Island in the western Pacific but the same whale has been photographically identified in the eastern Pacific (Laguna San Ignacio; M. Scott, unpublished data). Nevertheless, we assigned geographical names to whales based on sampling locations in order to be comparable with previous genetic work on gray whales [2, 19, 37]. The data utilized herein consisted of 2x100bp paired-end (PE) libraries from each whale (~1 billion reads per individual; ~700 million high-quality reads per individual after quality-control; Additional file 1: Table S1). For detailed sampling and genome sequencing methodology see DeWoody et al. [36]. For a summary of number of reads per individual and quality control effects, see Additional file 1: Table S1.

We used FASTQC v0.11.2 (www.bioinformatics.babraham.ac.uk/projects/fastqc) to generate summary statistics for the sequencing reads. TRIMMOMATIC v0.32 [38] was used to remove adaptor sequences and trim low quality bases (< 20 Phred scores) from both the 5' and 3' end of each read. BWA v0.7.12 [39] was used to map the PE reads to the published genome of the common minke whale (*B. acutorostrata*) (GenBank accession: SAMN02192642, [40]) using the 'bwtsw' function that indexes whole genomes, and the 'mem' function for mapping. PICARD-TOOLS v2.0.1 (<http://broadinstitute.github.io/picard/>) was employed to mark duplicate reads. SAMTOOLS v1.3 [41] was used for alignment manipulation. Local realignment, duplicate removal, and SNP variant calling were carried out with GATK v3.5 [42] following 'Best Practices protocol' [43, 44]. Genotypes were called across all three samples together using the 'gvcf' option. We used a minimum base quality score of 20 (which corresponds to a base calling error rate of ~1% [45]) with a minimum mapping quality score of 20. In the downstream analyses, we only used SNPs with minimum 20x coverage, which should help minimize

the number of heterozygotes falsely scored as homozygotes [46, 47]. Eight minke whale scaffolds are X-linked [48], and we removed gray whale reads that mapped to these scaffolds so they would not bias our downstream analyses. None of our gray whale reads mapped to Y-linked scaffolds because [48] reported none in their minke genome assembly.

Genetic diversity

Nucleotide diversity can be used to assess ancient admixture as well as contemporary differentiation [34, 49, 50]. We estimated observed heterozygosity for each individual, θ_{genome} , based on the number of heterozygous sites / total number of sites where only sites with minimum 20× coverage were considered. We used θ values associated with each individual to independently estimate equilibrium effective population sizes (N_e) following $\theta = 4N_e\mu$ [51]. To quantify differences in N_e we compared θ among individuals, assuming that substitution rates do not vary appreciably across samples.

We directly quantified inbreeding levels by identifying the number and lengths of autosomal runs-of-homozygosity (ROHs) in each individual. A ROH is a genomic region that contains far less nucleotide variation than expected based on the genome-wide average for an individual [52]. Under random mating, the length of ROH regions is expected to decrease with increasing number of generations to the ‘most recent common ancestor’ (MRCA) due to recombination and de novo mutations. In contrast, with inbreeding—as is often the case for critically endangered species—autozygosity is expected to increase over time, thus increasing the number and length of ROHs in the genome each generation. Analysis of ROH abundance and extent thus provides information on a population’s demographic history and on the genetic relationships among individuals [53].

We estimated four different ROH parameters: i) number of ROHs in each genome (N_{ROH}); ii) the mean length of ROHs (L_{ROH}); iii) the heterozygosity outside ROHs (θ_{noROH}); and iv) the inbreeding coefficient F_{ROH} , the overall proportion of the genome contained in ROHs. We estimated θ_{noROH} as the number of heterozygous SNPs / (total number of SNPs – SNPs in ROHs). When F_{ROH} is compared to θ_{genome} , it quantifies the effect of inbreeding on overall levels of genomic variation. To compare our results directly to patterns of ROHs found in other species [54], we used PLINK v1.90b3.36 [55] and defined ROHs as portions of the genome that spanned at least 20 homozygous sites allowing for a single heterozygous SNP (e.g., due to de novo mutation) and 1 missing SNP (e.g., a site with missing data) following Howrigan et al. [56]. We searched the genomes for ROHs in consecutive 20 SNP sliding windows and, to facilitate detecting both short and long ROHs, we set the lower bound for ROHs to 1 kb. We used a Welch

two-sample t-test to test for pairwise differences in L_{ROH} among individuals whereas pairwise ROH frequency distributions were compared among all three gray whales using a two-sample Kolmogorov–Smirnov test. All statistical tests were conducted in R [57].

Relatedness and population structure

We used PLINK to measure relatedness among individuals. Pairwise identical-by-state (IBS) comparisons were estimated based on the ratio of probabilities between a heterozygote–heterozygote site, $p(\text{HetHet}) = 4p^2q^2$, to the probability of a homozygote–homozygote site, $p(\text{HomHom}) = p^2q^2$. For each pair of individuals, the number of variable sites where they share no alleles (IBS = 0; e.g., discordant homozygotes AA/BB and BB/AA) are counted along with the number of sites where they share two alleles (IBS = 2) (e.g., heterozygotes AB/AB, BA/BA). On average, we expect this probability ratio to be 1:2 if the pair comes from a randomly mating population [55, 58]. A ‘HetHet’: HomHom’ ratio > 2 suggests that the individuals are more related than expected by chance, and a ‘HetHet’: HomHom’ ratio < 2 suggests that the individuals have recent ancestry from different random mating populations. We used the ‘pairwise population concordance’ (PPC) test to evaluate if this probability ratio significantly deviated from the expected ratio under random mating, applying a significance level of 0.05, a minor allele frequency (MAF) of 0.01, and a minimum distance of 500 k base pairs between informative SNPs to limit the effects of linkage disequilibrium (LD).

Ancient admixture

To test for ancient admixture, we used the ABBA–BABA D -statistic test implemented in ANGSD v0.912 [34, 59]. The D -statistic tests for admixture between four individuals: two conspecific individuals (P1 and P2), a potential introgressor (P3), and an outgroup (O). At each polymorphic site in the genome the relationship among these four individuals and the topology of the species tree is compared. Sites that are inconsistent with the species tree are the sites where P2 shares a derived allele with P3 but not P1 (ABBA sites) or P1 shares derived sites with P3 but not P2 (BABA sites). An excess of either ABBA or BABA sites, compared to the sites supporting the species tree (i.e., AABB), is an indication of admixture between P2 and P3 or between P1 and P3, respectively. In the absence of ancient population structure, incomplete lineage sorting is the only process other than admixture that produces inconsistency with the species tree topology, but incomplete lineage sorting is expected to produce ABBA and BABA sites in an equal ratio [49, 50]. The D -test statistic evaluates the number (n) of ABBA and BABA sites ($D = (n_{\text{ABBA}} - n_{\text{BABA}}) /$

($nABBA + nBABA$) and $D < 0$ means that P1 is more closely related to P3 than to P2, whereas $D > 0$ indicates that P2 is more closely related to P3 than P1. The significance of the D test was evaluated with a Z-score, where $|Z\text{-scores}| > 3$ was used as the critical value for a significant test [50]. As an outgroup, we used the common minke whale. The phylogenetic relationships among baleen whales are not completely resolved [60, 61], but the common minke whale is the closest relative with a published genome sequence [62]. We used an LD block size of 10 Mb; increasing the block size (e.g., 20 Mb, 30 Mb) did not change the outcome of the ABBA-BABA test. We tested all scaffolds > 10 Mb in length in order to obtain a reliable Z-score. Admixture D -statistics were considered significant for $|Z\text{-scores}| > 3$.

Inference of demographic history

We used the PSMC' mode implemented in MSMC [33, 63] to infer ancient demographic histories. Eleven scaffolds larger than 30 Mb in length, corresponding to a total of ~400 Mb, were used to improve the accuracy of inferring past recombination events [33, 64]. We ran the MSMC analysis for each individual separately using default settings; 20 iterations and averaging over 30 time segments. To quantify the variance in N_e we bootstrapped using the same MSMC settings. For each individual, 20 bootstrapped datasets were generated by randomly sampling 5 Mb sequences from each of the 11 scaffolds used to trace the mean N_e . Substitution rates—for both mitochondria and nuclear loci—are reportedly 8–10 fold slower in baleen whales than in other mammals [65, 66]. In order to convert θ to N_e over time, we applied an autosomal substitution rate of $4.8 \times 10^{-10} \text{ bp}^{-1} \text{ year}^{-1}$ (credibility interval (CI): $1.5 \times 10^{-10} - 10 \times 10^{-10}$) [67], and a generation time of 18.9 years which corresponds to the midpoint of estimated generation times which range between 15.5 and 22.3 years [68, 69]. MSMC runs were assessed for convergence using the R package CODA [70].

Prediction of suitable habitat

We used AQUAMAPS [71] to predict the relative probability of the future gray whale distribution across the Northern Hemisphere based on contemporary local conditions. Suitable habitat was based on occurrence records available via Ocean Biogeographic Information System (<http://www.iobis.org>) using the contemporary environmental envelope settings suggested by Alter et al. [2] (Additional file 1: Table S2), and future (year 2100) envelope settings from AQUAMAPS [72]. We assumed that current environmental conditions are representative of the Holocene, as the Holocene climate has experienced relatively little variation compared to interglacial cycles [73].

Results

Genetic diversity

We mapped, from each individual, high-quality PE reads from one eastern and two western gray whales to the minke whale genome. The mean depth of coverage per individual ranged from 27× to 30× (Additional file 1: Table S1), and this relatively deep coverage allowed us to assess nucleotide diversity with confidence. The level of genetic diversity represented by theta (θ) was lower in the individuals from the Western population ($\theta = 6.69 \times 10^{-4}$ and 6.64×10^{-4}) relative to the individual from the putative Eastern population $\theta = 8.00 \times 10^{-4}$ (Fig. 2). Thus, there is about a 1.2-fold difference in genetic diversity between East and West.

Inbreeding

We found ROHs ranging from 1 to 559 Kb in length; few were longer than 300Kb (Fig. 3). Estimates of θ_{genome} and θ_{noROH} were lower in both WGWs than in the EGW (Table 1). The western individuals had fewer ROHs (WGW1: $n_{\text{ROH}} = 188,012$ and WGW2: $n_{\text{ROH}} = 126,893$) than the Eastern individual ($n_{\text{ROH}} = 263,877$), but their mean ROH length were significantly longer (WGW1: $L_{\text{ROH}} = 11\text{Kb}$ and WGW2: $L_{\text{ROH}} = 17\text{Kb}$; both $p = 2.2 \times 10^{-16}$) than in the eastern individual (EGW: $L_{\text{ROH}} = 6\text{Kb}$). ROHs covered a larger proportion of the western gray whale genomes (WGW1: $T_{\text{ROH}} = 2.1 \times 10^6 \text{ bp}$; WGW2: $T_{\text{ROH}} = 2.2 \times 10^6 \text{ bp}$) compared to the eastern gray whale (EGW: $T_{\text{ROH}} = 1.6 \times 10^6 \text{ bp}$) (Table 1). All individuals differed significantly from one another in L_{ROH} ($p = 2.2 \times 10^{-16}$), and the Kolmogorov–Smirnov test showed that the ROH distributions were significantly different from one another (WGW1 & EGW $D = 0.186$, $p = 2.2 \times 10^{-16}$; WGW2 & EGW $D = 0.322$, $p = 2.2 \times 10^{-16}$, and WGW1 & WGW2 $D = 0.142$ $p = 2.2 \times 10^{-16}$). This suggests that there are significant differences in genealogical histories between all individuals. Estimates of F_{ROH} were 0.088 (WGW1), 0.092 (WGW2), and 0.067 (EGW) and thus on average the WGWs were ~1.3 times as inbred as EGW.

Relatedness and population structure

To evaluate pairwise relatedness, we used the 'HetHet' to 'HomHom' ratios (where a ratio of 2.0 is expected for individuals from the same random mating population and a ratio > 2.0 suggests that the pair is more related to each other than expected based on chance alone). All pairwise comparisons yielded a 'HetHet' to 'HomHom' ratio ≥ 2 (Table 2), and the PPC test could not reject the null hypothesis: 'HetHet': HomHom' ratio = 2 (Table 2). Thus this test is uninformative as the three individuals may or may not belong to the same gene pool.

Fig. 2 Overview of nuclear genomic diversity (θ) in various cetaceans, marine mammals, and large herbivores. Data from the current study and Brüniche-Olsen et al. [54]. Mean θ is provided for the two western gray whales in this study

Fig. 3 Total number of runs of homozygosity (ROHs) and proportion of ROH size classes in sampled gray whale genomes. Shown for each individual is the number of ROHs in each size class (a), with an insert showing the 1–160Kb ROH length categories in detail) and the sum of ROH lengths (Mb) in the genome (b). A Kolmogorov–Smirnov test indicated that the pairwise comparisons of ROH frequency distributions between were significantly different from each other (WGW1 & EGW $D = 0.186$, $p = 2.2 \times 10^{-16}$; WGW2 & EGW $D = 0.322$, $p = 2.2 \times 10^{-16}$, and WGW1 & WGW2 $D = 0.142$, $p = 2.2 \times 10^{-16}$), suggesting that there are significant differences in genealogical histories between individuals

Ancient admixture

The ABBA–BABA test revealed no significant support for ancient admixture (e.g., historical panmixia) between the Western and Eastern gray whales (Fig. 4; Additional file 1: Table S3). If ABBA and BABA patterns are equally common, then in theory $D = 0$ and the data are consistent with the tree. Deviations where $D \neq 0$ can be due to: i) P3 exchanged genes with P1 or P2; ii) ancestral population (P1, P2 and P3's founder) structure leading to discordant gene trees; or iii) P1 or P2 could have received genes from an unsampled 'ghost' population (P_g). The test is not influenced by demographic events assuming that P1, P2 and P3's ancestral population was panmictic [49], which should be a reasonable assumption for gray whales [2].

Inference of long-term demographic history

We traced effective population size estimates over the last ~1,000,000 years using the PSMC' method (Fig. 5; Additional file 1: Figure S1). The three individuals exhibit very consistent trajectories, indicating a step decline in N_e from $N_e > 50,000$ in the interval of ~1,000,000 years before present (YBP) until 100,000 YBP followed by a more stable period (~100,000–30,000 YBP) with $N_e \sim 25,000$ for both EGW and WGW populations. Prior to the LGM both populations increase in size to $N_e \sim 45,000$; hereafter a reduction in N_e to a population size of $N_e \sim 20,000$ is observed in all three trajectories. These consistent results among individuals suggest there is relatively little noise in this PSMC' analysis and that the trajectories themselves are likely a realistic representation of historical population dynamics. Furthermore, the most recent estimate of census population size (N_c) of the EGW is 27,000 [21]. The concordance between N_c and

Table 1 Summary statistics for the gray whales. Heterozygosity across the entire genome (θ_{genome}), heterozygosity excluding ROHs (θ_{noROH}), number of ROHs (N_{ROH}), mean ROH length (L_{ROH}), sum of ROH lengths (T_{ROH}), and inbreeding coefficient (F_{ROH}) in the gray whale autosome. All results are based on sites with depth of coverage $\geq 20\times$. A genome size of 2.4Gb was used for calculating F_{ROH}

Sample	θ_{genome}	θ_{noROH}	N_{ROH}	L_{ROH} ($\times 10^3\text{nt}$)	T_{ROH} ($\times 10^6\text{nt}$)	F_{ROH}
WGW1	6.69×10^{-4}	6.79×10^{-4}	188,012	11.4 (16.0)	2.1	0.088
WGW2	6.64×10^{-4}	6.74×10^{-4}	126,893	17.1 (22.7)	2.2	0.092
EGW	8.00×10^{-4}	8.11×10^{-4}	263,877	6.1 (6.8)	1.6	0.067

recent N_e estimates (Fig. 5) suggests that the substitution rate we used ($4.8 \times 10^{-10} \text{ bp}^{-1} \text{ year}^{-1}$) is a reasonable approximation of the true genome-wide substitution rate.

Predictions of suitable habitat

Our environmental niche modelling suggests that current habitat suitability is relatively high from Taiwan to Kamchatka through much of the Bering Sea and along the coast of North America to the Gulf of California (Fig. 1a). Currently marginal habitat, which is expected to improve in the future due to ongoing climate change, includes the Arctic and Chukchi Seas (Fig. 1b).

Discussion

Anthropogenic factors are rapidly changing the global environment. We think that predictions regarding future biological impacts (e.g., species range shifts) are most informative when presented in a historical context. Genomic data have great potential in this regard as they can be used as a window to the past (e.g., the reconstruction of past demographic histories) and into the future (e.g., by identifying genes expected to face particular selection pressures, such as those related to thermoregulation). Using whole genome data from contemporary eastern and western gray whale populations, we quantified genetic diversity in gray whales and inferred key population attributes that bear on their evolution and conservation.

Table 2 Relatedness and population clustering. Estimates are based on PLINK genotype calls where the ‘identical by state’ (IBS) genotype pattern was estimated for a pair of samples and the test for population clustering was conducted using pairwise population concordance (PPC). The genotype pattern for each variable site is estimated as the sharing of two ancestral alleles, one ancestral and one derived allele, and two derived alleles between the individuals. The IBS ratios indicate that all pairs (ratios > 2.0) are more related than expected under random mating. The PPC results indicate we cannot reject the null hypothesis (ratio = 2) that all three individuals belong to the same population ($p = 0.05$)

Pair	HomHom	HetHet	Ratio	PPC
WGW1 & WGW2	1533	4377	2.9	1.00
WGW1 & EGW	1384	4513	3.3	1.00
WGW2 & EGW	1572	4252	2.7	1.00

Genetic diversity and inbreeding

The genome-wide heterozygosity in gray whales is similar to the minke whale, but lower than other marine mammals—e.g., sperm whales (*Physeter catodon*), common bottlenose dolphin (*Tursiops truncatus*), killer whales (*Orcinus orca*), and manatees (*Trichechus manatus latirostris*)—and considerably lower than terrestrial megafauna (i.e., African elephant (*Loxodonta africana*), camels (*Camelus bactrianus* and *C. ferus*), white rhinoceros (*Ceratotherium simum*)) (Fig. 2). We expect that the variation in θ may be explained in part by differences in body size; larger animals have slower mutation rates, longer generation times, and produce fewer offspring—all factors that impact θ [74, 75]. Gray whales are the largest of the mammals surveyed here, which could partly explain their low genomic diversity, but population declines over the last $\sim 20,000$ years (Fig. 5) may also be a significant contributing factor.

Reduced genomic diversity is a concern as it constrains adaptive potential [76]. We observed lower θ_{genome} and θ_{noROH} in western than eastern gray whales (Table 1), likely due to the smaller size of the western population compared to the eastern population. Small population sizes and reduced gene flow will lead to increased inbreeding that has the potential to reduce reproductive fitness due to homozygosity of deleterious recessive alleles and to reduced heterosis. The extent of ROHs in a genome is correlated with population size reductions and increased consanguinity [52, 53]. Our data indicate that, consistent with contemporary population sizes, ROHs significantly reduce overall nucleotide variation in the gray whale genome (Table 1). The timing and duration of bottlenecks are directly associated with the extent of ROHs; i.e., recent inbreeding leads to long ROHs whereas ancient inbreeding persists in the genome as shorter ROHs that have been disrupted by mutation and recombination [77, 78]. The eastern gray whale had more but shorter ROHs than the western gray whales (Table 1, Fig. 3). This is not surprising given that the eastern population is $\sim 100\times$ larger and has not experienced extensive recent inbreeding [20]. In contrast, the western gray whale individuals had fewer but longer ROHs and a larger proportion of their genomes in ROHs (Table 1), a pattern that can be produced by a continuous small population size or a genetic bottleneck

Fig. 4 Results from the ABBA-BABA tests for different possible topologies among gray whales from the eastern and western populations when using the common minke whale as the outgroup. The D -statistic for each topology is considered statistically significant, meaning the topology can be rejected, if the associated standard score ($|Z|$) has an absolute value > 3 . The two gray topologies were both rejected ($|Z| > 3$), but the black topology could not be rejected ($|Z| < 3$). This indicates that the signal of contemporary genomic structure we detected among geographic populations is stronger than the signal of historical admixture. WGW, western gray whale. EGW, eastern gray whale

that persists for multiple generations [53]. The small size of the western population (< 200 individuals) may not only have led to loss of genetic diversity, but also the loss of adaptive potential in the face of impending environmental change [8–10].

Relatedness, gene flow and geographical isolates

Gray whales are one of the most vagile species on earth; telemetry and photographic data indicate that some individuals annually move thousands of kilometres across the Pacific [22, 26]. This contemporary movement of individuals between eastern and western populations provides opportunities for gene flow. Furthermore, our niche modelling suggests that gray whales from the east and from the west could encounter the same suitable habitat (Fig. 1b). However, despite the potential overlap

in suitable habitat and the known movement of individuals between the populations, their genomes significantly differ in terms of homozygosity (Fig. 3). Thus the ROH data are consistent with previous reports of population structure between eastern and western gray whales [2, 19]. However the PPC test could not reject the null hypothesis of random mating (Table 2; $p = 1.00$) and the relatedness analysis showed that the EGW was more closely related to both of the WGWs than expected by chance. These PPC and relatedness results are consistent with an earlier relatedness analysis based on 88 gene-associated SNPs, which found the EGW was no more or less related to the WGW population than expected on the basis of chance alone [36].

During the Pleistocene, climate-dependent dispersal occurred between the Pacific and Atlantic gray whale

Fig. 5 Estimated historical effective population sizes (N_e) for western (red and blue) and eastern (black) gray whales. Thick lines represent the median N_e and thin light lines of the same colour represent 20 iterations of bootstrap sampling. Estimates represent averages based on 11 autosome scaffolds larger than 30 Mb. An estimated mutation rate of $4.8 \times 10^{-10} \text{ bp}^{-1} \text{ year}^{-1}$ and a mean generation time of 18.9 years were used in these PSMC analyses. The last glacial maximum (LGM) is indicated with a gray bar

populations; prior to the last glacial period (110,000–11,700 YBP) and after the opening of the Bering Strait, gray whales migrated between the Pacific and Atlantic oceans [2]. Analyses of mitochondrial sequences have documented haplotype sharing between the eastern and western populations, suggesting that recent maternal gene flow has occurred during the Holocene [2]. In 2010, a Pacific gray whale was observed in the Mediterranean Sea, a sighting which produced speculation that climate-induced shrinking of the Arctic Sea ice may ultimately enable gray whales to recolonize the Atlantic [79]. Thus, although gene flow between the western and eastern populations has no doubt occurred multiple times since the Pleistocene, the signal of contemporary genomic structure we detected between geographic populations is stronger than the signal of historical admixture (Fig. 4). For all D -test statistics we found the two WGWs to be more closely related to each other than either was to the EGW (Additional file 1: Table S3), although we could not reject the hypothesis that the individuals belong to the same randomly mating population (Table 2).

Dating and severity of population decline (s)

The dating of population size changes is inexact due to errors in the estimation of mutation rates and generation times, but genetic datasets are nevertheless often highly concordant with independent datasets (e.g., fossil evidence; [80, 81]). Demographic histories inferred from single whole genome sequences trace from the two haplotypes to their coalescence in the MRCA. This means that the most recent past is not well resolved, and if unphased haplotypes are used—as done in this study—this also affects deep (past) resolution [63]. Thus, our PSMC' analyses are unlikely to recover any Anthropocene population size changes associated with commercial whaling, as any genetic signal this may have left is much too recent for this method to detect. That said, trajectories of N_e over the last ~1,000,000 years are highly consistent with one another and suggest a similar demographic history in each lineage (Fig. 5). Pre-whaling eastern gray whale census population size (N_c) has been estimated at 96,000 (CI: 76,000–118,000) individuals based on nuclear microsatellites [67], whereas mitochondrial DNA sequences [20] yield N_c estimates of 100,670 (90% HPD: 59,940–111,550). These N_c estimates correspond to N_e of ~32,000 (CI: 25,000–39,000) for microsatellites, and N_e ~17,000 (90% HPD: 10,000–19,000) for mitochondrial DNA, which is similar to our post LGM N_e estimate ~20,000 (Fig. 5). These differences among studies may illustrate that using a subset of genomic markers does not accurately capture overall genomic diversity perhaps because of the ascertainment bias

associated with the selection of highly polymorphic markers such as microsatellites [82].

Our data suggest an ancient population decline during previous ice ages and a more recent decline in the last ~25,000 years (Fig. 5). Glacial periods are often associated with population declines, and the large shifts in climate have impacted both terrestrial [83, 84] and marine mammals [85–88]. Taken together with the evidence for contemporary bottlenecks—occurring around the time of commercial whaling [20]—these results support population models which indicate multiple bottlenecks have occurred in gray whales [3]. Cumulatively, these bottlenecks may have contributed to the relative paucity of genetic diversity observed in gray whales (Fig. 2).

Western gray whales (WGWs)

We were particularly interested in tracing the demographic history and quantifying genetic diversity within the WGW because of its conservation status. We found that WGWs had increased autozygosity (higher F_{ROH}) and lower θ_{genome} (Table 2) compared to the eastern gray whale, both of which would be expected in a small inbred population [52]. However, despite having a more than 100-fold difference in census population size, the genomic differences were modest as N_e only differed 1.2 fold between the two geographic populations. The observed ROH patterns suggest that the western population has experienced population size reduction and an elevated level of inbreeding relative to the eastern individual (Fig. 3). These ROH patterns likely result from recent processes (e.g., inbreeding and drift) as opposed to a long-term small population size, which should be reflected in the Pleistocene N_e (Fig. 5). The small population size and low genetic diversity limit the potential evolutionary responses to future environmental change, and thus ongoing efforts to conserve the WGW are critical. Our sample sizes are large in terms of number of genetic loci, but small in terms of individual animals. Future studies will reveal whether the patterns we observe herein are indicative of the species as a whole.

Conclusion

Whole genome sequencing of cetaceans provides new insights into how these enigmatic animals have responded to past and ongoing changes in the marine environment. Herein, we present the first genome-scale study of gray whale demographic history. Our results show that gray whales from the eastern and western Pacific have low genetic diversity, that the past gray whale population (s) was much larger and experienced multiple declines since the Pleistocene, and that there is some evidence of geographic structuring between the populations. Ecological predictions for the year 2100 suggest the current habitat of gray whales in the Pacific Ocean is

unlikely to decrease while their former habitat in the Atlantic Ocean could expand with global warming [2]. Combined with decreasing sea ice cover in the Arctic, this expanding habitat could provide gray whales with opportunities to use alternative migration routes that could genetically bind east and west [31] but only time will tell how anthropogenic effects, genetic drift, inbreeding, and climate change will impact the population viability of gray whales over the long-term.

Additional file

Additional file 1: Table S1. Information on raw reads filtering statistics. Paired-end libraries were sequenced on an Illumina HiSeq 2500. **Table S2.** Environmental variables used in AQUAMAPS to generate maps of suitable habitat for gray whales during the Holocene. **Table S3.** The *D*-test statistic evaluates the number (*n*) of ABBA and BABA sites ($D = (nABBA - nBABA) / (nABBA + nBABA)$) and $D < 0$ means that P1 is more closely related to P3 than to P2, whereas $D > 0$ indicates that P2 is more closely related to P3 than P1. The significance of the *D* test was evaluated with a Z-score, where $|Z\text{-scores}| > 3$ was used as the critical value for a significant test. **Figure S1.** Inferred effective population sizes (N_e) over time. Estimates are averages based on 11 autosomal scaffolds larger than 30 Mb. A substitution rate of a) $10 \times 10^{-10} \text{ bp}^{-1} \text{ year}^{-1}$ and b) $1.5 \times 10^{-10} \text{ bp}^{-1} \text{ year}^{-1}$ were used. (DOCX 446 kb)

CI: credibility interval; EGW: eastern gray whale; F_{ROH} : inbreeding coefficient; IBS: identical-by-state; IUCN: International Union for Conservation of Nature; IWC: International Whaling Commission; LD: linkage disequilibrium; LGM: Last Glacial Maximum; MAF: mean length of ROHs (L_{ROH}) minor allele frequency; MRCA: most recent common ancestor; N_e : effective population sizes; N_{ROH} : number of ROHs; O: outgroup; P1; P2: conspecific individuals; P3: potential introgressor; PPC: Pairwise population concordance test; ROH: runs-of-homozygosity; WGW: western gray whale; YBP: years before present; θ : theta; θ_{genome} : observed heterozygosity; θ_{noROH} : heterozygosity outside ROHs

Acknowledgements

We thank P. A. Morin and two anonymous reviewers for providing constructive comments on an earlier version of the manuscript. A. Albrechtsen provided constructive comments on the analyses. K. Kellner assisted with developing R scripts. T. Rowles provided assistance with permits (National Marine Fisheries Service Office of Protected Resources' Marine Mammal Health and Stranding Response Program permit 932-1905-MA-009526). A. Aziz, J. Dupont, M. Scott, and M. Swindoll provided support in obtaining the biopsies and associated metadata. The Institute of Ecology and Evolution of the Russian Academy of Sciences, the A.V. Zhirmunsky Institute of Marine Biology Far Eastern Branch, and Oregon State University provided invaluable support for the collection of the Western gray whale samples. C. George and R. Suydam (Department of Wildlife Management, North Slope Borough of Alaska) provided the Eastern gray whale sample.

Funding

This work was supported in part by Exxon Neftegas Limited and Sakhalin Energy Investment Company. The funding parties had no part in study design, data collection, analysis or interpreting the results. The content herein is solely the responsibility of the authors and does not necessarily represent the official views of the funding parties.

Availability of data and materials

Genome data were from Genbank acc. No. SRR5495100, SRR5495104, and SRR5495108.

Authors' contributions

ABO and JAD conceived the work and planned the research design; JWB, VVW and CGC helped obtain funding, requisite permits, and samples; RW, ZK

and ABO analysed the data. ABO and JAD wrote the manuscript with input and insights from JWB, VVW, and CGC. All authors approved the final version of the manuscript.

POPULATION STRUCTURE OF SAKHALIN GRAY WHALES (*ESCHRICHTIUS ROBUSTUS*) REVEALED BY DNA SEQUENCES OF FOUR mtDNA GENES

VLADIMIR A. BRYKOV, KSENIYA V. EFIMOVA, ANNA BRÜNICH-OLSEN, J. ANDREW DEWOODY, AND JOHN W.
BICKHAM

ABSTRACT

Two stocks of gray whales (*Eschrichtius robustus*), eastern and western, traditionally were considered to inhabit the North Pacific Ocean. The western gray whale migration was along the coast of Asia between summering grounds in the Sea of Okhotsk and wintering grounds presumed to be in the South China Sea. The eastern gray whale migration was along the coast of North America between summering grounds mainly in the Bering and Chukchi Seas and wintering grounds in the coastal lagoons of Baja, Mexico. The status of the current population of gray whales that summers in the Sea of Okhotsk, mainly near Sakhalin Island, Russia, is of uncertain affinity because the western stock previously was considered extinct, some members of the Sakhalin population are known to winter in Mexico, and an Asian wintering ground for this species has never been precisely located. A previously published analysis of 84 nuclear loci showed the Sakhalin population to be a mixed-stock aggregation comprised of animals with distinct “eastern” and “western” SNP genotypes. In the study reported here, a mitochondrial DNA (mtDNA) analysis of Sakhalin gray whales was conducted using control region and three protein coding gene sequences to test if animals with “western” genotypes might be descendants of the western stock. It was postulated that such a population would likely have distinct mtDNA haplotype lineages as observed in other marine mammals sundered in the North Pacific Ocean basin. From the mtDNA sequence data, haplotype networks were generated separately for the control region and the concatenated protein sequences. No clades of related haplotypes were found among the “western” genotype animals in either haplotype network. This is not consistent with long-term isolation during the Pleistocene as seen in many other marine mammals with similar distributions. Rather, the “western” and “eastern” genotypes likely have diverged recently, possibly since the end of commercial whaling in the early 20th century, but more likely post-Pleistocene.

Key words: gene flow, genetic structure, migration, western gray whales

АННОТАЦИЯ

Традиционно считалось, что в северной части Тихого океана обитают две популяции серых китов (*Eschrichtius robustus*): восточная и западная. Западная популяция серых китов мигрирует вдоль побережья Азии между летними участками нагула в Охотском море и предполагаемыми зимними участками нагула в Южно-Китайском море. Миграция восточной популяции серых китов происходит вдоль побережья Северной Америки между летними участками нагула, преимущественно в Беринговом и Чукотском морях, и зимними участками нагула в прибрежных лагунах мексиканского штата Баха. Принадлежность существующей популяции серых китов, находящихся в течение летнего сезона в Охотском море, преимущественно у о. Сахалин, не установлена, так как ранее западное стадо

считалось вымершим. При этом известно, что некоторые особи сахалинской популяции зимуют у побережья Мексики, а участки зимнего нагула данного вида в азиатском регионе никогда не были точно определены. Опубликованные ранее исследования по 84 ядерным локусам показали, что сахалинская популяция представляет собой смешанную популяционную группировку с отличающимися «восточными» и «западными» SNP-генотипами. Для проверки возможности происхождения животных с «западными» генотипами от животных западного стада нами проведен анализ митохондриальной ДНК (мтДНК) сахалинских серых китов с использованием контрольного региона и 3-х белок-кодирующих последовательностей. Предполагалось, что подобная популяция, по всей вероятности, имеет характерную гаплотипическую родословную мтДНК, как и в случае с другими видами морских млекопитающих, обитающих в водах северной части Тихого океана. По данным последовательностей мтДНК были построены гаплотипические сети отдельно для контрольного региона и отдельно на основе объединенных последовательностей белок-кодирующих генов. Ни в одной из гаплотипических сетей среди особей западного стада не было выявлено специфических «западных» гаплотипов, что противоречит гипотезе о долговременной изоляции в период плейстоцена, характерной для ряда других морских млекопитающих с аналогичными распределениями. Скорее всего, «западные» и «восточные» генотипы разошлись недавно; и это могло произойти после завершения китобойного промысла в начале XX века, однако более вероятным представляется разделение в пост-плейстоцен.

Ключевые слова: генетическая структура, генный поток, западная популяция серых китов, миграция

INTRODUCTION

In 2010, a satellite tag was placed on “Flex”, a male gray whale summering in the Sea of Okhotsk near Sakhalin Island, Russia (Fig. 1) in order to track him to the unknown western North Pacific wintering grounds thought to be in the South China Sea. On 12 December 2010, Flex instead was tracked from Sakhalin to the coast of North America. In 2011, transmitters were placed on two females, “Agent” and “Varvara,” that were feeding off of Sakhalin Island. Both were tracked travelling towards the east, and Varvara was tracked from Sakhalin to the eastern gray whale wintering grounds in the coastal lagoons of Baja California, Mexico, and then back to the Sea of Okhotsk (Mate et al. 2015). The study of Mate et al. (2015) was a landmark in gray whale science because it immediately upended the conventional wisdom of decades of North Pacific (NP) gray whale research. Specifically, it had been assumed two populations, or stocks, of gray whales are found in the North Pacific: western gray whales (WGWs) that migrate along the Asian coast between summering grounds in the Sea of

Okhotsk and wintering grounds somewhere in Asia; and eastern gray whales (EGW) that migrate between summering grounds mainly in the Bering and Chukchi Seas and wintering grounds in Mexico. The result has been an exhaustive reappraisal of gray whale stock structure hypotheses, including a 5-year “Rangewide Review of the Population Structure and Status of North Pacific Gray Whales” (Rangewide Review) conducted by the Scientific Committee of the International Whaling Commission (IWC) (IWC 2014, 2018).

North Pacific gray whales were hunted extensively during the 1800’s and early 1900’s by commercial whalers. WGWs were hunted primarily by Korean and Japanese whalers in the first half of the 20th century (Rice and Wolman 1971; Brownell and Chun 1977). EGWs were hunted by United States and Canadian whalers, and the independence of the two stocks was established based on presumed geographic isolation across the NP Ocean basin, and because hunting pressure on one population did not impact the other. This

Figure 1. Distribution of North Pacific gray whales. Habitat range is shown with blue shade and sampling location for western gray whales off Sakhalin Island is shown with a red dot. This map is redrawn from the IUCN range map (<https://www.iucnredlist.org/species/8097/50353881>).

is explained in the report of the first IWC Rangewide Review (IWC 2014, p. 11) which states, “Brownell reported that the large catches (>1,750 gray whales) by Japanese modern whalers in the East Sea of Korea from 1890–1966, but mainly in the first third of the 20th century (Kato and Kasuya 2002), came at a time when the population of gray whales in the eastern Pacific was seriously depleted as a result of 19th century whaling. This mismatch in the timing of peak catches in the eastern and western North Pacific is consistent with the hypothesis of separate populations.” This conclusion is corroborated by the historical catch data summarized in Appendix A of Bradford (2003). The Asian harvest was so great that by 1966 the WGW was considered by some to be extinct (Bowen 1974; Weller et al. 2002). However, this opinion was not shared by Brownell and Chun (1977) who documented sporadic sightings of gray whales in Asian waters during the early and mid-20th century. Nonetheless, the conclusion of Brownell and Chun (1977: p. 238) was as follows: “Therefore, we believe the western Pacific stock of gray whales will become extinct in the near future unless meaningful international protection is achieved.” In the late 1960s and the 1970s, some gray whales were sighted in the Sea of Okhotsk, South China Sea, and the Sea of Japan (Omura 1974), and gray whales

were observed in waters northeast of Sakhalin Island in the 1980s (Blokhin et al. 1985). It was assumed that the Sakhalin whales were surviving WGWs, and the population was estimated to be 100–200 individuals by Berzin and Yablokov (1978, cited in Ilyashenko 2011). While both WGW and EGW populations were hunted to near extinction, the EGW population has rebounded and now numbers approximately 27,000 (Durban et al. 2017), a number which exceeds most estimates of pre-whaling abundance (Henderson 1984). Based on photo-identification studies of the gray whales feeding off Sakhalin Island and the southern and eastern coasts of Kamchatka, the WGW population is estimated to consist of 320–410 individuals (Cooke et al. 2017) and is considered endangered by the IUCN (Cooke 2018).

The historical concept of separate stocks of gray whales on the eastern and western sides of the NP Ocean basin was supported by the catch data mentioned above, as well as genetics studies based on mtDNA and nuclear microsatellites (LeDuc et al. 2002; Lang et al. 2011). A similar biogeographic track is shared with some other marine mammals also possessing genetically differentiated eastern and western populations in the NP, such as Steller sea lions (*Eumetopias jubatus*) (Bickham et al. 1996; Baker et al. 2005; Harlin-Cognato

et al. 2006). However, recent genetic studies as well as the results of the IWC's 5-year Rangewide Review (IWC 2018) are indicative of alternative, plausible, stock-structure hypotheses. In a genetics study based on single nucleotide polymorphisms (SNPs, $n=84$ loci; Brüniche-Olsen et al. 2018a), Sakhalin gray whales were shown to comprise a mixed-stock aggregation containing individuals with either of two distinct genotypes as well as admixed individuals. Previous studies that have suggested dispersal between the eastern and western North Pacific within the last 10 ky based on mtDNA (Alter et al. 2015) are consistent with this. These distinct genotypes, as well as admixed genotypes, also were possessed by whales sampled at the EGW wintering grounds in Mexico but at substantially different frequencies. A "western" genotype was predominant in the Sakhalin population and an "eastern" genotype was predominant in Mexico. While it is tempting to assume that these two genotypes are representative of the historical EGW and WGW populations, the "western" genotype whales are of uncertain origin. Are these the descendants of the WGWs that migrated along the Asian coast that were previously believed to have been hunted to extinction? Alternatively, the "western" genotype whales might be a distinct subpopulation of EGW that has differentiated genetically because of a founder effect and/or genetic drift in a small population, a concept considered as plausible by the IWC's Rangewide Review (IWC 2018). Sakhalin whales with either of the "western" and "eastern" genotypes, as well as mixed, are known to migrate to Mexico. In this group are included reproductive females of both "eastern" and "western" genotypes (M. J. Scott, unpublished observations). Given the long migration between the Sea of Okhotsk and Mexico, and the fact that mating in gray whales takes place during the fall migration, within-group matings for the Sakhalin population might be a higher probability than outbreeding with EGWs who mainly begin the fall migration from the Bering and Chukchi Seas.

To determine if the Sakhalin whales with "western" genotypes are the descendants of the WGWs requires a different approach than simply estimating a statistically significant F_{ST} as was observed in the early studies that compared EGW and WGW samples (LeDuc et al. 2002; Lang et al. 2011). In those studies, it was established that the overall population of whales near Sakhalin have different microsatellite allele and

mtDNA haplotype frequencies than EGWs. However, that is not informative about the historical identities of the whales that currently summer off the coast of Sakhalin. Moreover, the presence of the two distinct SNP genotypes in the Sakhalin population was not known at the time of those early studies, so all Sakhalin whales were grouped together for analyses.

In this paper the following question is posed: Are the gray whales that currently summer off the coast of Sakhalin Island descendants of WGWs that migrated along the Asian coast? This question is addressed by sequencing four mtDNA genes from Sakhalin gray whales characterized as having "eastern", "western", or admixed nuclear SNP genotypes. These data are used to test hypotheses of the historical origin of the Sakhalin whales. The null hypothesis is that the "western" and "eastern" genotypes detected with SNPs (Brüniche-Olsen et al. 2018a) differ as a result of long-term isolation of two populations on either side of the North Pacific Ocean during the Pleistocene, i.e., the traditionally recognized WGW and EGW stocks. A trans-NP distribution is shared with other marine mammals, fish, and even terrestrial organisms. This was illustrated by Harlin-Cognato et al. (2006) who studied the phylogeography of Steller sea lions in this region and stated that "Congruence in the distribution of genetic diversity for a wide variety of plants and animals suggests glacial vicariance shaped the history of these species in a similar fashion." If this is the case for NP gray whales, then one would expect to see clades of related haplotypes in the phylogeny of NP gray whales with some clades unique to the Sakhalin population, and more specifically to animals with "western" genotypes. Note that if the Sakhalin "western" genotype whales are the descendants of the WGWs, they represent WGWs that have dispersed into the EGW population (at least those that migrate to Mexico; it is unknown if all or only part of the Sakhalin whales migrate to Mexico; IWC 2018).

The alternative hypothesis is that the "western" and "eastern" genotypes have originated as a result of recent dispersal of EGW into the Sea of Okhotsk, with subsequent divergence due to founder effect and/or drift. Although the isolation between these two genotypes might pre-date commercial whaling and be on the order of hundreds or a few thousands of years (i.e., post-Pleistocene), or possibly following the near-

extirpation of the WGW stock in the 20th century, it would not show the degree of strong differentiation including clades of related haplotypes expected of populations isolated on opposite sides of an ocean basin through the Pleistocene. In the case of recent dispersal, haplotypes would be expected to be shared among the “eastern” and “western” genotype whales, but with different frequencies, and no clades of haplotypes unique to the “western” genome animals. Also, one would not expect to find many, if any, unique haplotypes with such recent divergence, but the small sample size of “eastern” genotype whales in this study prevents unique haplotypes from being a meaningful metric. It is implicit that the extinction of the WGW, or simply their absence from the samples because they are not found at Sakhalin, is what prevents the observation of clades of related haplotypes.

In order to test the two hypotheses of gray whale population structure, extended mtDNA sequences including the non-coding control region as well as three protein-coding genes (*COI*, *Cyt b*, and *ND2*) were produced from 65 Sakhalin gray whales. Previous studies of Sakhalin gray whale mtDNA have included only control region (LeDuc et al. 2002; Lang et al. 2011) or multiple mtDNA genes (Meschersky et al. 2015) and have shown no evidence of unique haplotype lineages in the Sakhalin whales. However, those studies predated Brüniche-Olsen et al. (2018a) and thus a mixed sample of “eastern” genotype and “western” genotype whales likely were included. MtDNA divergence, analyzed separately using the control region alone and using an extended sequence of three protein coding genes, was estimated for “eastern” and “western” genotype whales sampled near Sakhalin.

MATERIALS AND METHODS

A total of 75 skin samples of gray whales was obtained by the remote biopsy method in accordance with permission of the Russian Federal Supervisory Natural Resources Management Service (Rosprirod-nadzor) along the coast of Sakhalin Island, Pil'tun Bay in August–September of 2012 (16 samples), 2013 (8 samples), 2014 (27 samples), 2015 (9 samples), and 2016 (15 samples). A total of 65 individual gray whales are represented among these samples as determined by unique SNP genotypes and photographic identification (Brüniche-Olsen et al. 2018a).

The tissues were stored in ethanol and shipped to the Laboratory of Genetics, National Scientific Center of Marine Biology, Far East Branch of the Russian Academy of Sciences (NSCMB FEB RAS, Vladivostok, Russia). Total genomic DNA was extracted using the standard phenol-chloroform method (Sambrook et al. 1989) or with a NucleoSpin® Tissue Kit (MACHEREY-NAGEL GmbH & Co.). Amplifications were performed using the DreamTaq DNA polymerase (Thermo Fisher Science, USA). The primers and conditions described by Alter et al. (2009) were used to amplify 621 base pairs of the mtDNA control region (CR) (including tRNA-Pro). The full 1,153 base pair sequence of the cytochrome *b* (*Cytb*) gene was obtained using overlapping pairs of primers developed by the Laboratory of Genetics, GW-CYTB F 5'-TACCATTAACCCAGAAACGAACCAC-3'

and GW-CYTB R 5'-GAGTCTTAGGGAGGTGTG-GTTTGTCT-3'; and GW-CYTB F2 5'-ATGGGTCT-GAGGCGGTTTTCTGTAG-3' and GW-CYTB R2 5'-GAAGTGGAAGGCAAAGAAGCGTGTTA-3'. The following pair of primers was selected for the subunit 2 of the NADH dehydrogenase gene (*ND2*): CET_ND2_F (5'-CATACCCCGAAAAT-GTTGGT-3') and CET_ND2_R (5'-TAGGGCTTT-GAAGGCTCTTG-3') described in Meschersky et al. (2015), combined to produce a 1,058 base pair amplicon. Amplification conditions for *Cytb* and *ND2* were as follows: denaturation at 95°C - 3 minutes, followed by 37 cycles at 95°C - 30 sec, annealing of primers at 54°C - 60 sec, chain extension at 72°C - 90 sec, and final extension at 72°C - 5 minutes. The cytochrome oxidase I (*COI*) gene fragment with a length of 650 base pairs was amplified using the primers that were also developed by the Laboratory of Genetics, GW-COI F 5'-ACCTACTCGGCCATCTTACCTA-3' and GW-COI R 5'-AAGCCTAAGAACCCGATGGATA-3'. Amplicons were subsequently purified using Exonuclease I (Exo I) and Shrimp Alkaline Phosphatase (rSAP) (New England Biolabs). The sequencing reactions were performed using BigDye Terminator v. 3.1 kit (Perkin-Elmer, Foster City, California, USA) in accordance with the manufacturer's recommendations. Capillary electrophoresis was performed using the automated ABI Prism GA3500 Genetic Analyzer

using a 50 cm capillary assembly with POP-7 polymer. Sequences were assembled using the Geneious R11 software (v11.0.3, Biomatters Limited, Auckland, New Zealand). The similarity of the obtained sequences to those of other available sequences in GenBank was determined by a BLASTn search (Altschul et al. 1990). Sequence data were deposited in GenBank under accession numbers: MH046943–MH047185, MH064256–MH064334.

CLUSTALW (Thompson et al. 1994) was used for sequence alignment. We analyzed the control region and a concatenation of the three protein coding sequences separately. Summary statistics and demographic change parameters were calculated with DNASP v5.10.1 (Librado and Rozas 2009). Genetic diversity was quantified as the number of haplotypes (h), haplotype diversity (h_{div}), the number of segregating sites (S), average number of nucleotide differences (k), and nucleotide diversity (π). Demographic changes were quantified with Tajima's D (Tajima 1989) and Fu's F (Fu 1997).

POPART (Leigh 2015) was used to construct neighbor joining networks for each of the alignments. Genetic differentiation was measured using the fixation metric G_{ST} (Hedrick 2005) and differentiation metrics ϕ_{ST} (Excoffier et al. 1992; Meirmans 2006) and D (Jost 2008). These were estimated in R (Team 2017) using ADEGENET v2.1.1 (Jombart 2008) and MMOD v1.3.3 (Winter 2012). Estimates and 95% CI across all loci for G_{ST} , ϕ_{ST} and D were based on 100 bootstraps replicates to identify variation across each point estimate. Fisher's exact test using 1,000 repetitions was used to test for allelic differentiation among subpopulations.

Of the 65 individuals, 46 were previously genotyped at 84 autosomal SNP loci (Brüniche-Olsen et al. 2018a). Genetic admixture coefficients (Q) results from Brüniche-Olsen et al. (2018a) were used to divide the dataset into three groups: "eastern", admixed or "western". The Q -values were estimated with LEA (Frichot and François 2015), which is similar to Bayesian clustering programs like STRUCTURE (Pritchard et al. 2000), where individual admixture coefficients are estimated from the genotypic matrix. The 46 individuals were grouped according to the following Q -values: eastern ($Q < 0.200$), admixed ($0.200 < Q < 0.800$), and western ($Q > 0.800$) for the summary statistics, demographic change and network analyses. Only individuals classified as "eastern" and "western" were included in the G_{ST} , ϕ_{ST} and D analyses. Our justification for using the LEA Q -values is based on the fact that independent LEA and STRUCTURE analyses produced highly similar results despite these two methods being based on different algorithms. In the LEA program, estimates of ancestry coefficients are calculated using least-squares estimates, whereas in STRUCTURE a likelihood model is used to calculate them. LEA and STRUCTURE were shown to produce similar results (Frichot et al. 2014), but LEA performed better under certain conditions. Specifically, the performance of LEA was better than that of the binomial model used by STRUCTURE where there are high levels of inbreeding, which appears to be the case in Sakhalin gray whales (Brüniche-Olsen et al. 2018b). Only a few individuals would have been assigned to different groups had the values based on the STRUCTURE analysis been used instead.

RESULTS

Of the 65 individuals, the control region (621 bp) was amplified for 64, and the protein coding regions (2,833 bp) were amplified for all individuals. There were 19 individuals with control region and protein coding regions sequenced for which SNP genotypes are not available. These are included in the haplotype networks (see Figs. 2 and 3) but not in Table 1. Variation in sample sizes from 5–32 individuals among the "western" genotype, "eastern" genotype, and admixed groups, respectively, are shown in Table 1. A total of

14 haplotypes were observed in the control region; of these, 9 were found in the "western" genotype group, 4 in the "eastern" genotype group, and 2 in the admixed group (Table 1a). Furthermore, the "western" genotype group was shown to have higher h_{div} , S and higher π than the eastern and admixed groups. Overall, no sign of demographic change was found for the entire dataset or in the "western" and "eastern" genotype groups; only in the admixed group was an indication of a population decline ($F > 0$) shown. A similar pattern was shown in

Table 1. Summary statistics for a) the mitochondrial control region sequence (621 bp) of 45 Sakhalin gray whales with known SNP genomes, and b) the mitochondrial protein coding sequences (2,833 bp) of 46 Sakhalin gray whales with known SNP genomes are given. Determination of groups was based on individual ancestry coefficients (see main text for details). For each group the number of individuals (n), number of haplotypes (h), haplotype diversity (h_{div}), number of segregating sites (S), average number of nucleotide differences (k), nucleotide diversity (π), Tajima's D , and Fu's F are given.

	Group	N	h	h_{div}	S	k	π	D	F
a)	Western	32	9	0.774	32	9.6	0.018	1.53	0.97
	Eastern	8	4	0.643	22	7.1	0.012	-0.83	-0.82
	Admixed	5	2	0.600	16	9.6	0.015	1.83	1.96*
	All	45	14	0.763	33	9.3	0.018	1.06	0.49
b)	Western	32	11	0.802	27	7.3	0.0036	0.31	-0.69
	Eastern	9	6	0.833	18	4.0	0.0014	-1.94*	-2.40*
	Admixed	5	3	0.800	13	7.6	0.0027	1.58	1.68
	All	46	18	0.808	29	6.6	0.0024	0.28	-0.28

* denotes $p < 0.05$

the summary statistics for the protein coding regions with the “western” haplotype group having more haplotypes (“western” $h = 11$, “eastern” $h = 3$, and admixed $h = 3$) and higher S and higher π than the “eastern” haplotype and admixed groups (Table 1b), but a lower h_{div} . A population expansion ($F < 0$) was identified in the “eastern” group, but none of the other groups showed indication of demographic change.

Two high-frequency haplotypes were observed in both networks (Figs. 2 and 3). In the control region, the high frequency haplotypes were represented by 69% of the individuals (Fig. 2). In the protein coding network, they were represented by 60% of the individuals (Fig. 3). For the control region, there was no indication of individuals identified as “western”, “eastern” or ad-

mixed to cluster together (Fig. 2). A slight indication was shown of “western” individuals clustering in part of the protein-coding network (Fig. 3).

Measures of G_{ST} , ϕ_{ST} , and D between whales with “western” and “eastern” genomes based on Q-values were higher for the control region $G_{\text{ST}} = 0.355$ (95% CI: 0.008–0.702), $\phi_{\text{ST}} = 0.247$ (95% CI: -0.142–0.635), and $D = 0.273$ (95% CI: 0.001–0.545), than the protein coding sequences $G_{\text{ST}} = 0.129$ (95% CI: -0.204–0.462), $\phi_{\text{ST}} = -0.044$ (95% CI: -0.410–0.322), and $D = 0.104$ (95% CI: -0.178–0.386). Fisher's exact test, $p = 0.034$ for the control region and $p = 0.013$ for the protein coding sequences, were suggestive of our predefined groupings being genetically differentiated according to maternally inherited DNA sequences.

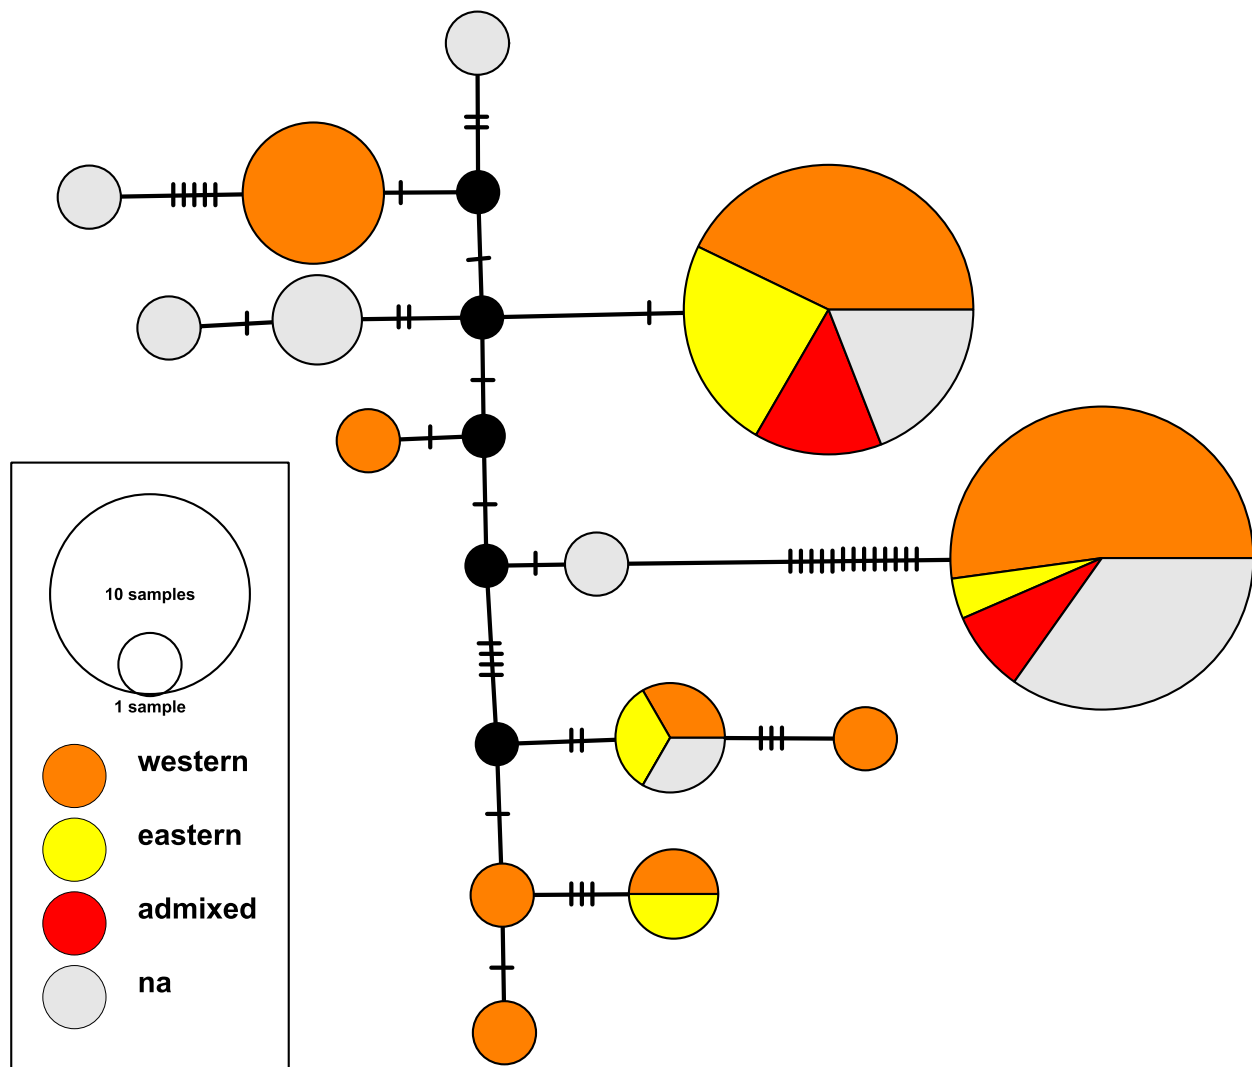

Figure 2. Haplotype network for the mitochondrial control region sequence. The haplotype frequency is indicated by the area of each circle and mutations are indicated on branches with hatch marks. The frequency of western (orange), eastern (yellow), and admixed (red) individuals based on autosomal SNPs (see main text for details) as well as individuals without autosomal SNP admixture coefficient information (gray) are indicated with color for each haplotype. Inferred haplotypes are represented by black dots.

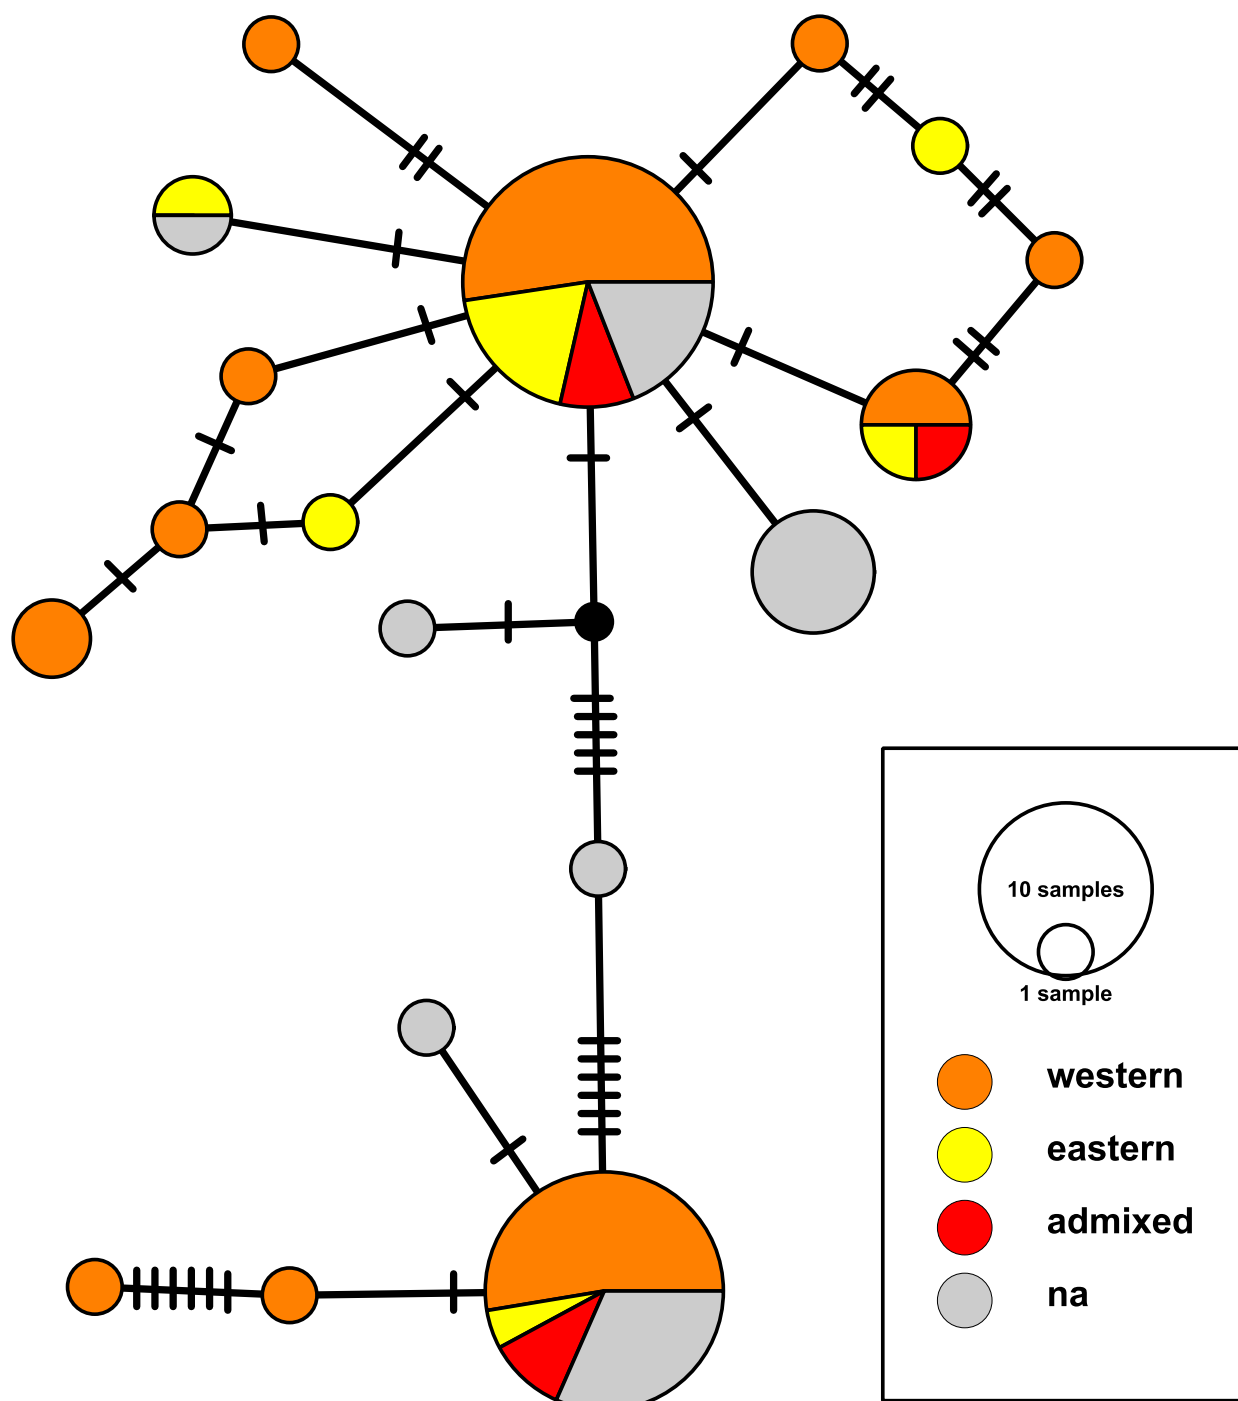

Figure 3. Haplotype network for the protein coding gene sequence. The haplotype frequency is indicated by the area of each circle and mutations are indicated on branches with hatch marks. The frequency of western (orange), eastern (yellow), and admixed (red) individuals based on autosomal SNPs (see main text for details) as well as individuals without autosomal SNP admixture coefficient information (gray) are indicated with color for each haplotype. Inferred haplotypes are represented by black dots.

DISCUSSION

Significant population structure in mtDNA sequences was revealed by Fisher's exact test for both the control region and protein coding genes. Thus, haplotype frequencies, whether identified by control region or protein coding sequences, were found to differ significantly between "eastern" and "western" genotype whales. This is indicative of the LEA scores measuring meaningful differences and that these two groups of whales likely have originated from different populations. The high degree to which there is ongoing or very recent gene flow (i.e., within a few generations) is indicated by the number of whales of admixed genotypes.

Measures of mtDNA diversity (h , S , k , and π) for both the control region and the protein coding genes are indicative of higher diversity in the "western" genotype whales compared to the "eastern" and admixed genotype whales (Table 1). However, limitations due to the small sample size of the "eastern" genome group that cause an underestimate of genetic variation in the very large EGW population, should be noted. Previous studies have shown higher mtDNA diversity for the EGW population than the small Sakhalin WGW population (LeDuc et al. 2002; Lang et al. 2011). More extensive sampling is needed to obtain better estimates of mtDNA diversity of the "eastern" and "western" genotype whales.

Haplotype networks for the control region and protein coding genes are shown in Figures 2 and 3, respectively. A comparison of the Figure 2 of this paper with Figure 3 in Lang et al. (2011), both of which are based on control region sequences, show that "western" genome whales from Sakhalin have haplotypes distributed throughout the network (Fig. 2), as does the larger sample of Sakhalin whales studied by Lang et al. (2011) but for which the SNP genotypes are not known. Haplotypes of "eastern" genotype animals also are found throughout the network in Figure 2, as are EGW haplotypes in Figure 3 of Lang et al. (2011).

The absence of any indication of a clade of similar haplotypes unique to the WGW in Lang et al. (2011) and in "western" genotype animals (Fig. 2) is consistent with the alternative hypothesis, that the "western"

genotype whales are likely a subpopulation of the EGW population (i.e., not likely the descendants of the WGW population that migrated along the coast of Asia). It is also consistent with the mtDNA control region study of Alter et al. (2015), whose Figure 1 dates ostensible dispersal events between western and eastern Pacific gray whales to <10 kya. However, the hypervariable control region in mammals is known to be prone to extensive homoplasy in the form of recurrent substitutions at certain variable positions (Phillips et al. 2009). It was shown by Phillips et al. (2009) that accounting for the homoplastic substitutions is necessary to obtain a fully resolved haplotype network. To illustrate the significance of this, Phillips et al. (2011) were able to resolve ostensible long-range dispersal of Steller sea lions as being the result of homoplastic mutations, not dispersal. In this study, recurrent substitutions in the control region were not investigated, but it is likely that they are present, so the protein coding genes were analyzed separately. In the haplotype network shown in Figure 3, as in Figure 2, two common alleles that are distantly related are seen, and "western" genotype whales are found throughout the network. These patterns have been observed in all mtDNA studies of gray whales. An examination of Figure 1 in Meschersky et al. (2015), which is a haplotype network based on two protein coding genes and the control region, and the Figure 3 of this paper confirms this. Moreover, as shown in Figure 3, both "eastern" and "western" genotype whales are present in both of the distantly related common haplotypes. Therefore, there does not appear to be strong evidence of clades of related haplotypes that are specific to "western" genome whales, even with the extended three protein coding genes.

It is also useful to compare the phylogeographic patterns of gray whales to other baleen whales. While baleen whales often show distinct phylogeographic patterns including clades of related haplotypes in comparisons of populations between ocean basins (Archer et al. 2013; Jackson et al. 2014; Alter et al. 2015), comparisons within ocean basins, as in this study, might not show such a pattern due to the high vagility of and dispersal capability of these animals. For example, in neither the North Pacific right whale, *Eubalaena japonica*, nor the North Pacific humpback whale,

Megaptera novaeangliae, are clades of related haplotypes found in comparisons made between populations that are otherwise strongly differentiated by mtDNA haplotype frequencies (Baker et al. 2013; Pastene et al. 2013). Clearly, a long period of isolation is needed for the establishment of clades of related haplotypes, and in species with high dispersal capabilities inhabiting Oceans without strong geographic boundaries it is possible that gene flow prevents this. Then why should we expect WGWs and EGWs to have clades of related haplotypes?

One unique aspect of gray whale distribution is that it is tightly correlated with coastal habitats. This is because gray whales are adapted to feed mainly on benthic organisms found in relatively shallow waters, and it is the only baleen whale species to do this. Thus, the Steller sea lion, which is also more closely tied to shallow waters and coastal habitats, seems to be a better comparison than pelagic species of baleen whales. And secondly, in the studies conducted on right whales and humpback whales only mtDNA control region sequences were used. Thus, the problem of recurrent mutations that mimic gene flow might obfuscate the finding of clades of related haplotypes if such have ever been established. The bowhead whale (*Balaena mysticetus*) might be an example of this. Two populations of bowhead whales are found in the North Pacific Ocean, one that inhabits the Sea of Okhotsk and the other in the Bering, Chukchi, and Beaufort Seas (BCB). As with the gray whales, the bowhead population in the Sea of Okhotsk is very small and endangered, and the BCB population is large. Studies that employed only control region sequences (Alter et al. 2012 and references therein) found four haplotypes among 24 Sea of Okhotsk bowhead whales, all of which were shared with BCB whales. Baird et al. (2018) examined control region and two protein coding gene sequences from seven Sea of Okhotsk whales and a large number of BCB whales and found five haplotypes of which three were unique to the Sea of Okhotsk whales. Of these five haplotypes, no clear examples of clades of related haplotypes were found, although two haplotypes were found that were one step different; one being a shared haplotype and the tip haplotype unique. Also, the five haplotypes found in the Sea of Okhotsk are restricted to one part of the very large 141-haplotype network.

Thus, examination of the extended sequence allows for a higher degree of resolution and a greater probability of finding clades of related haplotypes.

It should be recognized that this study is based on a small sample size, especially of the “eastern” genotype whales ($N = 8$). Thus, the results and conclusions can be considered as preliminary, but they nonetheless are the best indicators available of the historical relationships of gray whales currently summering at Sakhalin Island. When other lines of evidence are considered, namely that a sizeable number of Sakhalin whales have been confirmed to migrate to North American waters (Mate et al. 2015) and the number of gray whales observed in Asian waters south of the Sea of Okhotsk is small (Weller et al. 2008), the weight of evidence seems to be mounting that there is continuity in the gray whale gene pool, in contrast to the established view of discontinuity.

In conclusion, the analysis of mtDNA control region and three protein coding genes of gray whales summering near Sakhalin Island in the Sea of Okhotsk, Russia, failed to reveal the presence of clades of related haplotypes specific to the “western” genotype whales as identified by nuclear SNP loci. Rather, both “western” and “eastern” genotype animals had haplotypes found throughout the network. This is inconsistent with the null hypothesis of historical divergence (e.g., due to Pleistocene isolation) but consistent with the alternative hypothesis that the “western” and “eastern” genotypes originated as a result of recent dispersal of EGW into the Sea of Okhotsk. In the absence of archaeological or historical samples from the range of the WGW in Asia, further testing of this hypothesis is needed by employing larger sample sizes of Sakhalin whales. In particular, more whales with the minority “eastern” genome need to be analyzed. Other approaches to explore the historical demography of the “western” and “eastern” genotypes that can be applied to whole genome sequences as well as mitogenomic analyses need to be extended beyond the three whole genomes analyzed in Brüniche-Olsen et al. (2018b). The significance of this study is that the current mtDNA and nuclear SNP data suggest that the Sakhalin whales with “western” genotypes may simply be a geographical isolate of the larger EGW gene pool.

ABSTRACT

The western gray whale population is critically endangered and its continued ability to survive is of concern. The most recent population assessment, using a Bayesian individually-based stage-structured model, resulted in a median 1+ (non-calf) estimate of 130 individuals (90% Bayesian CI = 120-142). The collaborative Russia-U.S. research program on western gray whales summering off northeastern Sakhalin Island, Russia, has been ongoing since 1995 and has produced important data that has been used to determine the conservation status of this critically endangered population. This paper reviews findings from 2011 research activities and combines such with data from previous years, in some cases ranging back to an opportunistic survey in 1994. Photo-identification research conducted off Sakhalin Island in 2011 resulted in the identification of 83 whales, including twelve calves and two previously unidentified non-calves. Three new reproductive females were recorded in 2011, resulting in a minimum of 29 females now known to have produced calves at some point during the study. When 2011 data are combined with results from 1994-2010, a catalog of 200 photo-identified individuals has been compiled. In 2010 and 2011, a satellite tagging study on gray whales off northeastern Sakhalin Island collected photo-identification images. With data use permission from the International Whaling Commission, these photographs were processed and incorporated into our photo-identification catalog, bringing the total number of identified whales to 205.

KEYWORDS: WESTERN GRAY WHALE; RUSSIA; POPULATION BIOLOGY; BEHAVIOR; CONSERVATION

INTRODUCTION

As with other species of baleen whales, gray whales annually migrate great distances from the breeding grounds in the subtropical waters to cold and productive northern regions. Two genetically separated populations of gray whales exist in the Eastern North Pacific region. The eastern (California-Chukchi) population is abundant (about 22,000 whales (Punt and Wade, 2010)), breeds in the warm shallow lagoons off Baja California, and feeds in summer time in the Chukchi and Bering seas. The other population is the western (Korean-Okhotsk), which is extremely endangered numbering about 130 whales, including only 29 reproductive females producing calves once in about 2-3 years (Cooke, 2010).

Western gray whales travel for thousands of miles to feed on the abundant soft-bottom benthic communities in the western part of Bering and Okhotsk Seas. This feeding period is extremely important for these slow breeding whales, and any disturbance preventing, reducing or limiting feeding can potentially lead to stress in and compromise the health of these whales. The near-shore affinity of gray whales makes them particularly vulnerable to environmental fluctuations and anthropogenic activities. For the past decade, industrial development in the coastal waters of northeastern Sakhalin, namely oil and gas development and related exploration (including seismic surveys, offshore platform installation, pipeline construction, dredging, vessel traffic) became a cause for concern, especially since the oil and gas fields overlap with the primary feeding ground of western gray whales (Blokhin and Burdin, 2001; Gailey *et al.*, 2011). Many individual whales return annually to the same feeding sites off northeastern Sakhalin Island, indicating a site-specific dependence to this geographic area (Weller *et al.*, 2007). This critically important habitat is especially vital for nursing females and their calves, as female energetic requirements are increased during lactation, and calves need to be ready to separate and begin to feed on their own.

The western gray whale population is critically endangered and its continued ability to survive is of concern (Weller *et al.*, 2002a; Reilly *et al.*, 2008). Hunted to such low numbers in the mid 20th century that some thought it to be extinct, the population remains highly depleted today (Weller *et al.*, 2002a; Cooke *et al.*, 2008). The International Whaling Commission (IWC) and the International Union for Conservation of Nature (IUCN) have each expressed serious concern about the status of this population and have called for urgent measures to be taken to help ensure its protection (see Reilly *et al.*, 2008; IWC, 2004; Reeves *et al.*, 2005).

Recent data obtained by a satellite tagged gray whale from Sakhalin Island (Mate *et al.* 2011), along with photo-identification matches (Weller *et al.*, 2011), has shown that some whales migrate to Mexico to the well-known breeding grounds. But in November 2011, a female gray whale stranded in China in the Taiwan Strait area (Zhu, 2012). This record indicates some whales still inhabit the Asian coast, south from Korea. This novel information on gray mixing should stimulate further research on the gray whales coming to Russian waters during the summer because the number of the Korean-Okhotsk stock of gray whales may be even smaller than previously estimated (Weller *et al.*, 2011).

This report reviews summary findings from 2011 research activities on western gray whales off Sakhalin Island in the Russian Far East and integrates new information with data from previous years, in some cases ranging back to 1994. Discussion of the current status of the population and a review of threats to its continued survival, including potential impacts associated with large-scale oil and gas development activities on the summer feeding ground and entrapments in trap nets off Japan during migration, are provided herein.

METHODS

The overall consistency in research design, data collection techniques and data analysis maintained in 2011 allowed inter-annual comparisons to be made. Additional information, collected during more limited surveys off Piltun in 1994 and 1995 (Brownell *et al.*, 1997; Weller *et al.*, 1999), is also presented here to better describe inter-annual trends and facilitate a long-term interpretation for some results. Data from these 1994 and 1995 studies include gray whale photographs obtained between 7-12 September 1994 during the filming of a wildlife documentary by H. Minakuchi (for description see Weller *et al.*, 1999) and from 14-20 August 1995 during a pilot study to determine the feasibility of conducting boat- and shore-based research in the study area (Brownell *et al.*, 1997).

Study area

The study area is located near Zaliv Pil'tun (referred to as Piltun Lagoon) on the northeastern shore of Sakhalin Island, Russia (Fig 1). The lagoon is approximately 80-90 km long and 15 km across at its widest point. A single channel connecting the inner lagoon with the Okhotsk Sea occurs at 52° 50' N and 143° 20' E, and has considerable biological influence on the surrounding marine environment. A lighthouse, near the lagoon channel, served as the base from which studies reported here were conducted. The nearshore marine environment of the study site is mostly sand substrate, characterized by a gradually sloping and broad continental shelf. Water depths within 5 km of shore are mostly less than 25 m deep. Despite the similarity of Piltun Lagoon to the coastal lagoons used during the winter by eastern gray whales off Baja California, Mexico, whales do not enter this lagoon.

Photo-identification surveys

Gray whales have distinctive body markings, such as natural coloration and pigmentation patterns, as well as scars that are unique to an individual and can be used for individual recognition. Boat-based photo-identification surveys were conducted on all good weather days during the 2011 study period. Identical methodology was employed during each survey, with the primary objective of encountering and photographically identifying as many whales as possible. Previous photo-identification data gathered in the Piltun area between 1995 and 2010 used right-side dorsal flank markings for identification (Brownell *et al.*, 1997; Weller *et al.*, 1999, 2006a), and for the sake of intra- and inter-annual reliability, we continued this methodological approach. Attempts were made to photograph the right dorsal flank of each whale, followed by efforts to photograph the left dorsal flank and fluke. The majority of whales identified to date now have images of right and left flanks as well as ventral surface of flukes in the photo-identification catalog allowing for useful identification images to be collected from nearly any body region. The western gray whale photo-identification catalog compiled by our Russia-U.S. research program is available on request to all interested parties (Weller *et al.*, 2006a).

Photographic surveys involved slow travel in a 4.5 m outboard-powered inflatable boat. To photograph whales we used a Nikon D7000 digital camera with a 100-400 mm Nikon lens. Measures of environmental conditions, water depth, geographic position, and group size were recorded for each group photographed.

In 2010 and 2011, a satellite tagging study on gray whales off northeastern Sakhalin Island collected photo-identification images (see Mate *et al.*, 2011). With data use permission from the International Whaling Commission, these photographs were processed and incorporated into our photo-identification catalog.

RESULTS

Survey effort and photo-identification catalog

Fourteen photo-identification surveys, with a total of 77.2 hrs spent at sea and 32.7 hrs spent in direct observation of 83 whale groups, were conducted between 28 June and 26 August in 2011 (Table 1). The most surveys in 2011 were conducted in July (10 surveys). One photo-ID survey was completed in June, and due to the poor weather conditions (heavy fog and high sea state), only three surveys were conducted in August. Between 1994 and 2011, 200 western gray whales have been identified during 384 boat-based surveys off northeastern Sakhalin Island (Table 1). Ninety-six of the whales in the photo-catalog were animals first identified as calves, while the remaining 104 whales were considered non-calves (i.e. adults or subadults). In combination with the additional photo-identification data from the aforementioned satellite tagging study (Mate *et al.*, 2011), our western gray whale catalog contains a total of 205 identified individuals. However, not all of these 205 individuals are considered to be alive (see Cooke *et al.*, 2008).

Table 1. Annual survey effort, groups encountered, and whales identified in 1994-2011.

Year	Sampling Period	Number of Surveys	Observation Hours	Groups Encountered	Whales Identified
1994	09/07 - 09/12	1			9
1995	08/15 - 08/19	5	10.1	23	28
1997	07/09 - 09/08	22	33.4	114	47
1998	07/06 - 09/29	35	50.5	125	54
1999	06/29 - 10/13	56	122	434	69
2000	06/25 - 09/16	40	56.5	365	58
2001	06/25 - 09/25	49	101.8	448	72
2002	07/01 - 09/25	36	75.6	411	76
2003	07/15 - 09/13	22	41.7	219	75
2004	07/29 - 09/12	21	33.8	194	94
2005	07/04 - 09/09	20	40.9	160	93
2006	07/23 - 08/25	10	24.1	96	79
2007	07/26 - 09/09	20	32.2	187	83
2008	07/08 - 08/21	12	47.0	38	45
2009	06/24 - 08/26	17	67.0	126	82
2010	08/09-08/26	4	11.5	40	42
2011	06/28-08/26	14	32.7	83	83
Overall		384	780.8	3063	200 ¹ (205) ²

¹ The number of whales identified annually includes resightings of individuals from previous years, resulting in a total of 200 identified individuals. The number of whales identified does not correspond to the size of the population.

² The total number of identified individuals in the catalog is 205 when data collected during a separate satellite tagging study (see Mate *et al.*, 2011) are included.

Eighty-three naturally marked individual whales, including 12 calves, were identified during 2011 (Table 2). Of the 71 non-calves identified in 2011, 69 whales (97.2%) had previous sightings in the Piltun area during 1994-2010 photographic efforts (Table 2). The mean pod size for all groups (n=83) encountered during 2011 was 2.2 ± 1.47 ranging from 1 to 8 individuals per pod. The majority of sightings were of single whales (39.8%) and groups of two (32.5%). Two groups were encountered with the largest group size of eight individuals. The first sighting of a large group occurred on 18th July. Eight adult whales, all known from previous years, were observed feeding together. The second group of eight whales was sighted on 28th July and consisted of individuals of different ages interacting with

each other: three mother-calf pairs, one calf from 2010 (now a yearling), and a non-calf individual new to the Sakhalin catalog.

Forty-two individual gray whales were observed only once throughout the season; twenty-four whales were sighted twice. The maximum number of resightings in 2011 was seven, recorded for a calf that was observed both with its mother and alone (after separation from the mother). Two individuals identified as calves in 2010 were also sighted this year. One of them was photographed three times throughout the 2011 season. Also, four calves of 2009 were encountered this year; all of them were observed off Sakhalin in 2010 as well.

Table 2. Annual sighting trends and resighting percentages, 1994-2011.

Year	Whales Identified	Number of Calves	New Non-Calves	% Non-Calves Previously Identified
1994 ¹	9			
1995 ¹	28	2	20	23.1%
1997	47	2	25	44.4%
1998	54	8	5	89.1%
1999	69	3	12	81.8%
2000	58	3	3	94.5%
2001	72	6	6	90.9%
2002	76	9	3	95.5%
2003	75	11	2	96.9%
2004	94	8	3	96.5%
2005	93	6	4	95.4%
2006	79	4	3	96.0%
2007	83	9	2	97.3%
2008	45	3	0	100.0%
2009	82	7	2	97.6%
2010	42	3	1	97.4%
2011	83	12	2	97.2%
		(15) ²		

¹ Data from 1994 and 1995 were opportunistic and pilot in nature (respectively) and are thereby viewed as incomplete for some of the reported values.

² Total of 15 calves identified in 2011 when data collected during a separate satellite tagging study (see Mate *et al.*, 2011) are included.

Mother-calf pairs

Eleven mother-calf pairs and one already weaned calf were identified in 2011. This is the highest number of calves identified off northeastern Sakhalin among all years of our research. In addition, two more mother-calf pairs and another weaned calf were photographed by the satellite tagging team, summing up the total number of calves identified in 2011 to 15. All thirteen mothers have been sighted in the study area prior to 2011, however, three of them have never been observed in previous years with calves. Therefore, a total of 29 known reproductive females have been documented between 1995 and 2011. One of the females observed as a mother in 2011, also had a calf in 2009, and was first identified in 1998 as a calf herself. We presume that this is her second calf and her first calving interval was 2 years. All other nine females have had multiple offspring during the 1995-2011 study.

The first sighting of a mother-calf pair in 2011 occurred during our second photo-ID survey on 7 July. Eight different mother-calf pairs were identified in July, and three other pairs were sighted in August only. The calf that was already weaned prior to the first sighting was observed on 20 August in association with two mother-calf pairs.

Two mother-calf pairs and one weaned calf photographed during the satellite tagging study were sighted in August and September.

Biopsy sampling

Our second research objective during the 2011 survey was biopsy sampling of gray whales observed in the area. A total of 14 biopsy samples were obtained in 2011. Eight of these samples were from calves of this year; one sample was taken from a calf of 2010, and one from the calf of 2009.

DISCUSSION

A number of biological parameters in concert with a variety of human-related threats, as identified during the current long-term study and discussed below, raise concern about the ability of the western gray whale population to rebound from its highly depleted state and highlight the importance of continuing the long-term Russia-U.S. collaborative research and monitoring program.

Population size

The size of the western gray whale population is extremely small compared to most other baleen whale populations. Photo-identification studies off northeastern Sakhalin Island have identified a total of 200 individual whales during 384 surveys conducted between 1994 and 2011. Although the photo-catalog now contains 205 whales (combining satellite tagging data), not all of these individuals are assumed to be alive. The most current mark-recapture analysis conducted estimated the abundance for the population to be 99 (95% CI = 90-109) in 2003 (Bradford *et al.*, 2008). A population assessment by Cooke *et al.* using a Bayesian individually-based stage-structured model fitted to the same photo-identification data as used in the mark-recapture studies, but also including data from 2004 through 2007 has recently been completed. Should current population and demographic trends continue, this assessment projected a median 1+ (non-calf) estimate of 130 (90% Bayesian CI = 120-142) in 2008 (Cooke *et al.*, 2008).

Reproduction and survival

Although calves are being born annually, the limited number of known reproductive females in combination with relatively low calf survival is likely to be limiting potential population growth (Bradford *et al.*, 2006; IISG, 2006; Cooke *et al.*, 2008). In recent years, the calving interval in the western population appears to be shifting from a three-year interval to a two-year interval (Weller *et al.*, 2009). If this change persists, the general increase in calf production will continue and, in turn, contribute to an increase (albeit slow) in the growth rate of the population.

Mother-calf pairs

Thirteen mother-calf pairs were identified during the 2011 season. All thirteen mothers have been sighted in the study area prior to 2011, however, three of them have never been observed in previous years with calves. Therefore, a total of 29 known reproductive females have been documented between 1995 and 2011. The annual return of reproductive females while pregnant, resting and lactating indicates that the nearshore Sakhalin Island feeding area is of significant importance to the continued survival of this population. The behavior of these females indicates that this feeding ground is vital to population survival and growth.

Threats to the population

In addition to the biological difficulties (e.g., small population size, low number of reproductive females) that western gray whales face, the onset of large-scale oil and gas development programs off Sakhalin Island in the mid-1990s introduced new threats to the future survival of the population (Weller *et al.*, 2002a; Reeves *et al.*, 2005; IISG, 2006). Sakhalin Island is a region rich with large reserves of offshore oil and gas that, until recently, have been unexploited. Industrial activities on the continental shelf of this region have steadily increased in the past ten years and are scheduled to expand at a rapid pace into the future. Oil and gas development activities that may negatively impact western gray whales include: (1) disturbance from underwater noise associated with seismic surveying (Weller *et al.*, 2002b; 2006b, 2006c), pipeline dredging, ship and helicopter traffic and platform operations; (2) direct interactions between whales and an oil spill or other waterborne chemicals, ships, and possible entanglements in cables or lines; and (3) habitat changes related to seafloor modifications associated with dredging and sand pumping activities that may adversely impact gray whale prey (for reviews see Reeves *et al.*, 2005; IISG, 2006).

The number of individual whales photo-identified on the nearshore feeding ground in 2008 was very low in comparison to 2009 and previous years with a similar amount of spatial and temporal survey effort (see Table 1). Given the short nature and small number of surveys in 2010, a direct comparison with 2009 data was inappropriate;

nonetheless 42 whales identified during four surveys suggest 2010 was similar to previous years except 2008. In 2011, a high number of individual gray whales were encountered, which is comparable to the results of 2009-2010. While the low numbers observed in 2008 continues to be of concern, it is clear that results from 2009-2011 are more typical. It is possible that the observed pattern in 2008 was anomalous and was simply attributable to natural variation in behavior. It is also plausible, however, that the change reflected whales being displaced from the feeding area or, worse, indicates partial abandonment of what has traditionally been a critical feeding habitat (especially for mother-calf pairs) for the population. While natural variation in food resources and other biological factors are being investigated by industry-sponsored research groups, additional investigations need to be undertaken to examine the possible contributions of pile driving activities and a seismic survey that both occurred in close proximity to the nearshore feeding ground in summer 2008. Until more conclusive explanations can be drawn with regard to the low number of whales observed in 2008, the influence of industrial activities cannot be ruled out as contributing factors.

Another significant threat to the western gray whale population involves incidental catches in coastal net fisheries, particularly off Japan, within their migratory route (Weller *et al.*, 2002a; Kato *et al.*, 2005, 2006, 2007; Brownell *et al.*, 2007; Weller *et al.*, 2008). In 2005, three female western gray whales (one mother-calf pair and one yearling) died in fishing nets on the Pacific coast of Japan during their northward migration. Unfortunately, in 2007 another young female western gray whale died after being entrapped in a trap net also on the Pacific coast of Japan (Anonymous, 2007a,b,c; Brownell *et al.*, 2007; Kato *et al.*, 2007; Weller *et al.*, 2008). Projections from recent population assessments suggest that if this level of net-related mortality continues, there is a high probability the population will decline to extinction (Cooke *et al.*, 2008). In addition, an analysis of anthropogenic scarring of western gray whales found that 18.7% ($n = 28$) of 150 individuals identified between 1994 and 2005 were determined to have been previously entangled in fishing gear (Bradford *et al.*, 2009), further highlighting the overall risks coastal fisheries pose to western gray whales. Finally, while nothing is known about net entrapments or entanglements in other regions (e.g., Korea and China) within the range of the population, it is likely that coastal net fisheries outside of Japan also contribute to some level of mortality.

Although there are historical data on gray whales sightings in waters off Japan, South Korea and China, and also documented net entrapments near Japan, the wintering grounds for western population remain unclear (Weller *et al.*, 2008). Some western gray whales are seen near Kamchatka, and both intra-annual and intra-seasonal exchange of individuals between feeding grounds off Sakhalin and Kamchatka are documented (Tyurneva *et al.* 2010). In 2010, a satellite tagging project was initiated off northeastern Sakhalin (Mate *et al.*, 2011)¹. A male gray whale, which was observed as a calf in 1997 and sighted in most years of study in the Piltun area, was tagged and tracked during October 2010–February 2011. This individual traveled over 7500 km from Sakhalin feeding grounds to the Oregon coast (USA). Five more whales observed on the feeding grounds off Sakhalin in different years were confirmed with photographic matches to the whales from a eastern North Pacific catalog (Weller *et al.* 2011). This highlights that the range and potential threats this population may face may be on a larger scale than previously anticipated.

Such a wide range in distribution makes whales vulnerable to other unknown threats to the western gray whale population including continued mortality from an undetermined level of suspected poaching in the central portion of the range (Brownell and Kasuya, 1999; Baker *et al.*, 2002), as well as a potential increase in the likelihood of disturbance, exposure to pollution, and probability of ship strikes due to substantial nearshore industrialization and shipping congestion throughout the migratory corridor(s).

Genetics

Previous genetic research on the western gray whale population has documented clear genetic differentiation from the eastern population on the basis of mitochondrial DNA haplotype frequencies (LeDuc *et al.*, 2002). Given the small size of the western population and its isolation from the eastern population, the potential for continued loss of genetic diversity due to genetic drift or removal of individuals with rare alleles is of concern (Lang *et al.*, 2004; 2005). The limited number of females in the population may hinder reproductive output and in turn slow population recovery. The male bias observed for calves indicates lower recruitment of females into the adult population. This pattern further perpetuates the problem of a limited number of females being available to reproduce. Although, the recent genetics results of comparing microsatellite markers show some degree of movements between western and eastern populations, it supports their recognition as two separate populations (Lang *et al.*, 2010).

CONCLUSIONS

Based on the results reported here, it is clear that the western gray whale population is precariously balanced between survival and extinction. In addition to the variety of biological factors that may be limiting population

growth, large-scale oil and gas development programs that may alter the prey base or introduce disturbance to feeding whales, as well as entrapment and entanglement in fishing gear, especially in trap nets off Japan, are of serious concern with regard to the future survival of the population.

Given the continued uncertainty regarding the ability of the western gray whale population to increase from its depleted state, impacts from oil and gas development activities off the northeastern Sakhalin Island coast need to be closely monitored and stringently mitigated to reduce disturbance to the lowest possible level. In addition, net entrapments of western gray whales off Japan and possibly elsewhere can lead the population to extinction (IISG, 2006; Cooke *et al.*, 2008; Brownell *et al.*, 2007; Weller *et al.*, 2008). Thus, human related mortality during migration and in the (yet to be determined) wintering area(s) must be addressed and mitigated to the lowest possible level. Where scientific knowledge is lacking, the precautionary principle should be applied as the best measure of protection. With this in mind, the photo-identification and genetic biopsy research conducted since 1995, and reviewed here, must be continued to further monitor survival of individuals, describe the overall population trend and to recommend further conservation and protection measures.

In conclusion, protection of the Sakhalin Island feeding habitat, including the coastal lagoon systems that appear integrally related to the high benthic biomass used by the whales in the nearshore area, is clearly paramount to successful conservation of the western gray whale population. The unique method of benthic feeding by these whales makes them an "umbrella" species (Hooker and Gerber, 2004), whereby protection of their habitat provides protection for the biological diversity of the entire northeastern Sakhalin Island shelf. Thus, the feeding habitat of the western gray whale needs to be considered a "hot spot" for conservation planning now and in the future and every effort should be taken to protect its biological integrity. In continuation of this research and looking for the development of additional western gray whale conservation measures, the next step should be intensifying research of gray whales off Kamchatka.

ACKNOWLEDGEMENTS

New young researchers joined the western gray whale project in 2011. We were fortunate to work with a wonderful cast of characters during the 2011 field season, with special thanks to Eugenia Dolgova, Vitalii Vorobiov, Alexei Sereda, Dmitry Fedin, Aleksandr Likhanov. We gratefully acknowledge the support of the International Fund for Animal Welfare (IFAW) who funded this study. This project was conducted as part of the Marine Mammal Project under Area V: Protection of Nature and the Organization of Reserves within the U.S.-Russia Agreement on Cooperation in the Field of Environmental Protection.

Updated analysis of abundance and population structure of seasonal gray whales in the Pacific Northwest, 1998-2010

(SC/M12/AWMP2-Rev)

John Calambokidis, Jeffrey L. Laake, Amber Klimek

Abstract

The existence of a small number of Eastern North Pacific gray whales that spend the spring, summer and fall feeding in coastal waters of the Pacific Northwest has been known for some time and localized short-term studies have examined aspects of the natural history of these animals. We report the results of a 13-year (1998-2010) collaborative study examining the abundance and the population structure of these animals conducted over a number of regions from Northern California to British Columbia using photographic identification. Some 14686 identifications representing 1031 unique gray whales were obtained. Gray whales seen after 1 June (after the northward migration) were more likely to be seen repeatedly and in multiple regions and years and therefore 1 June was used as the seasonal start date for the data included in the abundance estimates. Gray whales using the Pacific Northwest in summer and fall include two groups: 1) whales that return frequently and account for the majority of the sightings and 2) apparent stragglers from the migration seen in only one year, generally for shorter periods and in more limited areas. Abundance estimates for whales present in summer and fall using four different methods over different geographic scales revealed the abundance of animals to be at most a few hundred individuals. All of the estimators except those based on Lincoln-Petersen, which was likely biased by the violation of population closure, showed an increase in abundance in the late 1990s and early 2000s. This was during the period the eastern North Pacific gray whale population was experiencing a high mortality event and this created an apparent influx of animals into the area. While estimates during that period may have been altered by this event, the abundance since then has been very stable. Recent matches of photo-identified gray whales from the Pacific Northwest to other regions have provided new insights into the movement of some of these individuals including matches to Barrow, Alaska. The proportion of calves documented was generally low but varied dramatically among years and may have been biased downward by weaning of calves prior to entry in the study area or prior to much of the collaborative seasonal effort. Observations of calves returning to the Pacific Northwest in subsequent years documents one possible mechanism for recruitment. The results we present will be valuable in assessing the impacts of potential resumption of a gray whale hunt by the Makah Tribe.

1 Introduction

Although most gray whales in the Eastern North Pacific stock migrate each spring from calving lagoons in Baja Mexico to feeding grounds in the arctic, the existence of gray whales that spend the spring, summer and fall feeding in coastal waters of the Pacific Northwest has been known for some time. Starting in the 1970s, photographic identification demonstrated that some whales returned regularly to feed off the west coast of Vancouver Island (Darling 1984). The proximity of these whales to the traditional whale hunting grounds of the Makah Tribe coupled with the Tribe's interest in resuming gray whale hunts in the 1990s, made determination of the status and number of these whales of greater importance to management.

Beginning in 1996, a collaborative effort among a number of research groups was initiated to conduct a range-wide photographic identification study of gray whales in the Pacific Northwest (Calambokidis et al. 2000, 2002b). An initial publication of findings from 1998 demonstrated there was considerable movement of individual whales among sub-areas from northern California to southeastern Alaska (which we broadly refer to as the Pacific Northwest) and also provided initial estimates of the abundance of whales within that geographical area (Calambokidis et al. 2002a). The ability to look at movements and employ more sophisticated capture-recapture models, however, was restricted by the lack of multiple years of data with broad geographic coverage. A subsequent report by Calambokidis et al. (2004) characterized the group of whales feeding in these survey areas during the summer-fall period as a "Pacific Coast Feeding Aggregation" (PCFA). They proposed that a smaller area within the PCFA survey areas – from Oregon to Southern Vancouver Island (OR-SVI) – was the most appropriate area for abundance estimation for managing a Makah gray whale hunt (Calambokidis et al. 2004). Subsequently the IWC has adopted the term PCFG for Pacific Coast Feeding group so we will use PCFG in place of PCFA.

The collaborative effort to collect photographic identifications of gray whales from California to Alaska has continued since 1998 and these data now cover 13 years (1998-2010) and span fifteen survey regions along the coast from Southern California to Kodiak, Alaska (Figure 1). We provide estimates of abundance for the summer-fall seasons (1 June to 30 November) for survey regions comprising different combinations of subareas within this range.

2 Methods

Gray whales were photographed during small boat surveys conducted from California to Alaska by Cascadia Research, National Marine Mammal Laboratory and collaborating researchers between 1998 and 2010. Gray whale identifications were divided into the following regions (Figure 1): 1) SCA: Southern California, 2) CCA: Central California, 3) NCA: Northern California, 4) SOR: Southern Oregon, 5) OR: central Oregon, 6) GH+: Gray's Harbor and the surrounding coastal waters, 7) NWA: Northern Washington coast, 8) SJF: Strait of Juan de Fuca, 9) NPS: Northern Puget Sound, 10) PS: which includes southern Puget Sound, Hood Canal (HC), Boundary Bay (BB) and San Juan Islands (SJ), 11) SVI: Southern Vancouver Island, 12) WVI: West Vancouver Island, 13) NBC: Northern Van-

couver Island and coastal areas of British Columbia, 14) SEAK: Southeast Alaska, and 15) KAK: Kodiak, Alaska. The NWA and SJF survey areas together make up the Makah Usual and Accustomed grounds (MUA). With some exceptions, research groups work primarily in one or two regions. Details of identifications obtained by the different research groups are summarized in Tables 1-2.

Each year from 1998 to 2010, between 548 and 1500 identifications were obtained of gray whales totaling 14686 photos of 1031 unique gray whales for the entire period (Table 1). These were conducted from March through November with most effort from June to September. Surveys were most numerous in British Columbia, along the south and west coasts of Vancouver Island and just north of Vancouver Island (Table 2).

2.1 Photographic Identification Procedures

Procedures during surveys by different research groups varied somewhat but were similar to one another in identification procedures. When a gray whale was sighted, the time, position, number of animals, and behaviors were recorded. Whales were generally approached to within 40-100 m and followed through several dive sequences until suitable identification photographs and associated field notes could be obtained.

For photographic identification of gray whales, both left and right sides of the dorsal region around the dorsal hump were photographed when possible. Most identification photographs were obtained with 35mm cameras most often with large 300mm lenses. Researchers also photographed the ventral surface of the flukes for further identification when possible. The latter method was not as reliable since gray whales did not always raise their flukes out of the water. Markings used to distinguish whales included pigmentation of the skin, mottling, and scarring, which varied among individuals. These markings have provided a reliable means of identifying gray whales (Darling 1984). We also identified gray whales using the relative spacing between the knuckles along the ridge of the back behind the dorsal hump. The size and spacing of these bumps varies among whales and has not changed throughout the years these whales have been tracked, except with injury. Figure 2 shows typical photographs and features used in making gray whale identifications.

Comparisons of whale photographs were made in a series of steps. All photographs of gray whales were examined and the best photograph of the right and left sides of each whale (for each sighting) were selected and printed (7 x 2.5 inch). To determine the number of whales seen during the year, the prints were then compared to one another to identify whales seen multiple days. Finally a comparison was made to the CRC catalog of whales seen in past years. Whale photographs that were deemed of suitable quality but did not match our existing catalog (compared by two independent persons) were considered “unique” identifications and assigned a new identification number and added to the catalog.

2.2 Data Analysis

The abundance of gray whales was estimated with open and closed population models for four nested spatial scales consisting of contiguous survey regions (Figure 1; Table3) 1)

NCA-NBC: the survey regions from Northern California (NCA) through Northern Vancouver Island/British Columbia (NBC), 2) OR-NBC: survey regions from southern Oregon through NBC, 3) OR-SVI: survey regions from southern Oregon through Southern Vancouver Island (SVI), and 4) MUA-SVI: the survey regions from MUA which includes Northern Washington coast (NWA) and Strait of Juan de Fuca (SJF) and SVI. The proposed hunt by the Makah Tribe would be in NWA.

Gray whales photographed and identified anytime during the period between 1 June and 30 November (hereafter referred to as the “sampling period”) within the defined region were considered to be “captured” or “recaptured”. For each unique gray whale photographed, a capture history was constructed using 13 years of data from 1998-2010. For example, the capture history 0100100100000 could represent a gray whale photographed in 1999, 2002 and 2005 in the PCFG. The same gray whale may have had a capture history 0100100000000 for a smaller spatial scale such as OR-SVI or may not have been seen at all (0000000000000) and would not be used for the smaller spatial scale.

Multiple “detections” of a single whale within the sampling period were not treated differently than a single detection. A “1” in the capture history meant that it was detected on at least one day during the sampling period. However, multiple detections in the same year were used to construct an observed minimum tenure (MT) for each whale. MT was defined as the number of days between the earliest and latest date the whale was photographed with a minimum of one day for any whale seen.

2.2.1 Abundance using closed population models

Closed models for capture-recapture assume that the population is both geographically and demographically closed with no losses or gains. Closure would not be a reasonable assumption for the entire 13 year period but previous analysis has assumed closure for two consecutive years (e.g., Calambokidis et al. 2004). For those abundance estimates, a Lincoln-Petersen (LP) estimator (Seber 1982) was used in which each of the consecutive years (June-November) was a sampling occasion. Those estimates were based on the assumption that all whales that were available to be photographed in year y were also available to be photographed in year $y+1$ and vice versa. If new whales joined in $y+1$ or whales seen in year y did not return in $y+1$, the closure assumption would be violated. It is well known that the LP estimator is unbiased if there are only losses or only gains (Seber 1982) but not both (Kendall 1999). The only exception is a population with completely random movement into and out of the population but that is not plausible with gray whales because with approximately 20,000 whales there would be few if any matches between years if movement in and out of the PCFG was completely random.

The losses and gains each year are primarily from “transient” whales that are seen in one of the years and are never seen again in any other year. To remove this source of bias, we developed the following ad-hoc approach to remove the transients. For each pair of years in the computation of abundance with the LP estimator, we only used whales that were seen in one or more years other than the years being considered. For example, in computing an abundance estimate with 1999 and 2000 we only used whales that were also seen in 1998 or at least one year after 2000. This removed any transients that would have only been seen in either 1999 or 2000. It also removes those seen only in both years; while

these are technically not single-year transients their removal was unavoidable using this approach. This was done for each year pairing and we have called this estimation method “Limited LP”. We would expect these estimates to be biased low at the end of the time sequence because new whales at the end of the time sequence have had little or no opportunity to be sighted again and thus would not be included in the analysis. The bias will be apparent by comparing the estimates for 2007 and 2008 from Calambokidis et al. (2010) and the same estimates in this paper with the data extended through 2010.

2.2.2 Abundance using open population models

In addition to the closed models, we fitted open population models to the 13 year time series of capture history data for each spatial scale to estimate abundance and survival. Open models allow gains due to births/immigration and losses due to deaths/emigration. Using the RMark interface (Laake and Rexstad 2008) to program MARK (White and Burnham 1999), we fitted a range of models to the data using the POPAN model structure. The POPAN model structure (Schwarz and Arnason 1996) provides a robust parametrization of the Jolly-Seber (JS) model structure in terms of a super population size (N), probability of entry parameters (immigration), capture probability (p), and survival/permanent emigration (φ).

It is essential to consider the population structure and its dynamics to build adequate models. In particular, we know from previous analysis of a subset of these data (Calambokidis et al. 2004) that some whales were seen in only one year between 1 June and 30 November and were never seen again. Transient behavior is a well-known problem in capture-recapture models and it is often addressed using a robust design which involves coordinated multiple capture occasions within each year and typically assumes closure within the sampling period (June-November). Region-wide coordinated surveys may be possible but would be difficult with variation in weather conditions. Also, the closure assumption within the year would be suspect due to variable timing of whales arrivals and departures into the PCFG, so it would require nested open models. We know from prior analysis that whales newly seen in year (y) were less likely to return (i.e., seen at some year $>y$) than previously seen whales but also newly seen whales that stayed longer during their first year (i.e., longer MT) in the PCFG were more likely to return. Likewise, previously seen whales were more likely to be seen in the following year ($y+1$), if they had a longer MT in year y . Calambokidis et al. (2004) postulated that these observations were consistent with whale behavior that was determined by foraging success.

Transient behavior in which an animal is seen only once can be modeled by including a different “first year” survival (Pradel et al. 1997) for the newly seen animals. Survival in the time interval after being first seen is dominated by permanent emigration rather than true mortality. Survival in subsequent time intervals represents true survival under the assumption that animals do not permanently emigrate except in their first year. Pradel et al. (1997) were working with release-recapture data (Cormack-Jolly-Seber) where modeling this transient effect on survival is straightforward. For a Jolly-Seber type analysis where the first capture event is also modeled, the inclusion of a transient effect is less easily accommodated. We considered two approaches to accommodate the “transient” effect in these open models to remove the transients from the estimate of abundance. We will refer

to these as JS1 and JS2.

Approach JS1 The first approach divided the whales into cohorts based on the year in which they were first seen (“newly seen”). In the models their first year survival could differ from subsequent annual survival as in Pradel et al. (1997). The first year survival was also allowed to vary as a function of MT. “Newly seen” is not a particularly useful concept for the first year of the study (1998), because all whales were being seen for the first time. Thus, we also considered a model that allowed for a different first year survival and effect of MT for 1998 than for years after 1998 and a model in which each cohort had a different first year survival to allow for different transient proportion in each year if this was not adequately modeled by MT. We also considered models that allowed a different first-year survival for whales identified as calves under the presumption that their true survival might be lower but that their probability of returning to the PCFG might be higher. Discussion at the 2012 intersessional AWMP meeting led to consideration of an additional covariate which split whales into 2 groups for estimation of post-first-year survival. Whales seen initially as calves and any whale newly seen in 1998 or was in the CRC catalog because it had been seen prior to 1998 were put in one group and the remaining whales newly seen in 1999 or later were put in another group. The expectation was that the first group would have higher post-first-year survival because many of the newly seen whales that entered after the stranding event in 1999/2000 might eventually emigrate. When this covariate was included it made such a large improvement that any model without it would have no support. Therefore, it was included in all 10 models for survival (Table 5).

In Calambokidis et al. (2010) we estimated a cohort-specific super-population size for each cohort using the median MT covariate value for unseen whales but during the April 2011 AWMP meeting it became apparent that this may lead to bias in estimating abundance. Therefore, we used the method outlined in the 2011 AWMP report which is similar to the method used by Calambokidis et al. (2004) in that we assume that all whales in the PCFG for the first year are seen so the super-population size for each cohort is the number seen and thus there are no unknown covariate values. We fixed capture probability (p) and probability of entry (p_{ent}) to 1 for each cohort in their entry year. We are not interested in the number of transient whales so we used an estimator of abundance for non-transient whales (2011 AWMP report) which is a modification of the Jolly-Seber estimator which for any year can be expressed as:

$$\hat{N} = n / \hat{p} = (u + m) / \hat{p}$$

where $n = u + m$, n is the number seen in a year being composed of new animals (u =unmarked) and previously seen animals (m =marked), and \hat{p} is the capture probability estimate. For the PCFG we are assuming that any new whale is sighted ($p = 1$) and we are only interested in estimating the abundance of whales that will remain part of the PCFG which is portion of the new whales that do not permanently emigrate from the PCFG. We can modify the estimator for year j as follows:

$$\hat{N}_j = u_j \hat{\phi}_j + m_j / \hat{p}_j$$

where ϕ_j is the first year survival rate of “new” whales. When ϕ and p contain whale specific covariates like minimum tenure (MT) the estimator becomes:

$$\hat{N}_j = \sum_{i=1}^{u_j} \hat{\phi}_{ij} + \sum_{i=1}^{m_j} 1/\hat{p}_{ij}.$$

To obtain an abundance estimate for 2010, we assumed that the parameter for first year survival intercept in that year was the same as in 2009. A variance-covariance matrix for the abundance estimates was constructed using the variance estimator in Borchers et al. (1998) for a Horvitz-Thompson type estimator with an adaptation for the first component of the abundance estimator for prediction of number of new whales that do not permanently emigrate. For the estimated capture probabilities (p) not fixed to 1, we fitted 3 models that varied by time (year) and/or varied by MT in the previous year (Table 5).

We used Test 2 and Test 3 results from the Cormack-Jolly-Seber structure (Lebreton et al. 1992) as a general goodness of fit for the global model and as a measure of possible over-dispersion creating the lack of fit. We fitted each combination of models for S (survival) and p (capture probability) and used AICc (Burnham and Anderson 2002) to select the most parsimonious model of the 30 fitted models. Model averaging was used for all models to compute estimates and unconditional standard errors and confidence intervals.

Approach JS2 The first approach will certainly underestimate the abundance in the initial years and particularly in the first year where the abundance estimate is less than or equal to the number seen in the first year because $m=0$ in the first year. As previously unseen non-transient whales are “discovered” the abundance estimator should approach the true abundance. However, that may distort any assessment of population trend and growth, so we devised the following alternative approach. If we assume that transient whales are those that are seen once and never seen again, then we can remove those from the data and use the remaining capture histories from whales seen in at least 2 years to estimate the abundance trend of non-transients with a standard POPAN model that estimates both p and pent and abundance through time. For this analysis we ignored covariates because they are not known for whales that enter but are not seen in the year they enter. Covariates for ϕ are less important because we are effectively assuming that transients have $\phi = 0$ and the non-transients have a common survival rate. We fitted a single model with time varying p and pent and a constant ϕ and used the derived estimates of abundance for the POPAN model of the data from NCA-NBC only. This is an admittedly ad-hoc approach and we expect that ϕ will be biased high because some of those seen only once will be non-transients that died before they were resighted. The abundance estimates at the end of the time series will be biased low because those newly seen in the 2010 and those seen in 2009 not resighted in 2010 are removed. Also, for the JS models it is not possible to estimate both a time-varying pent and p for 1998 without constraints. We chose to set $p = 1$ for that year which will likely underestimate abundance.

A better approach would be a Jolly-Seber model that allowed for a mixture of entrants of transients with $\phi = 0$ and non-transients similar to the closed version of Conn et al. (2011) but we are unaware of any existing software that will fit that model. Current JS mixture models in MARK allow a mixture for p but it does not carry the mixture through to the remainder of the parameters like ϕ .

2.3 Simulation

We performed a small-scale simulation study to investigate the properties of the various estimators of abundance that we have used. We considered 2 scenarios with constant $\phi=0.95$ for non-transient whales, $\phi=0.0$ for transient whales which are assumed to permanently emigrate and never return and for all whales a time constant p with values of 0.7 and 0.8 which cover the range of estimated probabilities for the gray whale data. In the first scenario, we simulated a population at equilibrium in which the number of new non-transients and transients matched the expected number of mortalities of non-transient whales ($N(1 - \phi)$). In the second scenario, we used the observed number of transients (seen only in one year) and recruits to the non-transients from the PCFG gray whale data from NCA-NBC and a initial population size of 120 non-transients from previous years still alive in 1998. We constructed a single population entry structure for each scenario but then simulated 100 replicates of the survival and capture process. Even though p was constant in the simulated data, we fitted each open model with time varying p to make them similar to the real data analysis and to make the more similar to the closed estimators which estimate a separate p for each year. The biggest impact will be in the first abundance estimate in 1998 because it is necessary to assume $p=1$ which will result in an underestimate. For that reason we drop the first estimate which also makes the comparison to closed estimators consistent because we only get a single estimate for 1998-1999 which is assigned to 1999. We summarized the abundance time series for the 100 replicates for each estimator to examine bias in abundance and trend.

3 Results

The database from all thirteen years (1998-2010) contains 14686 records; however 2291 are replicate identifications of whales on the same day. The database contains photographs of 1031 unique whales seen from Southern California to Kodiak, Alaska with an average of 12 sightings/whale (range: 1- 240) where a “sighting” is one or more photographs on a day. Only 50.3% of the whales were seen on more than one day but many of these identifications are from early in the season during the migration as well as from peripheral areas such as Kodiak, Alaska (Table 6).

3.1 Seasonality

Whales have been photographed in every month of the year (Table 6) but with very few during December-February when most of the whales are in or migrating to Mexico and survey effort is reduced. Previous analysis of these data have always used 1 June - 30 November as the sampling period to describe the whales in the PCFG because whales seen prior to 1 June are more likely to be whales that are migrating through the region. The separation between May and June is clearly supported by the data. For example, of the 1031 unique whales, 286 whales were only seen before 1 June and 84.3% of those were only sighted once. In comparison, of the 745 whales sighted between June and November, 39.7% were only sighted once. If sightings in Alaska are excluded, then only 32.7% of the 630 were seen only once.

The break between May and June is apparent in various measures such as proportion of whales sighted more than once, sighted in more than one region, and sighted in more than one year (Figure 3). However, the break is more apparent if we separate out SJF, NPS and SVI from the other survey regions (Figure 4). The difference across months is not as strong for inland waters of Washington and British Columbia (NPS, SJF) because these are whales that have diverted from the migration and are either more likely to remain after 1 June or demonstrate high year-to-year fidelity during spring such as with NPS. Also, even though Southern Vancouver Island (SVI) is in the main migration corridor and not an inland water, the pattern across months is also weaker because the sampling has been focused on the spring herring spawn in Barkley Sound (effectively an inland waterway) and has purposefully undersampled passing migrant whales (Brian Gisborne, pers. comm.). The break between May and June is much more apparent for NWA and the other areas in the migration corridor which is consistent with the northbound migration of gray whales proceeding past Washington through May. Resighting rates of whales seen after 1 June remained high through November.

The proposed Makah gray whale hunt in the Makah Usual and Accustomed area (NWA and SJF) may occur in NWA after 30 November and prior to 1 June. A hunt conducted in spring (March-May) potentially could take whales from the PCFG although those chances are less in NWA than in SJF. There have been 118 whale sightings in NWA prior to 1 June of which 30% (35) were of whales that were seen in the PCFG after 1 June at some time. We tested whether this result was biased by the quality of photographs or the selection process by also looking at the resighting rate of only a subset of the animals with highest quality photographic identifications from that period. We found 17 of 48 (35%) were resighted after 1 June, fairly close to the 30% found with all whales. In comparison, 46 whale sightings were in SJF prior to 1 June of which 70% (32) were of whales that were seen in the PCFG after 1 June at sometime, emphasizing the importance of restricting a hunt to coastal waters of the MUA (i.e., the NWA) to limit the take of whales from the PCFG.

3.2 Regional Sighting Patterns

There is considerable variation in the annual regional distribution of numbers of whales photographed during the sampling period (Table 7) which is in part due to variation in effort. Although not a true measure of effort, the number of days whales were seen (Table 8) does reflect the amount of effort as well as abundance of whales. In particular, in comparison to other regions, the large number of sightings in SVI partly reflects large numbers of sampling days by Brian Gisborne who has routinely sampled SVI 2-3 days a week. On the other hand, the decline in sightings in SVI during 2007 was not due to reduced effort but to the distribution of whales with many of the whales having moved to waters off Oregon and Washington (Calambokidis et al. 2009b).

Whales were sighted across various survey regions and the interchange of whales (Table 9) between survey regions during 1 June - 30 November depends on proximity of the regions (Calambokidis et al. 2004). Of the whales sighted in regions from SOR to NBC, depending on the region, from 57.8% to 72.7% of the whales were seen at some point within MUA-SVI (Figure 6). However, whales seen in California or Alaska were less likely to be

seen in MUA-SVI.

If we look at latitudes of sightings of individual whales across the 13 years using whales that have been sighted on at least 6 different days (Figure 7), we see that sightings of some whales are highly clustered; whereas, sightings of other whales are highly dispersed across several regions. We defined each whale's primary range by the 75% inner quantile which is the middle of the range that includes 75% of the locations. The length of the 75% inner quantile in nautical miles exceeded 60 nautical miles (or 1 degree of latitude) for 41.2% of the whales (Figure 8) and it was more than 180 nautical miles for more than 17.9% of the whales. Thus, it makes little sense to compute an estimate of abundance for any region that spans less than a degree of latitude.

There was a large variation in the frequency of sightings for whales (Table 10). Most whales that were seen during June-November 1998-2010 in the PCFG (NCA to NBC) were only seen in one year and the whales that were seen in more years were sighted more often each year and therefore represented a large proportion of the sightings (Figure 9). Likewise, examination of MT in the first sighting year demonstrates that whales who stay longer in their first year were more likely to be seen in a following year (Figure 10). Whales "first" seen in 1998 includes some whales that were truly new to the PCFG in that year but many were only "new" because it was the first year of the study. This is evident (Figure 10) in the much higher proportions for 1998 than for the other years. These relationships are important in the capture-recapture models for abundance estimation. In a closed model, these transients can cause bias because there are both gains and losses. In an open population model, whales that do not return after their first year (a large percentage in this analysis) would appear to have not survived because they have permanently emigrated (with a small fraction that died).

3.3 Mothers and calves

Mother and calf data were only available from some collaborators and much of the effort in the PCFG occurs during and after the period of weaning. Likely due to those factors, a relatively low proportion of calves have been sighted from the summer and fall sightings of gray whales through 2010 (Table 11). Through 2010, 35 different gray whales identified as PCFA whales were seen as definite or probable mothers with calves representing 45 likely births, eight whales were seen with calves multiple seasons (two or three). Despite the many years of study, only two individuals were sighted with calves in three separate years, the most documented, however, in one of these cases one of the calves was documented prior to the 1998 start of regular effort. One individual (ID#81) was observed with a calf in 2001, 2003, and 2009 and the other individual (ID#67) was seen with a calf in 1995, 2002 and 2004.

Overall, 3 of the 45 occurred prior to 1998, leaving 42 or just over three per year during our primary study period 1998-2010 (Table 12). These likely represent a minimum estimate of the births occurring because: 1) collaborators did not always note the presence or absence of calves, 2) as described below, calves weaned from their mothers, making them unidentifiable as calves, as early as June and July. Both these factors would tend to result in underestimates of the presence of calves.

The number of mothers of calves seen varied dramatically by year from 0 to 9 and was

concentrated in a four-year period (2001-2004) which accounted for 28 of the 45 sightings of known mothers with calves. During this 4-year period an average of 7 calves were seen while an average of 1.5 calves per year was seen in the other nine years (14 calves in 9 years). Even among these known or suspected mothers, the proportion of years they were seen where they had a calf average only 14% although it was 39% and 36% during the peak years of 2001 and 2002, which would be closer to what would be expected if females were getting pregnant almost every other year. The most recent year of data, 2010, also showed a higher number of calves from known PCFG whales with 4 documented mothers and calves out of 12 known mothers seen (33%). While these years with higher number of calves were likely higher birth years, it is also possible that longer weaning times those years may have contributed to a higher proportion of new calves still with their mothers being documented.

In 20 cases, a calf was seen associated with its mother early in the season and then the mother or the calf was resighted later in the season separately, suggesting weaning had occurred. The latest a mother was seen still seen associated with its calf was 6 September (CRC 67 with calf CRC 698 in 2002) and there were indications of separation of calves from their mothers as early as June. In two cases either the mother or calf was seen separated in June, however, in neither case was the calf resighted in the future year (although the mother was) suggesting these calves may not have survived. In at least eight cases the weaning had occurred prior to a July sighting (and possibly earlier).

Of the 35 likely mothers documented, 23 had been seen four or more years in the study area (12 had been seen only 1, 2, or 3 years). Even those animals with long sighting histories were seen with calves in only a small proportion of the years but as shown in Table 11, often the initial sighting of these animals was in late August or later, past the period when weaning may have occurred.

Some of these whales commonly seen in the Pacific Northwest were sighted with calves outside of this region and the somewhat atypical locations may suggest they may behave differently in years they have a calf. One mother (ID#281) was regularly sighted in the PCFA area every year from 1999 to 2007. In only one of those years was she with a calf (2002) and in 2008 she was seen on 19 April off Santa Barbara, S California apparently in the migration with a small calf but neither of them were seen that year in any of our effort farther north from Northern California to SE Alaska. Another case not included in our summary because the calf was never seen in the our study area and also there was uncertainty of who was the mother, was an apparent calf (ID 962) sighted off San Miguel Island on 27 July 2006 but which was accompanied by two adults (ID 359 and 718) both of whom were seen in most years from 2002 to 2008 in the Pacific Northwest (N California to SE Alaska), but not in 2006. Both the mothers and calves from these two sightings were not seen in the Pacific Northwest in their birth year (despite the mothers being seen most other years) and were only opportunistically sighted outside the region, suggesting there may be additional calves born to animals that use the Pacific Northwest that perhaps do not come into sampled areas (either within or outside the Pacific Northwest) in their birth year. This would negatively bias estimates of the number of calves born to these animals.

One important question in evaluating the population structure of the gray whales using the Pacific Northwest feeding areas is how animals are recruited to this group. We examined the sighting histories of the identified calves to determine if they tended to be seen in

future years. Animals that were not seen in future years could reflect either mortality in the first year of life or animals that did not continue to feed in the Pacific Northwest in future years. There were 42 calves or suspected calves identified with their mothers through 2010 in the study area with 38 of these seen through 2009 and which had at least one subsequent year they would have had an opportunity to have been seen. Just over half of these (21 or 55%) had been seen in a year subsequent to the year they were calves. Using only the 30 calves seen through 2004 (to allow a longer follow up period to resight animals, 19 (63%) have been resighted in a later year. The 37% not seen in a following year could be the result of: 1) the calf dying, 2) the calf not returning to the area or not yet resighted during its return, 3) the calf not being recognized by photo-ID since calves can undergo changes in markings rapidly especially if not seen for several years. Given all these factors the resighting rate of calves does suggest a high proportion of surviving calves appear to become part of the small feeding aggregation that uses the Pacific Northwest.

3.4 Open Population Capture-Recapture Models

If the yearly cohorts were pooled, Test2+Test3 statistics indicated a significant lack of fit for the PCFG and subsets (Table 13) primarily resulting from Test 3. This was expected due to the different “survival” rates of previously seen whales (true survival) and newly seen whales of which many never returned (i.e., permanently emigrated) (Table 14). By separating the cohorts, survival for each cohort was time-varying and thus each cohort has a separate first year survival. In this case, the goodness of fit test (Test 2 only) did not demonstrate a lack of fit except for OR-NBC and NCA-NBC. For those regions, we estimated over-dispersion values of $\hat{c}=1.79$ and $\hat{c}=2.09$ respectively, to adjust AICc and estimated standard errors. The lack of fit for those regions is probably related to the inclusion of NCA, WVI and NBC which are at the fringes of the PCFG. Effort in NCA and WVI has been less regular than the other survey regions and whales in NBC have a higher degree of interchange with Alaska.

The best fitted model (Table 15) was always model 2 for p with capture probability varying across years and higher when MT was greater in the previous year. For φ the best model was either model 4 or 5 with roughly equal support for each model. Both models included a separate first year survival which depends on MT. In both models the intercept for first year survival in 1998 differs from the other years and in model 5 the slope for MT differs for 1998. These results were consistent with Calambokidis et al. (2004) who demonstrated strong support for the effect of MT on first year survival (Figure 11-12) and capture probability (Figure 13) in the following year for all spatial scales. These results differ from Calambokidis et al. (2010) due to the use of MT directly rather than a median centered value. Use of MT with median centering was necessary to construct open model abundance estimates in the manner described in Calambokidis et al. (2010). However, that was not necessary for JS1 and JS2 and use of MT directly resulted in lower AICc values.

There was large year to year variation in capture probability. The values for MUA-SVI ranged from 0.23 to 0.97 depending on the year and value of MT (Figure 13). The lowest values were from 2007 which reflects the temporary emigration of whales from MUA and SVI to waters offshore of Oregon in that year.

First year survival estimates were dominated by permanent emigration. For MUA-SVI,

the estimates varied from 0.42 to 0.51 for non-calf whales with $MT=1$ in their first year and from 0.80 to 0.94 for $MT>80$ in their first year (Figure 11). For calves, they were slightly higher but there was little support for a different first year calf survival. Survival subsequent to the first year was assumed to be constant but was less for non-calf whales that were newly seen in 1999 or later. Post-first-year survival for calves and whales present in 1998 or earlier presumably represents true survival assuming there was little permanent emigration after the first year. Those estimates were 0.97 ($se=0.0088$), 0.972 ($se=0.0078$), 0.971 ($se=0.0093$) and 0.968 ($se=0.0093$) for MUA-SVI, OR-SVI, OR-NBC, NCA-NBC respectively. The post-first-year survival estimates for whales that entered in 1999 or later and not identified as a calf were 0.864 ($se=0.0217$), 0.878 ($se=0.0183$), 0.871 ($se=0.0228$) and 0.881 ($se=0.0217$) for MUA-SVI, OR-SVI, OR-NBC, NCA-NBC respectively.

3.5 Abundance and Recruitment

For MUA-SVI, OR-SVI, OR-NBC, and NCA-NBC annual estimates of abundance were constructed with LP, Limited LP and model averaged values for JS1 and JS2 (Figure 14, Tables 16-23). Estimates in Figure 14 are only shown for 1999-2010 because with the closed models only 12 estimates can be constructed with the 13 years of data and with the open models $p = 1$ for 1998 so it will be an underestimate. In general, the JS1 and JS2 estimates were similar to the Limited LP estimates because they are all removing the transients from the estimates. In contrast, LP attempts to estimate the total abundance which includes transient whales; however, as we show below with the simulation, it is positively biased because there are losses and gains in each set of years and even the trend is unreliable.

The Limited LP abundance estimates for 2010 are biased low because new whales that enter that year have no chance to be re-sighted and thus they were excluded even though some may return in the ensuing years. To a lesser degree, the estimate for 2009 and possibly 2008 are influenced in a similar manner because the whales may have been simply not seen yet even though they are returning. The bias is evident by comparing the higher estimates for 2007 and 2008 in Tables 18- 19 to the same values given in Calambokidis et al. (2010) using data through 2008. This same problem occurs with JS2 because new whales that enter in 2010 are excluded because they are all presumed to be transients. Likewise, those that enter in 2009 and are non-transients but are not seen in 2010 are also excluded. This is not a problem for JS1 which includes those data and predicts the proportion of new whales that are non-transients based on the value of MT in their first year seen.

The JS1 sequence provides the best estimate for current N_{min} from 2010 because the LP estimator is biased high and the JS2 and Limited LP estimates for 2010 are biased low. The values of N_{min} range from 104 (Table 20) to 173 (Table 21) across the four spatial scales. To gain a sense for how these values might be relevant to estimating a possible level of removal (e.g., due to harvest) we computed the MMPA's Potential Biological Removal (PBR) (typically reserved for stock-level assessments). Using the PBR formula, with a default R_{max} of 4% and a recovery factor of 1, the PBR for the smallest region considered (MUA-SVI), would be 2.1 and the PBR for the largest region (NCA-NBC) would be 3.5 .

New whales have continually appeared annually and many of these new (non-calf) whales have subsequently returned and been re-sighted (Table 14). In MUA-SVI from 1999-2010 ,

an average of 21.2 (range: 5.0, 56.0) new whales were seen each year. Of these new whales, on average 9.4 (range: 1.0, 19.0) whales returned and were seen in subsequent years. Currently recruitment appears to be offset by losses (either mortality or permanent emigration) as the abundance estimates have been fairly stable for the last 8 or 9 years. Presumably if there was a directed harvest recruitment would increase but if the take was 2-4 whales, it will take 5 to 10 years to see much change.

The AWMP implementation trials for the gray whale assessment is based on 1+ abundance. It is not possible to identify every calf when they entered and many were likely missed because much of the survey effort was conducted when calves could have been weaned. As an approximation to the 1+ abundance, we removed observed calves from the u_j in JS1. For NCA-NBC, there were 37 observed calves during the 13 years, but the total reduction in abundance across all years was approximately 20 because the JS1 estimator discounts newly seen whales based on their predicted survival probability. The reduction for OR-SVI is less because there were fewer calves observed in the smaller region. The sequence of estimates for NCA-NBC and OR-SVI are provided in Table . These estimates do not exclude whales first seen as calves in the abundance estimates when they were age 1 or older.

3.6 Abundance Simulation

The simulations clearly showed the positive bias that occurs with the LP estimator when a portion of the population are transients that are only in the population for one occasion (Figure 15). The LP estimates were greater than both total abundance and the abundance of the non-transients. When there was a decreasing trend in transients and an increase in non-transients as with the PCFG gray whales, the LP estimator produced a flat trend hiding the abundance increase. The bias in LP can be demonstrated algebraically. Assume that the population between 2 occasions is constant at N but only a proportion δ remains throughout both occasions and the remaining proportion $1 - \delta$ are transient individuals which are only available in each occasion. The number of unique individuals in the population during the 2 occasions is $N\delta + 2N(1 - \delta)$. The transient individuals at time 1 have no chance to be seen at time 2 and vice versa. The expected value of the LP estimator is $E(\hat{N}) = Np_1 * Np_2 / (N\delta p_1 p_2) = N/\delta > N$. The proportional bias is $(1 - \delta)/\delta$ for the annual abundance and $(\delta^2 - 2\delta + 1)/(2\delta - \delta^2)$ for the total unique number of individuals present at any time. Both are positive unless $\delta=1$. For consecutive pairs of years, if δ changes so does the bias which can distort any trend.

The limited LP had far less bias for the non-transient abundance although it tended to underestimate slightly at the beginning and end of the time series due to the way it was constructed. Excluding the initial 1998 estimate, there was also only a slight negative bias for JS1 and JS2, although the latter did better at the beginning of the time series and the former at the end of the time series which was expected due to the way they were constructed. For JS1 and JS2, the estimated population growth rates were generally slightly higher than the true rates (Table 25) except for the end of the series for JS2 due to the negative bias in abundance. Both JS1 and JS2 were less variable than the limited LP rates. If estimates from JS1 or JS were used to fit a generalized logistic growth model it would bias RMax, the maximum rate of increase, and z , the exponent that controls the

location of the inflection point but it would not affect the conclusion that the population is above MNPL, maximum net productivity level, with the abundance pattern evident in the PCFG abundance. The sequences of JS1 and JS2 abundance estimates for the PCFG were quite similar so you would expect the same conclusion from either; however, given that JS1 does not suffer from bias at the end of the sequence, the JS1 abundance estimates from 1999-2010 would provide the best sequence for the population growth assessment.

3.7 Movements outside the PCFG area

Gray whale photographic identifications obtained since the analysis in Calambokidis et al. (2010) have revealed additional long distance matches of gray whales of potential significance to the status of whales in the Pacific Northwest. These are described below representing three specific insights that came from some of these specific comparisons.

3.7.1 Matches to western gray whales

A comparison of Cascadia's entire catalog of photo-identified whales regardless of location or time of year was made to gray whales identified in the western North Pacific off Sakhalin Island. No matches of known PCFG whales were found between these collections. As reported in Weller et al. (2011), six matches were found between these two collections but these six whales were known in the Cascadia catalog. As reported in Weller et al. (2011), the WNP/ENP catalog comparison resulted in six confirmed matches of individuals, including three known males and two known females. All six of the matches were from only two days of effort off southern Vancouver Island, with three whales identified on 2 May 2004 and three on 25 April 2008 by collaborators Brian Gisborne and Wendy Szaniszlo. While the above findings have major implications regarding western gray whales, one other implication relates to whales feeding in the PCFG. That this many (six) matches found to western gray whales was surprising even if most western gray whales did migrate through this area. The Cascadia ENP catalog focuses on gray whales seen in summer and fall and has a relatively small sample of a few hundred gray whales from the spring migration. Given the approximately 20,000 gray whales likely migrating in spring through the PCFG area, finding six matches to the small western gray whale population seems highly improbable. It suggests that western gray whales that come to the eastern wintering grounds may spend periods feeding in the spring in the PCFG area prior to making their longer migration to the west. This could account for their higher probability of having been photographed. Given that the sightings were from just two days, it also could have been more coincidental that these identifications were taken from a potentially associated group of gray whales going to feeding areas in the western North Pacific.

3.7.2 PCFG whales identified near Barrow, Alaska

Of greater significance to the potential status of PCFG whales, two matches were found to nine gray whales identified near Barrow, Alaska and provided by the North Slope Borough (thanks to Craig George and Lori Quakenbush). Five of these were identified in August 2006 and four in August and early September of 2010. Two of these were determined to be

whales identified in other regions. Most surprisingly, one of the whales identified in 2010 off Barrow (CRC ID 850) had been seen in the PCFG area three years in the summer and fall. Sightings included a total of 10 resightings: two days in September and October 2004 and September and October 2006 in the Strait of Juan de Fuca and in June 2008 off west Vancouver Island. The 2nd whale identified off Barrow in August 2006 (CRC ID 1010), was resighted on a single day (24 March 2007) off southern Vancouver Island, consistent with an animal caught in migration. While a single whale out of nine identified off Barrow to be an animal intermittently seen as a part of the PCFG is more anecdotal, it does demonstrate that at least some of the whales seen in repeat years in the PCFG area do travel and feed to some of the farthest away feeding areas.

3.7.3 Photo-identification of satellite tagged migrating gray whales

Additional insights into some of the movements of PCFG whales were gained from recent photo-identification matches to satellite tagged gray whales. Movements of five gray whales were tracked by satellite tags as they migrated north from S Vancouver Island north through British Columbia (Ford et al. res). Comparison of photographs of these whales to Cascadia's catalog revealed that three of the five were whales previously identified:

- CRC ID 307 (tag 1 tagged 26 March 2009 in Ford et al. res): This whale was identified twice in June 1998 and July 1998 off W Vancouver Island but not identified again until the photographed 26 March 2009 in the tagging effort. It transmitted 13 days moving 1,354 km to 58.1N at an average speed of 4.9 km/h (Ford et al. res).
- CRC 178 (tag 2 in Ford et al. res): This animal is another long history animal with 94 sightings starting in 1995 almost every year since in many regions including many in WA as well as BC. After being tagged on 24 March 2010, it transmitted 16 days moving 893 km to 55N at an average speed of 1.1 km/h (Ford et al. res). Unlike the other two tags of matched whales Tag 2 hung around Hesquiat and looks like may have visited Cape Caution before heading north.
- CRC 135 (tag 3 in Ford et al. res): After being tagged on 24 March 2010, it transmitted 8 days moving 1,141 km to 56.6 N at an average speed of 5.8 km/h (Ford et al. res). This whale has been identified 168 times every year from 1998 to 2010 in many regions but mostly off S Vancouver Island. These identifications were from June on. These resightings included 29 on 2010 after it had been tagged and appeared to migrate north and were from 9 June to 14 September all at the south end of Vancouver Island near where the tagging had occurred.

There are a couple of important things these satellite tag data reveal. They suggest that some of the PCFG whales may migrate at least part way north and appear to be migrants prior to returning south to primary feeding areas in the PCFG. Only one of the three (ID 135) was actually documented feeding back south in the tag year and the other two either did not come back to the PCFG area that year or where there but did not happen to be photo-identified. The finding of a PCFG whale migrating north of the PCFG area in spring was also revealed by one of the gray whales tagged by OSU in fall 2009 that kept transmitting into spring 2010 (Mate et al. 2011). That animal after spending some time in the southern Vancouver Island area after migrating north from Baja, then continued north to Icy Bay in the Gulf of Alaska before the tag stopped transmitting. While that

animal had been identified in the PCFG in 7 different years going back to 1985, most of these sightings were at the northern end of the PCFG (north of Vancouver Island) and was last identified in 2007 prior to being tagged in December 2009.

While at least two of these animals (Tags 1 and 3) appeared to be migrating animals, it is likely they were engaged in some type of behavior different than typical gray whales from the overall migration otherwise it seems highly improbable that three of the five tagged whales were known PCFG whales given how small a proportion of the overall gray whale migration would be PCFG whales.

4 Discussion

The population structure of gray whales using the Pacific Northwest in summer and fall is complicated and involves two elements. One group of whales return frequently and account for the majority of the sightings in the Pacific Northwest during summer and fall. This group is certainly not homogeneous and even within this group, there is some degree of preference for certain subareas. Despite widespread movement and interchange among areas, some of these gray whales are more likely to be seen returning to the same areas they were seen before. The second group of whales are apparent stragglers encountered in this region after the migration. These animals are seen in only one year, tend to be seen for shorter periods that year, and in more limited areas.

The existence of these two groups in the study area and their dynamics complicate estimating abundance. The various methods we used here for estimating abundance try to deal with this in different ways. The estimates from the unadjusted Lincoln Petersen incorporate whales from both of these groups and the inclusion of the stragglers violates the closure assumption and creates a positive bias. This explains the higher estimate obtained with this method. Even the trend can be distorted as we demonstrated in the simulations. The Limited Lincoln Petersen estimate specifically excludes the stragglers and only estimates the abundance of whales that return after the year of the initial sighting. It is useful except for the last year in which new whales that may return are excluded because they have not had a chance to return. The Limited Lincoln Petersen estimates were similar to the JS1 and JS2 estimates from the open models which also attempt to estimate the non-transient abundance. Excluding 1998, the JS1 sequence of abundance estimates provides the most reliable assessment of trend in the non-transient abundance and the best estimate of current abundance in 2010.

Despite extensive interchange among subregions in our study area, whales do not move randomly among areas. Abundance estimates were lower when using more limited geographic ranges but these more limited areas do not reflect closed populations. While the use of geographically stratified models can be useful in cases where populations have geographic strata they use (see for example Hilborn 1990), this would be difficult in our case because of the frequent sightings of animals in multiple regions within the same season and these models typically only allow an animal to be sighted in one strata per period. This could be dealt with by assigning animals to only a single region per season but this would be forcing the data into a somewhat inaccurate construct.

Several studies have considered the question of gray whale population structure. There

is widespread agreement that at least two populations of gray whales in the North Pacific exist, a western North Pacific population (also called the Korean population) and an eastern North Pacific (ENP) population (sometimes called the California population) (Swartz et al. 2006; Angliss and Outlaw 2008; Rugh et al. 1999). The population structure of the gray whales feeding in the Pacific Northwest has remained in question and only a few studies have examined this. Steeves et al. (2001) did not find mtDNA differences in a preliminary comparison of gray whales from the summer off Vancouver Island and those from the larger ENP population. Ramakrishnan et al. (2001) did not find evidence that the Pacific Northwest whales represented a maternal genetic isolate, although even very low levels of recruitment from the larger overall population would prevent genetic drift. More recently, Frasier et al. (2011) generated mtDNA sequences from a larger sample of gray whales from Vancouver Island than tested by Steeves et al. (2001). They found significant differences in the haplotype frequencies between that sample and mtDNA sequence data reported for ENP gray whales, most of which were animals that stranded along the migratory route. The Frasier et al. (2011) samples were from a relatively small area; however, Lang et al. (2011) evaluated biopsy samples from California to southern Vancouver Island in the PCFG and ENP samples from whales sampled north of the Aleutians and also found significant mtDNA haplotype frequency differences. These two studies provide the strongest evidence to date that the Pacific Northwest whales might be sufficiently isolated to allow maternally inherited mtDNA to differ from the overall ENP population.

Population structure in other large whales has been the subject of recent inquiry and has revealed diverse results for different species. Clapham et al. (2008) examined 11 subpopulations of whales subjected to whaling that were extirpated possibly due to the loss of the cultural memory of that habitat and concluded subpopulations often exist on a smaller spatial scale than had been recognized. Studies of other baleen whales, particularly humpback whales, have shown evidence of maternally directed site fidelity to specific feeding grounds based on photographic identification studies (Calambokidis et al. 1996, 2001, 2008). This high degree of fidelity to specific feeding areas is often discernible genetically. In the North Pacific strong mtDNA differences were found among feeding areas even when there was evidence of low level of interchange from photo-ID (Baker et al. 2008). Similar findings were documented for humpback whales in the North Atlantic which feed in different areas but interbreed primarily on a single breeding ground (Palsboll et al. 1995) like ENP gray whales. In the North Pacific the differences for humpback whales were often dramatic. For example, humpback whales that feed off California have almost no overlap in mtDNA haplotypes with humpback whales feeding in Southeast Alaska (Baker et al. 1990, 1998, 2008). One difference between humpback and gray whales is the coastal migration route of gray whales which means gray whales going to arctic waters to feed would migrate right through the feeding areas to the south. Other species of large whales have not shown as strong site fidelity to specific feeding grounds. Blue whales have undergone an apparent shift in their feeding distribution in the North Pacific apparently due to shifting oceanographic conditions (Calambokidis et al. 2009a). Fin whales in the North Pacific have long migrations and while there do not appear to be multiple distinct feeding areas as was the case for humpback whales, there were some distinct and isolated apparently non-migratory populations (Mizroch et al. 2009; Berube et al. 2004).

Even though the population structure of gray whales off the Pacific Northwest remains

unresolved, there is a consistent group of animals that use this area and we provide several estimates of their abundance. Different abundance methods and geographic scopes yield varied results but all suggest the annual abundance of animals using the Pacific Northwest for feeding through the summer is at most a couple hundred animals depending on the estimating method and how broadly the region is defined geographically.

The apparent rapid increase in the abundance estimates derived from the limited LP and Jolly-Seber models in the first five years of this study appear incompatible with this being a relatively distinct group since it would require a high rate of external recruitment, however, the exact rate of this increase should be viewed with caution. This rapid increase at the start of our study occurred during a period the overall eastern North Pacific gray whale population was experiencing a high mortality event that included unusually high numbers of gray whales showing up in areas they were not common. The simulation did show that the initial estimates were negatively biased low and would over-estimate recruitment but reflected the general trend. We did expand the analysis to include the 1996 and 1997 data and the 1998 estimate did increase by about 7% but the sampling prior to 1998 was opportunistic and not broad scale, so it is possible that some of the “new” whales seen during 1999-2001 may have been present in the PCFG prior to 1998 in areas that were not sampled and included in the CRC database. The high rate of increase in the late 1990s and early 2000s should be verified with additional data such as compiling photographic identifications for this area from multiple sources to attempt to verify if the abundance of animals prior to the start of our study was as low as suggested by these trends. Even though the rate of increase may be too high, we believe the abundance did increase and now appears to be relatively stable since 2002.

Acknowledgments

This analysis would not have been possible without the collaborating organizations and individuals contributing identification photographs (the primary contributors are listed in Methods and Tables 1 and 2). Support for the photographic identification reported here, the comparison of gray whale photographs and preparation of this report came primarily from the National Marine Mammal Laboratory. Permission to conduct some portions of this research in U.S. waters was provided by the U.S. National Marine Fisheries Service and the Makah Tribal Nation. Portions of the research in British Columbia were conducted collaboratively with Fisheries and Oceans Canada (thanks to John Ford and Graeme Ellis). Volker Deecke assisted in analysis and matching of identifications from S. Vancouver Island. William Megill coordinated providing sightings and identifications from CERF, Dawn Goley coordinated effort for HSU, Christina Tombach and Dave Duffus coordinated efforts for UVIC, Carrie Newell provided identification photographs from Oregon, Merrill Gosho, Pat Gearin, Nate Pamplin and Jon Scordino provided photos from Washington. Brian Gisborne’s diligence and hard work provided an immense amount of data and photographs from Vancouver Island. A number of people assisted in the field effort and in the printing and matching of photographs at Cascadia Research. Erin Falcone and Lisa Schlender helped compile the data from different contributors and conducted some of the photographic matching. Randy Lumper conducted gray whale matching in the early

years of this study. Steve Stone, Donna Darm and Jon Scordino provided helpful comments.

Table 3: Survey regions and region subsets used for abundance estimation. Numbers refer to locations on the map in Figure 1.

Survey Region	Region Description	NCA-NBC	OR-NBC	OR-SVI	MUA-SVI
(1) SCA = Southern California					
(2) CCA = Central California					
(3) NCA = Northern California	Eureka to Oregon border; mostly from Patricks Pt. and Pt. St George	x			
(4) SOR = Southern Oregon		x	x	x	
(5) OR = Oregon Coast	Primarily central coast near Depoe Bay and Newport, OR	x	x	x	
(6) GH+ = Gray's Harbor	Waters inside Grays Harbor and coastal waters along the S Washington coast	x	x	x	
(7) NWA = Northern Washington	Northern outer coast waters with most effort from Cape Alava to Cape Flattery	x	x	x	x
(8) SJF = Strait of Juan de Fuca	US waters east of Cape Flattery extending to Admiralty Inlet (entrance to Puget Sound)	x	x	x	x
(9) NPS = Northern Puget Sound	Inside waters and embayments from Edmonds to the Canadian border				
(10) PS = Puget Sound	Central and southern Puget Sound (S of Edmonds), including Hood Canal, Boundary Bay, and the San Juan Islands				
(11) SVI = Southern Vancouver Island	Canadian waters of the Strait of Juan de Fuca along Vancouver Island from Victoria to Barkley Sound, along West Coast Trail	x	x	x	x
(12) WVI = West Vancouver Island		x	x		
(13) NBC = Northern British Columbia	British Columbia waters north of Vancouver Island, with principal effort around Cape Caution	x	x		
(14) SEAK = Southeast Alaska	Waters of southeastern Alaska with the only effort in the vicinity of Sitka				
(15) KAK = Kodiak, Alaska					

Table 5: Model specifications for survival (φ) and capture probability (p) parameters in POPAN models for gray whale photo-identification data. For survival models, β_0 is the baseline intercept for non-transient survival. Fy is 1 if it is year the whale was first seen and 0 otherwise. Fc is 1 for 1998 cohort and 0 otherwise. C is 1 if identified as a calf in its first year and 0 otherwise. R is 1 for calves or any whale seen in 1998 or was already in the catalog prior to 1998 and 0 otherwise. β_r is an adjustment to post-first-year survival. MT is minimum tenure value of a whale and β_M is the estimated slope parameter for φ or p . $\beta_{M,1998}$ applies only to 1998 and $\beta_{M,1999}$ applies to 1999-2010. $\beta_{Fy,1999}$ is the first-year survival intercept adjustment for cohorts 1999-2009 and $\beta_{Fy,c}$ represents 11 cohort-specific first year survival parameters for 1999-2008. β_{CF} is an adjustment for calf first year survival and β_{CM} is an adjustment for calves to the slope of MT for survival. For the capture probability models, β_t has 11 levels for $t=2000, \dots, 2010$ and β_0 represents the 1999 value. For 1998 $p=1$.

Model	Parameter Logit Formula	Number of parameters
φ		
1	$\beta_0 + \beta_{Fy} Fy + \beta_r R(1 - Fy)$	2
2	$\beta_0 + \beta_{Fy} Fy + \beta_M MT Fy + \beta_r R(1 - Fy)$	3

Table 11: History of mothers seen with calves during study. Each year a whale was seen, the first confirmed sighting date is shown for that year. Years where a calf was documented are shown with an asterisk. Total years seen includes 16 sightings of whales during 1984,1988, 1990-1993 that are not shown but no calves were seen in those few cases.

Table 25: Simulation assessment of bias for in population trend for limitedLP, JS1 and JS2 estimators with $p=0.7$ and 0.8 with an increasing trend in non-transients and decreasing trend in transients and no trend (lower 2 plots). Value is $(\hat{N}_{t+1} - \hat{N}_t)/\hat{N}_t - (N_{t+1} - N_t)/N_t$ using average estimated abundance and true abundance for each time. Estimate from 1998 was excluded because it is not available for limitedLP and for JS1 and JS2 it was assumed that $p = 1$ for 1998 which will create bias.

	JS1		JS2		Limited LP	
	p=0.7	p=0.8	p=0.7	p=0.8	p=0.7	p=0.8

Figure 1: Locations for photo-identifications of gray whales. Numbers refer to values in Table 1.

Figure 2: Characteristics used for gray whale photo-identification.

Figure 3: Monthly measures of proportion of whales that were seen in more than one region, seen on more than one day and seen in more than one year. The values include sightings from 1998-2010 in all regions from California to Alaska. Lower values imply whales were simply migrating through the area in a short time frame and were thus less likely to be seen at other times and in other regions. Values are not shown for months with fewer than 20 sightings.

Figure 4: Region and monthly measures of proportion of whales that were seen in more than one region, seen on more than one day and seen in more than one year. The values include sightings from 1998-2010 in all regions from California to Alaska. Lower values imply whales were simply migrating through the area in a short time frame and were thus less likely to be seen at other times and in other regions. Values are not shown for months with fewer than 20 sightings.

Figure 5: Proportion of the 14 whales seen in NWA during the spring and in the PCFG after 1 June that were seen in each PCFG sub-region after 1 June at least once from 1998-2010.

Figure 6: Proportion of whales in PCFG sub-regions that have been seen in the MUA-SVI using sightings after 1 June from 1998-2010.

Figure 7: Distribution of latitudes of sightings (points) for whales with 6 or more sightings after 1 June from 1998-2010, the 75% inner quantile (solid thick line), and full range (light dashed line). Each position on the x axis represents an individual whale. Whales have been arranged on the plot by sorting first on the lower bound of the inner quantile (to a half-degree) and then the upper bound of the quantile. This has the effect of sorting from south to north and clusters whales with smaller quantile ranges followed by whales with larger ranges.

Figure 8: Distribution of ranges of 75% inner quantiles of latitudes expressed in nautical miles for whales sighted on 6 or more days during 1998-2010.

Figure 9: Average number of sightings per year and distribution of whales and numbers of sightings based on numbers of years a whale was seen in NCA-NBC between June-November during 1998-2010.

Figure 10: Influence of minimum tenure (MT) in the first year the whale was photographed on the probability it will be re-sighted in one or more following years for whales seen in NCA-NBC for June-November 1998-2010. The bar graphs are divided for 1998 and >1998 because 1998 is the start of the study and it may not be the first year for many of those whales. Re-sightings for 2010 are used but initial sightings for 2010 are excluded because there are no data beyond to evaluate re-sighting probability.

Figure 11: For MUA-SVI analysis of 1998-2010 data, model-averaged estimates of first year survival of non-calves for each cohort at 5%, 25%, 50%, 75%, and 95% quantiles of minimum tenure values for that cohort.

Figure 12: For MUA-SVI analysis of 1998-2010 data, model-averaged estimates of first year survival of calves for each cohort at 5%, 50%, and 95% quantiles of minimum tenure values for that cohort of calves. Cohorts 1999 and 2000 are not shown because no calves were identified in those years.

Figure 13: For MUA-SVI analysis of 1998-2010 data, model-averaged estimates of capture probability for each year at 5%, 25%, 50%, 75%, and 95% quantiles of minimum tenure values for whales in the previous year.

Figure 14: Annual abundance estimates for 1999-2010 in four sub-regions using closed population models, Lincoln-Petersen (LP) and Limited LP and the open (Jolly-Seber; POPAN parametrization) population models using the 2 alternative approaches JS1 and JS2.

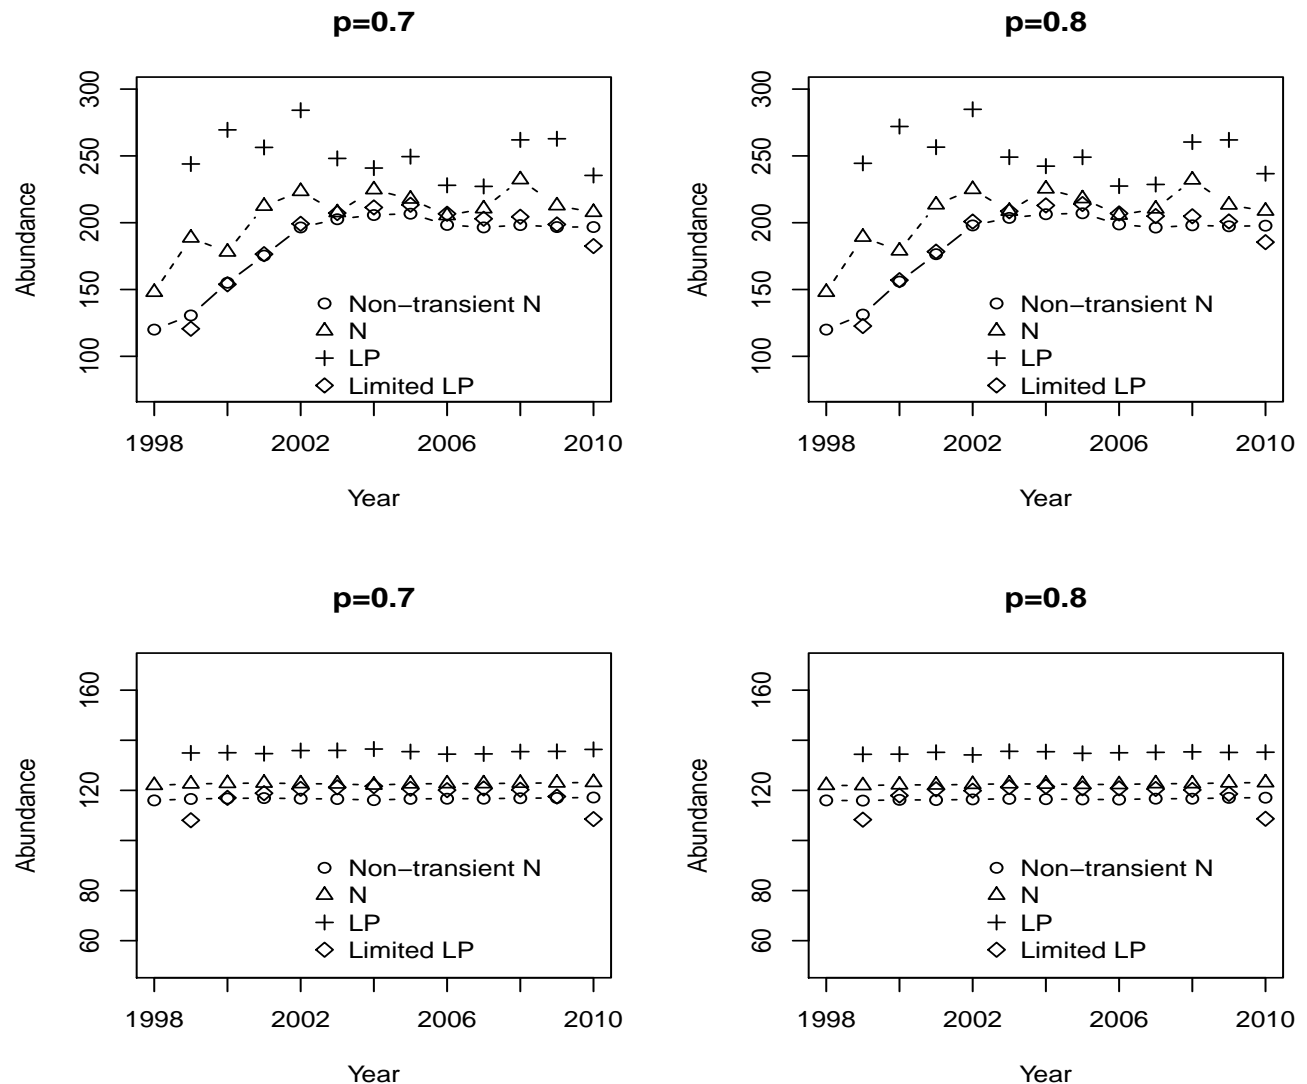

Figure 15: Simulation results for closed estimators with $p=0.7$ and 0.8 with an increasing trend in non-transients and decreasing trend in transients (upper 2 plots) and no trend (lower 2 plots). The true average simulated non-transient N and total N are shown with lines and the average estimates for LP and limited LP are shown with symbols.

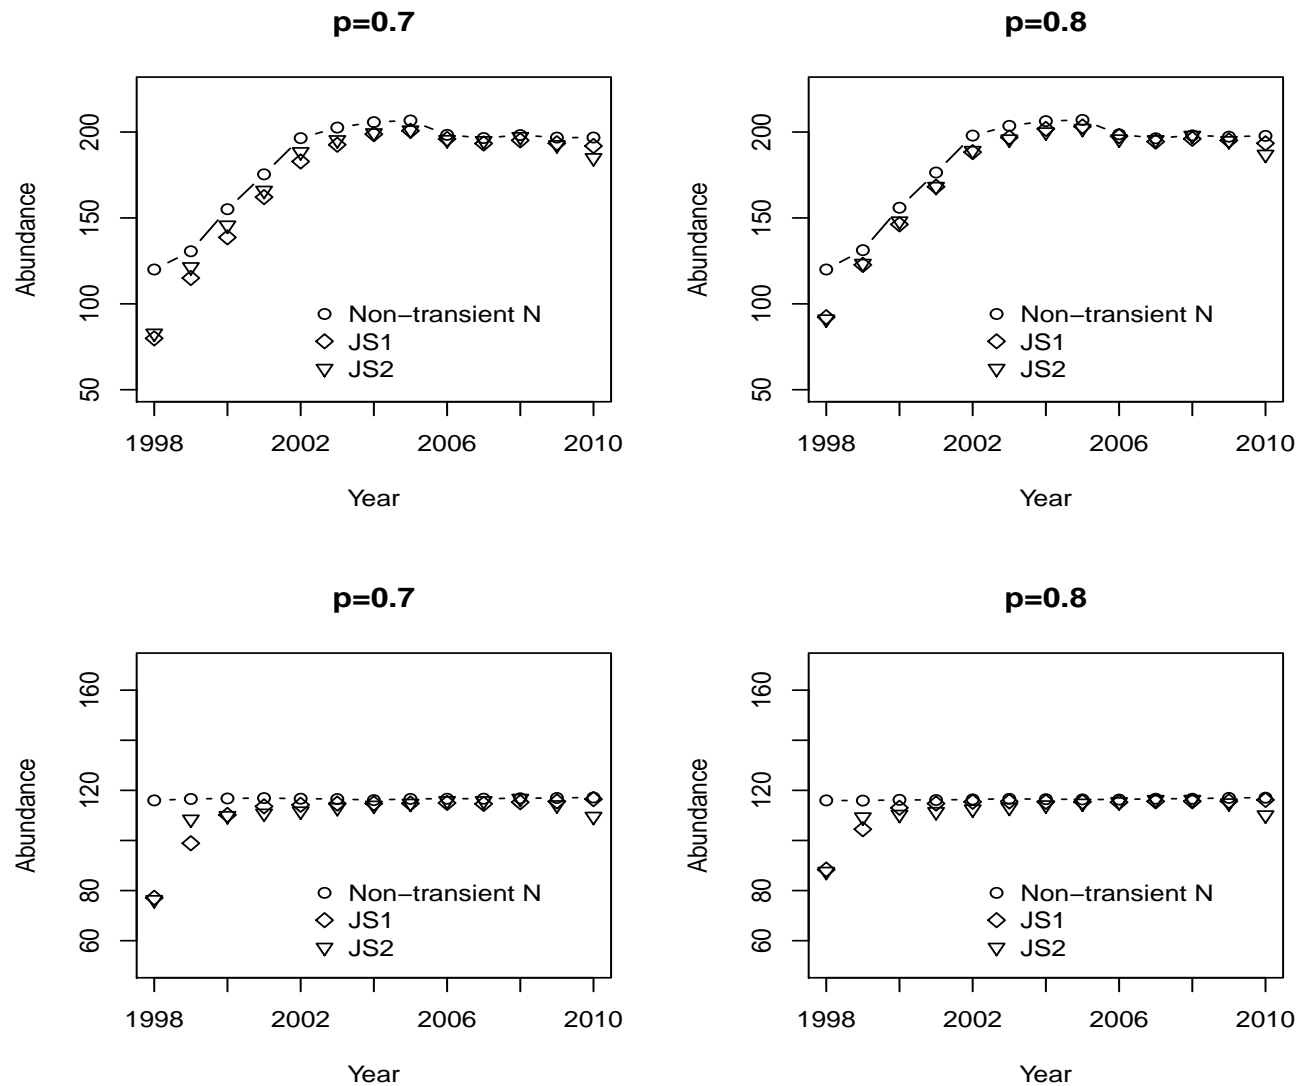

Figure 16: Simulation results for JS estimators with $p=0.7$ and 0.8 with an increasing trend in non-transients and decreasing trend in transients (upper 2 plots) and no trend (lower 2 plots). The true average simulated non-transient N is shown with the line and the average estimates for JS1 and JS2 are shown with symbols.

Updated analysis of abundance and population structure of seasonal gray whales in the Pacific Northwest, 1996-2015

John Calambokidis, Jeffrey Laake, and Alie Pérez

Abstract

We update the results of a 20-year (1996-2015) collaborative study examining the abundance and the population structure of these animals conducted over a number of regions from Northern California to British Columbia using photographic identification. Some 21235 identifications representing 1638 unique gray whales were obtained during 1996-2015 from Southern California to Kodiak, Alaska. Gray whales seen from 1 June - 30 Nov (after the northward and before southward migrations) were more likely to be seen repeatedly and in multiple regions and years; therefore only whales seen during those data were included in the abundance estimates. Gray whales using the Pacific Northwest in summer and fall include two groups: 1) whales that return frequently and account for the majority of the sightings and 2) transients seen in only one year, generally for shorter periods and in more limited areas. A time series of abundance estimates of the non-transient whales for 1996-2015 was constructed for the region from N. California (NCA) to N. Vancouver Island (NBC). The most recent estimate for 2015 was 243 whales ($se=18.9$). The estimated abundance increased in the late 1990s and early 2000s during the period when the eastern North Pacific gray whale population was experiencing a high mortality event and this created an apparent influx of whales into the area. The earlier estimates for 1996-1997 are biased low because the survey coverage area was much smaller but those data were included to improve estimates later in the time series. The abundance estimates since the early 2000s has been relatively stable but it has increased in 2013-2015.

1 Introduction

Beginning in 1996, a collaborative effort among a number of research groups was initiated to conduct a range-wide photographic identification study of gray whales in the Pacific Northwest (Calambokidis et al. 2000, 2002b). An initial publication of findings from 1998 demonstrated there was considerable movement of individual whales among sub-areas from northern California to southeastern Alaska (which we broadly refer to as the Pacific Northwest) and also provided initial estimates of the abundance of whales within that geographical area (Calambokidis et al. 2002a). The ability to look at movements and employ more sophisticated capture-recapture models, however, was restricted by the lack of multiple

years of data with broad geographic coverage. A subsequent report by Calambokidis et al. (2004) characterized the group of whales feeding in these survey areas during the summer-fall period as a “Pacific Coast Feeding Aggregation” (PCFA). They proposed that a smaller area within the PCFA survey areas – from Oregon to Southern Vancouver Island (OR-SVI) – was the most appropriate area for abundance estimation for managing a Makah gray whale hunt (Calambokidis et al. 2004). Subsequently the IWC has adopted the term PCFG for Pacific Coast Feeding group so we will use PCFG in place of PCFA.

This report updates information through 2015 from a collaborative effort to collect photographic identifications of gray whales from California to Alaska has continued since 1996 and these data now cover 20 years (1996-2015) and span fifteen survey regions along the coast from Southern California to Kodiak, Alaska (Figure 1). We provide estimates of abundance for the summer-fall seasons (1 June to 30 November) during 1996–2015 for survey regions between Northern California and Northern British Columbia (NCA-NBC), the region chosen by the IWC to represent the PCFG. For the National Marine Fisheries Service development of an Environmental Impact Statement, we also provide estimates for the smaller regions between Oregon and Southern Vancouver Island (OR-SVI) and Makah Usual and Accustomed area (MUA) which includes the outer coastal area of the Olympic Peninsula (NWA) and the Strait of Juan de Fuca (SJF), even though this area is quite small relative to the observed movements of whales within the PCFG.

2 Methods

Gray whales were photographed during small boat surveys conducted from California to Alaska by collaborating researchers (Table 1) between 1996 and 2015. Gray whale identifications were divided into the following regions (Figure 1): 1) SCA: Southern California, 2) CCA: Central California, 3) NCA: Northern California, 4) SOR: Southern Oregon, 5) OR: central Oregon, 6) GH+: Gray’s Harbor and the surrounding coastal waters, 7) NWA: Northern Washington coast, 8) SJF: Strait of Juan de Fuca, 9) NPS: Northern Puget Sound, 10) PS: which includes southern Puget Sound, Hood Canal (HC), Boundary Bay (BB) and San Juan Islands (SJ), 11) SVI: Southern Vancouver Island, 12) WVI: West Vancouver Island, 13) NBC: Northern Vancouver Island and coastal areas of British Columbia, 14) SEAK: Southeast Alaska, and 15) KAK: Kodiak, Alaska. With some exceptions, research groups work primarily in one or two regions. Details of identifications obtained by the different research groups are summarized in Tables 1-2.

2.1 Photographic Identification Procedures

Procedures during surveys by different research groups varied somewhat but were similar to one another in identification procedures. When a gray whale was sighted, the time, position, number of animals, and behaviors were recorded. Whales were generally approached to within 40-100 m and followed through several dive sequences until suitable identification photographs and associated field notes could be obtained.

For photographic identification of gray whales, both left and right sides of the dorsal region around the dorsal hump were photographed when possible. Most identification pho-

tographs were obtained with were obtained with 35mm cameras prior to 2004 and primarily with digital SLR after 2004 with both camera types paired with a telephoto lens (generally 200-300 mm). Researchers also photographed the ventral surface of the flukes for further identification when possible. The latter method was not as reliable since gray whales did not always raise their flukes out of the water. Markings used to distinguish whales included pigmentation of the skin, mottling, and scarring, which varied among individuals. These markings have provided a reliable means of identifying gray whales (Darling 1984). We also identified gray whales using the relative spacing between the knuckles along the ridge of the back behind the dorsal hump. The size and spacing of these bumps varies among whales and has not changed throughout the years these whales have been tracked, except with injury. Figure 2 shows typical photographs and features used in making gray whale identifications.

Comparisons of whale photographs were made in a series of steps. All photographs of gray whales were examined and the best photograph of the right and left sides of each whale (for each sighting) were selected. Identification photographs were initially compared within year to identify resightings and compared to the CRC catalog of whales seen in past years. Whale photographs that were deemed of suitable quality but did not match our existing catalog (compared by two independent persons) were considered “unique” identifications and assigned a new identification number and added to the catalog.

2.2 Data Analysis

The abundance of gray whales was estimated with open population models for three nested spatial scales consisting of contiguous survey regions (Figure 1; Table 3) 1) NCA-NBC: the coastal survey regions from Northern California (NCA) through Northern Vancouver Island/British Columbia (NBC) which matches the IWC definition of the PCFG, 2) OR-SVI: survey regions from southern Oregon through Southern Vancouver Island (SVI) identified in the Makah waiver request, and 3) MUA - survey regions NWA and SJF. Inland waters in WA (other than SJF) and in BC are excluded from the abundance estimates because these are used primarily by transient whales in the northward spring migration.

Gray whales photographed and identified anytime during the period between 1 June and 30 November (hereafter referred to as the “sampling period”) within the defined region were considered to be “captured” or “recaptured”. For each unique gray whale photographed, a capture history was constructed using 20 years of data from 1996-2015. For example, the capture history 00010010010000000000 could represent a gray whale photographed in 1999, 2002 and 2005 in the PCFG. The same gray whale may have had a capture history 00010010000000000000 for a smaller spatial scale such as OR-SVI or may not have been seen at all (00000000000000000000) and would not be used at the smaller spatial scale.

Multiple “detections” of a single whale within the sampling period were not treated differently than a single detection. A “1” in the capture history meant that it was detected on at least one day during the sampling period. However, multiple detections in the same year were used to construct an observed minimum tenure (MT) for each whale. MT was defined as the number of days between the earliest and latest date the whale was photographed with a minimum of one day for any whale seen.

We fitted open population models to the 20 yearly time series of capture history data for each spatial scale to estimate abundance and survival. Open models allow gains due to births/immigration and losses due to deaths/emigration. Using the RMark interface (Laake and Rexstad 2008) to program MARK (White and Burnham 1999), we fitted a range of models to the data using the POPAN model structure. The POPAN model structure (Schwarz and Arnason 1996) provides a robust parametrization of the Jolly-Seber (JS) model structure in terms of a super population size (N), probability of entry parameters (immigration), capture probability (p), and survival/permanent emigration (φ).

It is essential to consider the population structure and its dynamics to build adequate models. In particular, we know from previous analysis of a subset of these data (Calambokidis et al. 2004) that some whales were seen in only one year between 1 June and 30 November and were never seen again. Transient behavior is a well-known problem in capture-recapture models and it is often addressed using a robust design which involves coordinated multiple capture occasions within each year and typically assumes closure within the sampling period (June-November). Region-wide coordinated surveys may be possible but would be difficult with variation in weather conditions. Also, the closure assumption within the year would be suspect due to variable timing of whales arrivals and departures into the PCFG, so it would require nested open models. We know from prior analysis that whales newly seen in year (y) were less likely to return (i.e., seen at some year $>y$) than previously seen whales but also newly seen whales that stayed longer during their first year (i.e., longer MT) in the PCFG were more likely to return. Likewise, previously seen whales were more likely to be seen in the following year ($y+1$), if they had a longer MT in year y . Calambokidis et al. (2004) postulated that these observations were consistent with whale behavior that was determined by foraging success.

Transient behavior in which an animal is seen only once can be modeled by including a different “first year” survival (Pradel et al. 1997) for the newly seen animals. Survival in the time interval after being first seen is dominated by permanent emigration rather than true mortality. Survival in subsequent time intervals represents true survival under the assumption that animals do not permanently emigrate except in their first year. Pradel et al. (1997) were working with release-recapture data (Cormack-Jolly-Seber) where modeling this transient effect on survival is straightforward. For a Jolly-Seber type analysis where the first capture event is also modeled, the inclusion of a transient effect is less easily accommodated.

We divided the whales into cohorts based on the year in which they were first seen (“newly seen”). In the model, their first year survival could differ from subsequent annual survival as in Pradel et al. (1997). “Newly seen” is not a particularly useful concept for the first year of the study (1996), because all whales were being seen for the first time. The survey effort and coverage in 1996 and 1997 were not nearly as expansive as 1998 and later. We considered models that had three different first year survivals (1996&97, 1998, and >1998) and we also considered a model that allowed for a different first year survival for each year (cohort) to allow for different transient proportion in each year. The first year survival was also allowed to vary as a function of MT with a model in which the relationship was constant across years and varied for (1996&97, 1998, and >1998). We also considered models that allowed a different first-year survival for whales identified as calves under the presumption that their true survival might be lower but that their probability of returning to

the PCFG might be higher. Discussion at the 2012 intersessional AWMP meeting led to consideration of an additional covariate which split whales into 2 groups for estimation of post-first-year survival. Whales seen initially as calves and any whale newly seen in 1998 or was in the CRC catalog because it had been seen prior to 1998 were put in one group and the remaining whales newly seen in 1999 or later were put in another group. The expectation was that the first group would have higher post-first-year survival because many of the newly seen whales that entered after the stranding event in 1999/2000 might eventually emigrate. When this covariate was included it made such a large improvement that any model without it would have no support. Therefore, it was included in all 10 models for survival (Table 4).

In Calambokidis et al. (2010) we estimated a cohort-specific super-population size for each cohort using the median MT covariate value for unseen whales but during the April 2011 AWMP meeting it became apparent that this may lead to bias in estimating abundance. Therefore, we used the method outlined in the 2011 AWMP report which is similar to the method used by Calambokidis et al. (2004) in that we assume that all whales in the PCFG for the first year are seen so the super-population size for each cohort is the number seen and thus there are no unknown covariate values. We fixed capture probability (p) and probability of entry (p_{ent}) to 1 for each cohort in their entry year. We are not interested in the number of transient whales so we used an estimator of abundance for non-transient whales (2011 AWMP report) which is a modification of the Jolly-Seber estimator which for any year can be expressed as:

$$\hat{N} = n/\hat{p} = (u + m)/\hat{p}$$

where $n = u + m$, n is the number seen in a year being composed of new animals (u =unmarked) and previously seen animals (m =marked), and \hat{p} is the capture probability estimate. For the PCFG we are assuming that any new whale is sighted ($p = 1$) and we are only interested in estimating the abundance of whales that will remain part of the PCFG which is the portion of the new whales that do not permanently emigrate from the PCFG. We can modify the estimator for year j as follows:

$$\hat{N}_j = u_j\hat{\phi}_j + m_j/\hat{p}_j$$

where ϕ_j is the first year survival rate of “new” whales. When ϕ and p contain whale specific covariates like minimum tenure (MT) the estimator becomes:

$$\hat{N}_j = \sum_{i=1}^{u_j} \hat{\phi}_{ij} + \sum_{i=1}^{m_j} 1/\hat{p}_{ij}.$$

To obtain an abundance estimate for 2015, we assumed that the parameter for first year survival intercept in that year was the same as in 2014. A variance-covariance matrix for the abundance estimates was constructed using the variance estimator in Borchers et al. (1998) for a Horvitz-Thompson type estimator with an adaptation for the first component of the abundance estimator for prediction of number of new whales that do not permanently emigrate. For the estimated capture probabilities (p) not fixed to 1, we fitted 3 models that varied by time (year) and/or varied by MT in the previous year (Table 4).

We used Test 2 and Test 3 results from the Cormack-Jolly-Seber structure (Lebreton et al. 1992) as a general goodness of fit for the global model and as a measure of possible over-dispersion creating the lack of fit. We fitted each combination of models for S (survival) and p (capture probability) and used AICc (Burnham and Anderson 2002) to select the most parsimonious model of the 30 fitted models. Model averaging was used for all models to compute estimates and unconditional standard errors and confidence intervals.

3 Results

The database contains 25580 records for whales photographed between 1996 to 2015 from California to Kodiak, Alaska; however 4345 are replicate identifications of whales on the same day. We define a sighting as one or more photographs of a whale on a day. The number of sightings varied annually from 131 and 1959 with a total of 21235 sightings of 1638 unique gray whales (Table 1). The average number of sightings/whale was 13 (range: 1-339). Identifications were made throughout the year but with most effort from June to September. Number of sightings were most numerous in NCA, SVI, WVI, and NBC and (Table 2). The number of uniquely identified whales was greatest in NCA, NWA, SVI and WVI (Table 2).

3.1 Seasonal Sighting Patterns

Whales have been photographed in every month of the year (Table 5) but with very few during December-February when most of the whales are in or migrating to Mexico and survey effort is reduced. Previous analysis of these data have always used 1 June - 30 November as the sampling period to describe the whales in the PCFG because whales seen prior to 1 June and after 30 November are more likely to be whales that are migrating through the region. The southbound migration starts in December and the separation between May and June is clearly supported by the data. For example, of the 1638 unique whales sighted from California to Kodiak, Alaska, 666 whales were only seen between 1 Dec - 31 May and 87.2% of those were only sighted once (one day). Of the 972 whales sighted between 1 June -30 November at some time, 38.8% were only sighted once (one day). If sightings in Alaska are excluded, then only 31.7% of the 833 were seen only once (one day).

The break between May and June is apparent in various measures such as proportion of whales sighted more than once, sighted in more than one region, and sighted in more than one year (Figure 3). However, the break is more apparent if we separate out SJF, NPS and SVI from the other survey regions (Figure 4). The difference across months is not as strong for inland waters of Washington and British Columbia (NPS, SJF) because these are whales that have diverted from the migration and are either more likely to remain after 1 June or demonstrate high year-to-year fidelity during spring such as with NPS. Also, even though Southern Vancouver Island (SVI) is in the main migration corridor and not an inland water, the pattern across months is also weaker because the sampling has been focused on the spring herring spawn in Barkley Sound (effectively an inland waterway) and has purposefully undersampled passing migrant whales (Brian Gisborne, pers. comm.).

The break between May and June is much more apparent for NWA and the other areas in the migration corridor which is consistent with the northbound migration of gray whales proceeding past Washington through May. Resighting rates of whales seen after 1 June remained high through November.

A large photo-ID sample of gray whales in the MUA was conducted in 2015 by Makah Tribal biologists. At the time of this report the full comparison of these whales to historical images had not been completed but in the future will provide a better indication of proportion of PCFG whales present prior to 1 June.

Capture (sighting) histories of whales seen at least once in the PCFG from 1 June - 30 November are provided in Appendix Table 1 which show sightings of whales in 1 Mar -31 May only, 1 June - 30 Nov only and in both time periods within a year.

3.2 Regional Sighting Patterns

There is considerable variation in the annual regional distribution of numbers of whales photographed during the sampling period (Table 6) which is in part due to variation in effort. Although not a true measure of effort, the number of days whales were seen (Table 7) does reflect the amount of effort as well as abundance of whales. In particular, in comparison to other regions, the large number of sightings in SVI partly reflects large numbers of sampling days by Brian Gisborne who has routinely sampled SVI from summer through fall on almost a daily basis. On the other hand, the decline in sightings in SVI during 2007 was not due to reduced effort but to the distribution of whales with many of the whales having moved to waters off Oregon and Washington (Calambokidis et al. 2009b). Similarly, there were 40 survey days in SJF in 2010 but only 4 whales were seen on 4 different days (Table 6, Table 7) so this drop relative to other years was not due to lack of effort.

Whales were sighted across various survey regions and the interchange of whales (Table 8) between survey regions during 1 June - 30 November depends on proximity of the regions (Calambokidis et al. 2004). During 1 June-30 November for 1996 to 2015, 793 unique whales were seen in the PCFG range and 68.6% (544 of the 793 whales seen in the PCFG range) were seen within the smaller OR-SVI region and approximately 36.3% (288 of the 793 whales seen in the PCFG range) were seen within the smaller MUA area; however, there is variation in interchange between areas in the PCFG and the MUA. Of the whales sighted in regions from NCA to NBC, from 39.8% to 59.6% of the whales were seen at some point within MUA (Figure 5). If we exclude transients (whales seen in only one year), the interchange rates with MUA are much higher but the pattern is similar (Figure 6) with a range of 47.7% to 77.5%. Appendix Table 2 provides capture histories using data from 1 June - 30 Nov of whales seen in the MUA at least once. For each year, the table shows whether the whale was sighted in PCFG but not in the MUA during that year, only seen in MUA that year, and seen in both MUA and another PCFG area in that year.

Whales seen in the PCFG exhibited a wide range of movement across and within years. The 143 whales seen in 9 or more years provide a useful example. None of those whales was seen exclusively in a single region, and 67.1% were seen in at least 4 of the 9 survey regions from 1996 to 2015. However, whales did regularly visit the same regions across years with 94.4% were seen in at least one of the regions during six or more of the years they were seen and 65.7% were seen in a region two-thirds or more of the years they were

seen. SVI was the region with the maximum number of years seen for 65 of the 143 whales, which in part reflects the larger amount of survey effort in SVI (Calambokidis et al. 2004a, Calambokidis et al. 2013). Thus, some whales regularly visit particular regions more often than others, but they are seen across the other regions as well.

Some of the whales not seen in the PCFG in a year were seen in Kodiak and Southeast Alaska (Table 9). Of the 25 whales identified in Southeast Alaska and the 153 whales identified in Kodiak, Alaska, 14 (56%) and 24 (15.7%), respectively have been seen farther south in the PCFG.

If we look at latitudes of sightings of individual whales across the 20 years using whales that have been sighted on at least 6 different days (Figure 7), we see that sightings of some whales are highly clustered; whereas, sightings of other whales are highly dispersed across several regions. We defined each whale's primary range by the 75% inner quantile which is the middle of the range that includes 75% of the locations. The length of the 75% inner quantile in nautical miles exceeded 60 nautical miles (or 1 degree of latitude) for 49.0% of the whales (Figure 8) and it was more than 180 nautical miles for more than 29.6% of the whales. Thus, it makes little sense to compute an estimate of abundance for any region that spans less than a degree of latitude.

3.3 Annual Sighting Patterns

The average number of whales identified in any one year was 156, 104, and 37 for the PCFG, OR-SVI, and MUA, respectively (Table 10). However, those numbers do not represent the total numbers of whales that use each of these areas because not all whales using a region in a year are seen, not all whales return to the same region each year, and not all of the whales return to the PCFG region each year. The annual average number of newly seen whales (excluding 1996-1998 when the photo-id effort expanded to cover all survey regions) was 37.2, 25.8, and 13.6 for PCFG, OR-SVI, and MUA, respectively. The annual average number of newly seen whales that were "recruited" (seen in a subsequent year), excluding 1996-1998 and 2015, was 14.9, 12.6, and 6.4 for PCFG, OR-SVI, MUA respectively. Thus, there were a substantial number of new whales seen each year and 40.6, 49.6, and 47 percent of those were seen again in a subsequent year in the 3 regions respectively. The number of newly seen whales and the number newly seen and recruited (i.e., seen in at least one more year after the initial year it was seen) (Table 11) are displayed as discovery curves in Figures 9 and 10.

Of the whales that were seen during June-November 1996-2015 in the PCFG (NCA to NBC) about half were only seen in one year and the whales that were seen in more years were sighted more often each year and therefore represented a large proportion of the sightings (Figure 11). Of the 750 identified whales first seen before 2015 between 1 June and 30 November in the PCFG range (NCA-NBC), 52% were seen in only one year and only represent about 5% of the sightings (Figure 11). Many of the newly seen whales did not return in subsequent years. Some whales were seen in every year with 9.3% that were seen in every year after their initial identification, including 5 whales first seen in 1996 that were seen in all of 20 subsequent years. The remaining 39% were seen more than once but not in every year.

Likewise, examination of MT in the first sighting year demonstrates that whales who

stay longer in their first year were more likely to be seen in a following year (Figure 12). Whales “first” seen in the first few years of the study (1996-1998) includes some whales that were truly new to the PCFG in those years but many were only “new” because it was the first year of the study or as the surveyed regions expanded over time. This is evident (Figure 12) in the much higher proportions for 1996-1998 than for the other years. These relationships will be important in the capture-recapture models for abundance estimation because whales that do not return after their first year (a large percentage in this analysis) would appear to have not survived because they have permanently emigrated (with a small fraction that died).

3.4 Open Population Capture-Recapture Models

If the yearly cohorts were pooled, Test2+Test3 statistics indicated a significant lack of fit for the PCFG and subsets (Table 12) primarily resulting from Test 3. This was expected due to the different “survival” rates of previously seen whales (true survival) and newly seen whales of which many never returned (i.e., permanently emigrated) (Table 13). By separating the cohorts, survival for each cohort was time-varying and thus each cohort has a separate first year survival. The goodness of fit test (Test 2) demonstrated a lack of fit for NCA-NBC and OR-SVI (Table 12). For those regions, we estimated an over-dispersion values of $\hat{c}=2.29$ and $\hat{c}=1.23$ respectively to adjust AICc and estimated standard errors.

For all areas, the best fitted model (Table 14) was model 2 for p with capture probability varying across years and higher when MT was greater in the previous year. Likewise, for φ the best model was model 4 for all areas. Model 9 was the second best model. Both models 4 and 9 included a separate first year survival which depends on MT. Model 9 included a different calf first-year “survival” which gave a higher survival for calves than non-calves the first year seen (redundant for calves) because they are more likely to return. In models 9 and 4, there are 3 intercepts for first year survival (1996&97, 1998, >1998) and in model 9 the slopes for MT differ as well. These results were consistent with Calambokidis et al. (2004) who demonstrated strong support for the effect of MT on first year survival (Figure 13) and capture probability (Figure 15) in the following year. These results differ some from Calambokidis et al. (2010) who used an annual median-centered MT. Use of MT with median centering was necessary to construct open model abundance estimates in the manner described in Calambokidis et al. (2010). However, that was not necessary for JS1 and the use of MT without median-centering resulted in lower AICc values.

There was large year to year variation in capture probability. The values for NCA-NBC ranged from 0.42 to 0.98 depending on the year and value of MT (Figure 15). The lowest values were from 2007 which reflects the temporary emigration of whales from MUA and SVI to waters offshore of Oregon in that year. In contrast, for MUA capture probabilities were much lower ranging from 0.08 to 0.76 depending on the year and value of MT (Figure 16). The lower overall capture probability and weaker relationship between capture probability and MT reflect the transitory behavior of whales in such a small area. The lower estimates of capture probability in 1999-2004 for MUA was due to decreased effort by NMML which spread their survey effort across MUA to WVI during 1999-2002, lost a vessel in 2002 and had no funding in 2004 (Figure 16).

First year survival estimates were dominated by permanent emigration. For NCA-NBC, the estimates varied from 0.30 to 0.81 for non-calf whales with MT=1 in their first year and from 0.69 to 0.95 for MT>80 in their first year (Figure 13). Calf survival is by definition a first year survival rate and potentially includes permanent emigration from the PCFG. Depending on the value of MT, calf survival estimates ranged from about 0.35 to over 0.90 (Figure 14). The average calf survival estimate was 0.63 (se = 0.090). There was some support for a different first year calf survival with model 9 being the second best model (ϕ in Table 14) because calves are less likely to permanently emigrate. Unfortunately there is no way to separate permanent emigration from mortality with the existing data.

Survival subsequent to the first year was assumed to be constant but was less for non-calf whales that were newly seen in 1999 or later. Post-first-year survival for calves and whales present in 1998 or earlier presumably represents true survival assuming there was little permanent emigration after the first year. Those estimates were 0.967 (se=0.0062) and 0.967 (se=0.0066) for OR-SVI and NCA-NBC respectively. The post-first-year survival estimates for whales that entered in 1999 or later and not identified as a calf were 0.912 (se=0.0125) and 0.917 (se=0.0142) for OR-SVI and NCA-NBC respectively.

3.5 Abundance and Recruitment

For NCA-NBC, OR-SVI and MUA annual estimates of abundance were constructed with model averaged values for JS1 (Table 15-16). Estimates for NCA-NBC in Figure 17 are only shown for 1998-2015 with the open models $p = 1$ for 1996 so it will certainly be an underestimate and the survey coverage in 1996 and 1997 was not as extensive as the later years.

The value of N_{min} for 2015 is 228 for NCA-NBC (Table 15). To gain a sense for how these values might be relevant to estimating a possible level of removal (e.g., due to harvest) we computed the MMPA's Potential Biological Removal (PBR) (typically reserved for stock-level assessments). Using the PBR formula, with an Rmax of 6.2% and a recovery factor of 0.5 (Caretta et al. 2013), the PBR for NCA-NBC (PCFG) would be 3.5.

New whales that are not identified as calves have appeared annually and many of these new (non-calf) whales have subsequently returned and been re-sighted (Table 13). In NCA-NBC from 1999-2014, an average of 32.1 (range: 8.0, 68.0) new whales not identified as a calf were seen each year. Of these new non-calf whales, on average 11.8 (range: 1.0, 28.0) whales returned and were seen in subsequent years. It is unknown what proportion of the non-calves used the PCFG as a calf but were not seen in that year. Currently recruitment appears to be offset by losses (either mortality or permanent emigration) as the abundance estimates have been fairly stable since 2002 and recently increasing.

4 Discussion

The population structure of gray whales using the Pacific Northwest in summer and fall is complicated and involves two elements. One group of whales return frequently and account for the majority of the sightings in the Pacific Northwest during summer and fall. This

group is certainly not homogeneous and even within this group, there is some degree of preference for certain subareas. Despite widespread movement and interchange among areas, some of these gray whales are more likely to be seen returning to the same areas they were seen before. The second group of whales are transients that are seen in only one year, tend to be seen for shorter periods that year, and in more limited areas.

The existence of these two groups in the study area and their dynamics complicate estimating abundance. While the JS1 estimator may not be optimal, it provides a practical way of handling transients in this open population. Excluding 1996-1997, the JS1 sequence of abundance estimates provides the most reliable assessment of trend for the non-transient abundance and the best estimate of current abundance in 2015.

Despite extensive interchange among subregions in our study area, whales do not move randomly among areas. Abundance estimates were lower when using more limited geographic ranges but these more limited areas do not reflect closed populations. While the use of geographically stratified models can be useful in cases where populations have geographic strata they use (see for example Hilborn 1990), this would be difficult in our case because of the frequent sightings of animals in multiple regions within the same season and these models typically only allow an animal to be sighted in one strata per period. This could be dealt with by assigning animals to only a single region per season but this would be forcing the data into a somewhat inaccurate construct.

Several studies have considered the question of gray whale population structure. There is widespread agreement that at least two populations of gray whales in the North Pacific exist, a western North Pacific population (also called the Korean population) and an eastern North Pacific (ENP) population (sometimes called the California population) (Swartz et al. 2006; Angliss and Outlaw 2008; Rugh et al. 1999). The population structure of the gray whales feeding in the Pacific Northwest has remained in question and only a few studies have examined this. Steeves et al. (2001) did not find mtDNA differences in a preliminary comparison of gray whales from the summer off Vancouver Island and those from the larger ENP population. Ramakrishnan et al. (2001) did not find evidence that the Pacific Northwest whales represented a maternal genetic isolate, although even very low levels of recruitment from the larger overall population would prevent genetic drift. More recently, Frasier et al. (2011) generated mtDNA sequences from a larger sample of gray whales from Vancouver Island than tested by Steeves et al. (2001). They found significant differences in the haplotype frequencies between that sample and mtDNA sequence data reported for ENP gray whales, most of which were animals that stranded along the migratory route. The Frasier et al. (2011) samples were from a relatively small area; however, Lang et al. (2011) evaluated biopsy samples from California to southern Vancouver Island in the PCFG and ENP samples from whales sampled north of the Aleutians and also found significant mtDNA haplotype frequency differences. These two studies provide the strongest evidence to date that the Pacific Northwest whales might be sufficiently isolated to allow maternally inherited mtDNA to differ from the overall ENP population.

Population structure in other large whales has been the subject of recent inquiry and has revealed diverse results for different species. Clapham et al. (2008) examined 11 subpopulations of whales subjected to whaling that were extirpated possibly due to the loss of the cultural memory of that habitat and concluded subpopulations often exist on a smaller spatial scale than had been recognized. Studies of other baleen whales, particularly

humpback whales, have shown evidence of maternally directed site fidelity to specific feeding grounds based on photographic identification studies (Calambokidis et al. 1996, 2001, 2008). This high degree of fidelity to specific feeding areas is often discernible genetically. In the North Pacific strong mtDNA differences were found among feeding areas even when there was evidence of low level of interchange from photo-ID (Baker et al. 2008). Similar findings were documented for humpback whales in the North Atlantic which feed in different areas but interbreed primarily on a single breeding ground (Palsboll et al. 1995) like ENP gray whales. In the North Pacific the differences for humpback whales were often dramatic. For example, humpback whales that feed off California have almost no overlap in mtDNA haplotypes with humpback whales feeding in Southeast Alaska (Baker et al. 1990, 1998, 2008). One difference between humpback and gray whales is the coastal migration route of gray whales which means gray whales going to arctic waters to feed would migrate right through the feeding areas to the south. Other species of large whales have not shown as strong site fidelity to specific feeding grounds. Blue whales have undergone an apparent shift in their feeding distribution in the North Pacific apparently due to shifting oceanographic conditions (Calambokidis et al. 2009a). Fin whales in the North Pacific have long migrations and while there do not appear to be multiple distinct feeding areas as was the case for humpback whales, there were some distinct and isolated apparently non-migratory populations (Mizroch et al. 2009; Berube et al. 2004).

Even though the population structure of gray whales off the Pacific Northwest remains unresolved, there is a consistent group of animals that use this area and we provide several estimates of their abundance. Different abundance methods and geographic scopes yield varied results but all suggest the annual abundance of animals using the Pacific Northwest for feeding through the summer is at most a couple hundred animals depending on the estimating method and how broadly the region is defined geographically.

The rapid increase in the abundance estimates at the start of this study is in part due to the smaller area of coverage during 1996 and 1997. We included those years to improve the estimate in 1998-1999 and the estimate for 1998 did increase by 7% from previous analysis. The increase from 1998-2000 occurred during a period the overall eastern North Pacific gray whale population was experiencing a high mortality event that included unusually high numbers of gray whales showing up in areas they were not common. The high rate of increase in the late 1990s and early 2000s should be verified with additional data such as compiling photographic identifications for this area from multiple sources to attempt to verify if the abundance of animals prior to the start of our study was as low as suggested by these trends. Even though the rate of increase may be too high, we believe the abundance did increase and now appears to be relatively stable since 2002.

Acknowledgments

This analysis would not have been possible without the collaborating organizations and individuals contributing identification photographs (the primary contributors are listed in Methods and Tables 1 and 2). Support for the photographic identification reported here, the comparison of gray whale photographs and preparation of this report came primarily from the National Marine Mammal Laboratory. Permission to conduct some portions

of this research in U.S. waters was provided by the U.S. National Marine Fisheries Service and the Makah Tribe. Portions of the research in British Columbia were conducted collaboratively with Fisheries and Oceans Canada (thanks to John Ford and Graeme Ellis). Volker Deecke assisted in analysis and matching of identifications from S. Vancouver Island. William Megill coordinated providing sightings and identifications from CERF, Dawn Goley and Jeff Jacobsen coordinated effort for HSU, Christina Tombach and Dave Duffus coordinated early efforts for UVIC, Carrie Newell provided identification photographs from Oregon, Merrill Goshö, Pat Gearin, Nate Pamplin and Jonathan Scordino provided photos from Washington. Brian Gisborne's diligence and hard work provided an immense amount of data and photographs from Vancouver Island. A number of people assisted in the field effort and in the printing and matching of photographs at Cascadia Research. Erin Falcone, Lisa Schlender, Jennifer Quan, and Amber Klimek helped compile the data from different contributors and conducted photographic matching. Randy Lumper conducted gray whale matching in the early years of this study. Jonathan Scordino, Steve Stone and Donna Darm provided many helpful comments, suggestions and edits.

Table 3: Survey regions and region subsets used for abundance estimation. Numbers refer to locations on the map in Figure 1.

Survey Region	Region Description	NCA- NBC	OR- SVI	MUA
(1) SCA = Southern California				
(2) CCA = Central California				
(3) NCA = Northern California	Eureka to Oregon border; mostly from Patricks Pt. and Pt. St George	x		
(4) SOR = Southern Oregon		x	x	
(5) OR = Oregon Coast	Primarily central coast near Depoe Bay and Newport, OR	x	x	
(6) GH+ = Gray's Harbor	Waters inside Grays Harbor and coastal waters along the S Washington coast	x	x	
(7) NWA = Northern Washington	Northern outer coast waters with most effort from Cape Alava (Sea Lion Rock) to Cape Flattery	x	x	x
(8) SJF = Strait of Juan de Fuca	US waters east of Cape Flattery extending to Admiralty Inlet (entrance to Puget Sound) with most effort ending at Sekiu Point	x	x	x
(9) NPS = Northern Puget Sound	Inside waters and embayments from Edmonds to the Canadian border			
(10) PS = Puget Sound	Central and southern Puget Sound (S of Edmonds), including Hood Canal, Boundary Bay, and the San Juan Islands			
(11) SVI = Southern Vancouver Island	Canadian waters of the Strait of Juan de Fuca along Vancouver Island from Victoria to Barkley Sound, along West Coast Trail	x	x	
(12) WVI = West Vancouver Island		x		
(13) NBC = Northern British Columbia	British Columbia waters north of Vancouver Island, with principal effort around Cape Caution	x		
(14) SEAK = Southeast Alaska	Waters of southeastern Alaska with the only effort in the vicinity of Sitka			
(15) KAK = Kodiak, Alaska				

Table 4: Model specifications for survival (φ) and capture probability (p) parameters in POPAN models for gray whale photo-identification data. For survival models, β_0 is the baseline intercept for non-transient survival. F_y is 1 if it is year the whale was first seen and 0 otherwise. A subscript for F_y means that it applies only for that cohort except that F_{y99} applies to cohorts 1999 and beyond and F_{y_c} represents each of the cohorts from 1996 to 2015. C is 1 if identified as a calf in its first year and 0 otherwise. R is 1 for calves or any whale seen in 1998 or was already in the catalog prior to 1998 and 0 otherwise. β_r is an adjustment to post-first-year survival. MT is minimum tenure value of a whale and β_M is the estimated slope parameter for φ or p . $\beta_{M,96-97}$ applies to 1996-97, $\beta_{M,98}$ to 1998 and $\beta_{M,99}$ applies to 1999-2014. $\beta_{F_y,96-97}$, $\beta_{F_y,98}$ and $\beta_{F_y,99}$ are the first-year survival intercept adjustments for 1996-97, 1998 and cohorts 1999-2014 respectively and $\beta_{F_y,c}$ represents 19 cohort-specific first year survival parameters for 1996-2014. β_{CF} is an adjustment for calf first year survival and β_{CM} is an adjustment for calves to the slope of MT for survival. For the capture probability models, β_t has 18 levels for $t=1998, \dots, 2015$ and β_0 represents the 1997 value. For 1996 $p=1$.

Model	Parameter Logit Formula	Number of parameters
φ		
1	$\beta_0 + \beta_{F_y} F_y + \beta_r R(1 - F_y)$	3
2	$\beta_0 + \beta_{F_y} F_y + \beta_M MT F_y + \beta_r R(1 - F_y)$	4
3	$\beta_0 + \beta_{F_y,96-97} F_{y96-97} + \beta_{F_y,98} F_{y98} + \beta_{F_y,99} F_{y99} + \beta_r R(1 - F_y)$	5
4	$\beta_0 + \beta_{F_y,96-97} F_{y96-97} + \beta_{F_y,98} F_{y98} + \beta_{F_y,99} F_{y99} + \beta_M MT F_y + \beta_r R(1 - F_y)$	6
5	$\beta_0 + (\beta_{F_y,96-97} MT) F_{y96-97} + (\beta_{F_y,98} MT) F_{y98} + (\beta_{F_y,99} MT) F_{y99} + \beta_r R(1 - F_y)$	8
6	$\beta_0 + \beta_{F_y,c} F_{y_c} + \beta_M MT F_y + \beta_r R(1 - F_y)$	22
7	$\beta_0 + \beta_{F_y,c} F_{y_c} + \beta_M MT F_y + \beta_{CF} C F_y + \beta_r R(1 - F_y)$	23
8	$\beta_0 + \beta_{F_y,c} F_{y_c} + \beta_M MT F_y + \beta_{CM} C MT + \beta_r R(1 - F_y)$	24
9	$\beta_0 + (\beta_{F_y,96-97} MT) F_{y96-97} + (\beta_{F_y,98} MT) F_{y98} + (\beta_{F_y,99} MT) F_{y99} + \beta_{CF} C F_y + \beta_r R(1 - F_y)$	9
10	$\beta_0 + (\beta_{F_y,96-97} MT) F_{y96-97} + (\beta_{F_y,98} MT) F_{y98} + (\beta_{F_y,99} MT) F_{y99} + \beta_{CM} C MT + \beta_r R(1 - F_y)$	10
p		
1	$\beta_0 + \beta_t$	19

Table 11: Discovery of new unique whales over years 1996-2015 for PCFG,OR-SVI and MUA. Recruited only means that the whale was seen in at least one more year after the initial year it was seen. The number 'recruited' will usually be greater than the abundance estimate because some whales die and others may permanently emigrate and do not return.

Region	1996	1997	1998	1999	2000	2001	2002	2003	2004	2005	2006	2007	2008	2009	2010	2011	2012	2013	2014	2015

Figure 1: Locations for photo-identifications of gray whales. Numbers refer to values in Table 3.

Figure 2: Characteristics used for gray whale photo-identification.

Figure 3: Monthly measures of proportion of whales that were seen in more than one region, seen on more than one day and seen in more than one year. The values include sightings from 1996-2015 in all regions from California to Alaska. Lower values imply whales were simply migrating through the area in a short time frame and were thus less likely to be seen at other times and in other regions. Values are not shown for months with fewer than 20 sightings. Whales seen more often are over-represented because they are used in each month they were seen. For example a whale seen in June, July and August will be in each summary. Thus, these values may be larger than values computed without splitting by month (e.g., overall proportion of whales seen in more than one year).

Figure 4: Region and monthly measures of proportion of whales that were seen in more than one region, seen on more than one day and seen in more than one year. The values include sightings from 1996-2015 in all regions from California to Alaska. Lower values imply whales were simply migrating through the area in a short time frame and were thus less likely to be seen at other times and in other regions. Values are not shown for months with fewer than 20 sightings. Whales seen more often are over-represented because they are used in each month they were seen. For example a whale seen in June, July and August will be in each summary. Thus, these values may be larger than values computed without splitting by month (e.g., overall proportion of whales seen in more than one year).

Figure 5: Proportion of whales in sub-regions from NCA to KAK that have been seen in the MUA using sightings after 1 June from 1996-2015.

Figure 6: Proportion of whales seen in at least 2 years in sub-regions from NCA to KAK that have been seen in the MUA using sightings after 1 June from 1996-2015.

Figure 7: Distribution of latitudes of sightings (points) for whales with 6 or more sightings after 1 June from 1996-2015, the 75% inner quantile (solid thick line), and full range (light dashed line). Each position on the x axis represents an individual whale. Whales have been arranged on the plot by sorting first on the lower bound of the inner quantile (to a half-degree) and then the upper bound of the quantile. This has the effect of sorting from south to north and clusters whales with smaller quantile ranges followed by whales with larger ranges.

Figure 8: Distribution of ranges of 75% inner quantiles of latitudes expressed in nautical miles for whales sighted on 6 or more days during 1996-2015.

Figure 9: Discovery curves for unique whales seen in PCFG, OR-SVI and MUA for 1996-2015.

Figure 10: Discovery curves for unique recruited whales seen in PCFG, OR-SVI and MUA for 1996-2015.

Figure 11: Average number of sightings per year and distribution of whales and numbers of sightings based on numbers of years a whale was seen in NCA-NBC between June-November during 1996-2015.

Figure 12: Influence of minimum tenure (MT) in the first year the whale was photographed on the probability it will be re-sighted in one or more following years for whales seen in NCA-NBC for June-November 1996-2015. The bar graphs are divided based on first year in 1996-1997, 1998 and after 1998. Re-sightings for 2015 are used but initial sightings for 2015 are excluded because there are no data beyond to evaluate re-sighting probability.

Figure 13: For NCA-NBC analysis of 1996-2015 data, model-averaged estimates of first year survival of non-calves for each cohort at 5%, 25%, 50%, 75%, and 95% quantiles of minimum tenure values for that cohort.

Figure 14: For NCA-NBC analysis of 1996-2015 data, model-averaged estimates of first year survival of calves for each cohort at 5%, 25%, 50%, 75%, and 95% quantiles of minimum tenure values for that cohort.

Figure 15: For NCA-NBC analysis of 1996-2015 data, model-averaged estimates of capture probability for each year at 5%, 25%, 50%, 75%, and 95% quantiles of minimum tenure values for whales in the previous year.

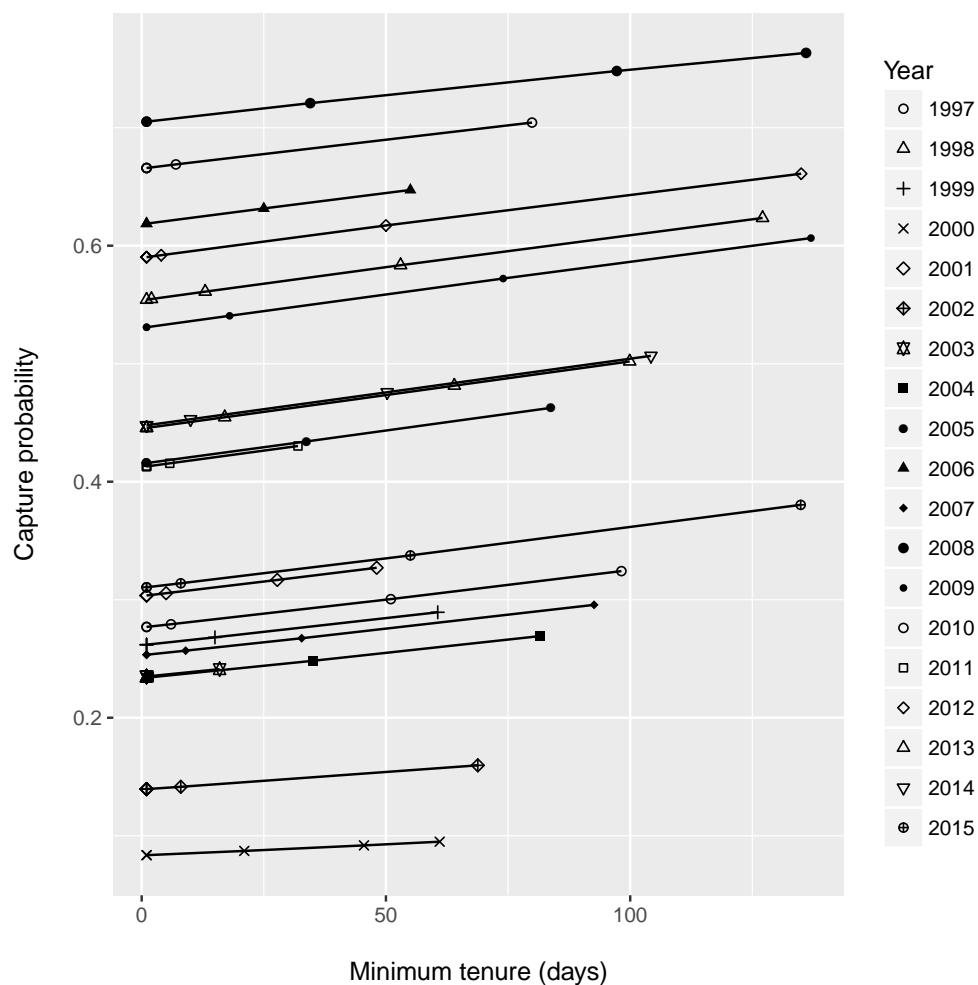

Figure 16: For MUA analysis of 1996-2015 data, model-averaged estimates of capture probability for each year at 5%, 25%, 50%, 75%, and 95% quantiles of minimum tenure values for whales in the previous year.

Figure 17: Annual abundance estimates for 1998-2015 in NCA-NBC using the open (Jolly-Seber; POPAN parametrization) population model approach JS1.

Appendix

Table 1 provides capture histories of whales seen in the PCFG at least once from 1 June - 30 November and displays by year, when they were seen only in spring (March-May), only from 1 June - 30 Nov and when they were seen in both time periods. Table 2 provides capture histories using data from 1 June - 30 Nov of whales seen in the MUA at least once. It shows when whales were seen only outside of the MUA but in the PCFG, only in the MUA and both inside the MUA and in the PCFG outside of the MUA

Table 1: Sighting histories of whales seen in the PCFG in at least one year. In year columns, a 1 means the whale was only sighted in the spring (March-May), 2 means it was only seen in June-Nov, and 3 means it was seen in both March-May and June-Nov. The region value is the number of years the whale was seen in that region.

Are social aggregation and temporary immigration driving high rates of increase in some Southern Hemisphere humpback whale populations?

Phillip J. Clapham · Alexandre N. Zerbini

Abstract Humpback whales (*Megaptera novaeangliae*) in the Southern Hemisphere were heavily exploited by commercial whaling. Today, their recovery is variable: Humpbacks remain surprisingly scarce in some formerly populous areas (e.g., New Zealand, Fiji), while in other regions (such as eastern Australia), they appear to be rebounding at or even above the maximum plausible rate of annual increase. Here, we propose that this phenomenon cannot be explained solely in demographic terms. Through simulation, we test the hypothesis that reported high rates of increase represent a combination of true intrinsic growth rates and temporary immigration, driven by a strong tendency to aggregate for mating. We introduce the idea that overexploitation diminished density at major breeding grounds such that these were no longer viable; then, during subsequent population recovery, a critical mass was attained in certain areas which drew in whales that formerly bred elsewhere. The simulations show that, to maintain high increase rates, the contribution to that rate by temporary immigration from a second, “source” population would have to represent a larger and larger proportion of the source stock and would require relatively high (but

quite plausible) intrinsic rates of increase for each population. In the modeling scenarios, the demand for immigrants would eventually exceed the supply and exhaust the source population, but the simulations demonstrated that high increase rates can be sustained over periods of more than 20 years. This hypothesis, if correct, would not only explain excessively high rates of increase in current “hot-spots” such as eastern Australia, but also imply that formerly important areas (e.g., Fiji) host few whales today not necessarily because of a failure to recover, but because the species’ mating system leads the whales concerned to migrate to higher-density breeding grounds elsewhere. Overall, we caution that assessments of depleted animal populations that do not consider the social behavior of a species are missing a potentially vital component of the picture.

Introduction

Humpback whales, *Megaptera novaeangliae*, were extensively exploited by modern commercial whaling in the twentieth century. In the Southern Hemisphere, humpbacks feed in Antarctic waters during the austral summer and migrate north to tropical mating and calving grounds in winter. For the purpose of management, the International Whaling Commission (IWC) recognizes six management zones (labeled Areas I–VI) in the Antarctic and seven “breeding stocks” (labeled A–G) which are variously connected to the feeding grounds in the six management Areas.

More than 200,000 Southern Hemisphere humpbacks were killed from 1904 to 1973 (Clapham and Baker 2008; Rocha et al. 2014). This total includes more than 48,000 whales taken in illegal whaling operations by the USSR after World War II; more than 25,000 of these were killed

in just two seasons (1959/1960 and 1960/1961), primarily in the Antarctic management regions Areas IV, V and VI which lie to the south of Australia, New Zealand and eastern Oceania (Clapham et al. 2009; Ivashchenko et al. 2011). The total number of twentieth-century humpback catches by all whaling operations in breeding area E (linked largely to Antarctic Area V) was 50,484 whales. Breeding stock D off western Australia (which has been linked to feeding grounds in Area IV) was also hit heavily by these catches. Catches in Areas I, II and III were smaller but still substantial, and in at least Area II (the western South Atlantic), the exploitation in the early part of the century was so intense that whales appear to have been effectively extirpated from at least one key historical habitat, South Georgia (Clapham et al. 2008).

It is not known how many humpback whales remained extant following these huge catches, but there is no doubt that the great majority of the Southern Hemisphere population was removed and many stocks were reduced to a low percentage of their pre-exploitation abundance (IWC 2006, 2010). Following this, humpback whales have shown apparently variable recovery rates in different regions. For example, off both western and eastern Australia (feeding ground Areas IV and V, and breeding areas D and E, respectively), the populations concerned are exhibiting strong recovery, with reported rates of increase in excess of 11 %/year (Bryden et al. 1996; Paterson et al. 2004; Noad et al. 2011a). A paradox (much discussed within IWC) is that these rates are close to, or exceed, the maximum plausible for the species given the biological factors that inevitably constrain reproduction. Maximum plausible rates were reviewed by Zerbini et al. (2010), who concluded that typical estimates of population growth rate are 7–8 %/year and an annual growth rate of 11.8 % is the maximum that can be realistically expected for a population of humpback whales. Furthermore, this maximum rate requires values for age at first parturition, birth rate and survival which are at the extremes of those observed in any humpback whale population.

In contrast, humpbacks in some other areas where they are known to have once been abundant have shown little or no recovery in recent years. One example is Fiji, a formerly important breeding area in which shore surveys directed by the late William Dawbin recorded hundreds of whales between 1956 and 1958, but where very few animals are observed today (Paton and Clapham 2002; Gibbs et al. 2006). Another is New Zealand, a migratory corridor where the population supported shore-based whaling at several locations until the huge Soviet catches of 1959–1961 caused a population crash and forced the fishery to close; although whales appear to be returning to Cook Strait today, numbers observed remain very small (Childerhouse and Gibbs 2005).

The assumption regarding these areas has been that the populations concerned were relatively discrete and were so heavily exploited in their Antarctic feeding grounds that they have failed to recover in recent times (Clapham et al. 2008; Constantine et al. 2012). Although this might be true, there may be an alternative explanation for the continued low densities of whales in these formerly populous areas, as well as the unusually high rates of increase observed in some other populations. Here, we explore what we term the Social Aggregation Hypothesis (SAH). This hypothesis proposes that overexploitation by whaling disrupted, reduced or even eliminated existing breeding aggregations of humpback whales and that, during recovery, new aggregations eventually formed, which drew in whales which formerly bred in other areas. In this scenario, the new aggregations might be expected to show high apparent rates of increase, while those populations from which temporary immigrants were drawn would appear to be depressed.

Here, using the IWC's breeding stock E (eastern Australia to Tonga) as an example, we first present the biological and historical background to the SAH, including the social ecology of the species, catch history and current abundance, and evidence for the plasticity of humpback whale distribution following major episodes of whaling. We then use simulation modeling to examine the population dynamics that would have to exist in order for an observed population to show a consistently high rate of increase if a significant portion of that rate was actually due to immigration from a second stock that formerly bred elsewhere.

Background to the Social Aggregation Hypothesis

Social ecology of the humpback whale

The social ecology of humpback whales is reviewed by Clapham (1996, 2000). Both male and female humpbacks undertake seasonal migrations from high-latitude feeding areas to mating and calving grounds in tropical or subtropical waters. The primary features of the mating system include male intra-sexual competition and singing; the system has been compared to a non-traditional lek in which males display (sing) and females presumably practice mate choice based upon characteristics that we do not fully understand.

Central to the argument evaluated here is the undisputed fact that this mating system involves areas of aggregation: Although humpbacks are found in widely varying (and sometimes low) densities throughout any winter breeding range, they frequently return in large numbers to specific locations. Some prominent examples include the Hawai'ian Islands (Cerchio et al. 1998), Silver and Navidad Banks in the West Indies (Whitehead and Moore 1982; Mattila et al. 1989) and Abrolhos Bank off Brazil (Martins et al. 2001).

Similar aggregations occur off the coasts of both western and eastern Australia (Bannister et al. 1991; Paterson et al. 1994); although traditionally labeled as migratory pathways, the widespread occurrence of newborn calves, singing and competitive behavior in these areas leaves little doubt that they also represent major mating and calving grounds in their own right (Franklin et al. 2011).

Another key characteristic of the humpback's mating system is that it does not involve dependence upon spatially fixed resources. Although the argument has been made that females require shallow, protected waters for calving or avoidance of male harassment (Whitehead 1981; Herman et al. 2011; Craig et al. 2014), there are usually many such sites within a breeding range. Furthermore, because all humpbacks fast during the winter, they are not tied to habitats with high biological productivity. Consequently, there is potentially considerable plasticity in their distribution.

Breeding stock E: catch history and current abundance

The range of breeding stock E as currently defined by the IWC extends from eastern Australia to the Tongan archipelago. Within this region are found current or formerly important humpback whale breeding habitats, including the eastern Australian coast, the Great Barrier Reef, Norfolk Island, New Caledonia, Fiji and the Tonga Island group, as well as the once-major migratory corridor around New Zealand; some movement among these areas has been documented with both photo-identification and genotyping of individual whales (Constantine et al. 2007; Steel et al. 2008). Discovery marking and photo-identification have established that whales from at least portions of this region feed primarily in Antarctic Area V, although there are also known connections to Areas IV and VI (IWC 2006).

During the early years of large-scale commercial whaling following World War II, humpback whales were known to be abundant in many of the breeding grounds listed above. The migratory corridors off eastern Australia, New Zealand and Norfolk Island became the sites of several coastal whaling stations which collectively caught hundreds of humpbacks each year, culminating in a peak catch of 1,341 animals in 1960 (Chittleborough 1965; Clapham et al. 2009). Following the large Soviet Antarctic catches of more than 25,000 humpbacks in 1959/1960 and 1960/1961, none of these stations met their quotas and all were forced to close by 1963 (Clapham et al. 2009).

There was no recorded twentieth-century whaling in New Caledonia or Fiji, and little is known about the abundance of humpbacks in the former area prior to the extensive catches made in the Antarctic feeding grounds. In Fiji, land-based surveys and Discovery tagging were conducted by the late William Dawbin during the austral winters of 1956, 1957 and 1958 (Paton and Clapham 2002). The

surveys recorded hundreds of whales passing through the region, with a peak weekly count of 238 animals in late August 1957.

Recovery in all of these areas within breeding stock E has been remarkably variable in the years since whaling ceased. The population off eastern Australia appears to be recovering strongly; the stock size in 2010 was estimated at 14,522 whales (95 % CI 12,777–16,504, Noad et al. 2011b), with a rate of increase estimated at 10.9 % (± 0.4 %). This is consistent with a rate of 10.5 % (95 % CI 10.0–11.5 %) reported by Paterson et al. (2004); an even higher rate of 12.3 % (95 % CI 10.1–14.4 %) was given by Bryden et al. (1996). The population using Tonga also appears to be recovering: A photo-identification mark-recapture estimate of 2,311 whales (CV = 0.22) was calculated by Baker et al. (2006), although the lack of long-term data precluded an estimation of trend.

In contrast, the observed density of whales elsewhere within breeding stock E ranges from moderate to very low. In New Caledonia, Garrigue et al. (2004) used photo-identification and genotype data collected from 1995 to 2001 to calculate mark-recapture estimates of 327 (CV = 0.11) and 533 (CV = 0.15), respectively, and a more recent estimate of 472 (CV = 0.18) for 2003 was given by Baker et al. (2006); there are no data with which to even qualitatively assess pre-whaling abundance for this population. In Fiji, observations made in 2001 at the same land sites used by Dawbin in the 1950s recorded very few whales (Gibbs et al. 2006). Similarly, surveys at Norfolk Island conducted over 3 years in 2003–2005 found only 14 whales in 300 h of survey effort (Paton et al. 2006); in contrast, catches at Norfolk from 1956 to 1962 totaled 884 whales. A recent mark-recapture study estimated the abundance of humpback whales throughout Oceania at 4,329 (95 % CI 3,345–5,313) and noted no statistically significant increasing trend in this region (Constantine et al. 2012).

The crash in sightings and catches in the various insular and coastal areas above confirmed their migratory links with Areas V and VI where the huge Soviet catches took place.

How plastic is the distribution of humpback whales?

There have been suggestions that humpback whales can radically change their winter distribution following periods of intensive whaling. Despite the high densities of humpback whales found in the Hawai'ian Islands today, Herman (1979) claimed there was no evidence for their occurrence there in historical times, before the major periods of commercial whaling in the North Pacific. He cited the absence of a name for the humpback whale in the Hawai'ian language, as well as the lack of reports of whales from local media. He also noted the absence of any mention of this

species in the logbooks and journals of Arctic whalers overwintering in Lahaina and other Hawai'ian ports during the nineteenth century. However, Herman's (1979) sample of read logs was very small. Furthermore, Lebo (2010) examined local newspapers, diaries and other historical material, as well as a larger sample of whaling logbooks and journals than that used by Herman, and found reports of the presence of humpback and sperm (*Physeter macrocephalus*) whales in Hawai'ian waters in the nineteenth century. Further work on this topic is ongoing (F. Sharpe, pers. comm.), but it appears that humpback whales were likely not uncommon in this region, especially during the winter months.

A similar case to Herman's was made by Reeves et al. (2001) for the northern West Indies. Today, the Silver and Navidad Banks region of the Dominican Republic hosts densities of humpback whales that are one to three orders of magnitude greater than anywhere else in the West Indies; in contrast, it is clear from whaling logbooks that a major center of aggregation during the nineteenth century lay in the southeastern Caribbean, where whales are found in very low densities today (Swartz et al. 2003). Reeves et al. (2001) suggested that social aggregation and chance were responsible for the distributional shift to the northern West Indies; Clapham et al. (2008) suggested that such a shift could have been influenced by the range over which humpback whale song can be heard. However, while it is possible that whales were not present in large numbers in this region in the nineteenth century, it appears more likely that the absence of whaling there was driving more by political considerations and an inability to obtain the necessary permissions (I. Bonnelly di Calventi, pers. comm.). Another suggestion of an apparent shift concerns the modern breeding area off the coast of Ecuador, to which humpback whales from the Antarctic Peninsula migrate in the austral winter. A study of local language, art, media and whaling records gives no indication that humpback whales occurred in this region prior to recent times, yet they are abundant there today (C. Castro, pers. comm.).

All three of the cases described above involve wintering grounds. As noted above, with the possible exception of protected water for mothers and calves (which can be found in numerous coastal locations), there are no required resources for humpback whale breeding areas. Consequently, and notwithstanding the disputable nature of the studies described above, this potentially lends considerable plasticity to the distribution of this species. In other words, humpback whales—whose mating system is strongly characterized by aggregation—should be free to seek suitable breeding habitats in other areas if a particular aggregation is greatly reduced or eliminated by whaling.

Materials and methods

To explore the SAH, we developed a hypothetical scenario simulating the population of humpback whales migrating past the coast of eastern Australia. This population has been well studied at several sites in recent years, and a variety of methods has been employed to estimate abundance and rates of increase. In our scenario, two hypothetical populations, named base and source, migrated from different feeding grounds (e.g., in the Antarctic) to different breeding grounds (e.g., to the coastal waters of eastern Australia and to islands in the western South Pacific). The term “population” is used here to represent two spatially separated groups that interact (breed) at some level through the exchange of individuals. The base population migrates past a location where the land-based abundance surveys are conducted (as off the eastern coast of Australia). The source population migrates from a different feeding ground and supplies individuals to the base population by social aggregation at an incremental annual rate. These individuals joined the base population during the migration before the abundance surveys were conducted. Individuals of the two populations may reproduce, but return to their original Antarctic feeding grounds for the austral summer.

With that, we tested whether the mixing of the two populations could produce an estimated (apparent) rate of increase higher than the actual (true) rates of each population. In this example, the base population corresponds to the eastern Australian stock. The identity of the source population is irrelevant to the theoretical argument explored here, but it is not unreasonable to assume that this constitutes the stock from western Oceania which, prior to whaling, migrated past New Zealand and on to breeding grounds in Fiji and elsewhere. Under the SAH, the low density of whales observed in Fiji today would be a consequence not of a lack of recovery, but of these whales abandoning their historical winter destination and instead migrating into centers of aggregation off eastern Australia. As noted above, while individuals of the two populations can mix in the breeding grounds, they return to their feeding ground of origin. Therefore, in this study, the term “immigration” refers to temporary immigration.

We assessed whether the apparent rate of increase measured in the migratory routes was equal to the recent estimate of trend of the eastern Australian population for the period 1984–2010 (10.9 %/year, 95 % CI 10.5–11.3 %/year; Noad et al. 2011b). This rate of increase is close to that proposed as the maximum possible (11.8 %) by Zerbini et al. (2010). We simulated the dynamics of the two populations from 1987 to 2015 by assuming that the biological rate of increase in the base and the source populations were actually less than the 10.9 % estimated from surveys off eastern Australia (Noad et al. 2011b). Through

this modeling exercise, we address the question of what proportion of temporary immigrants from the source stock would be required to maintain relatively high apparent rates of increase that would be consistent with the 10.9 %/year observed in the eastern Australian base population if the true biological rate was actually less than this. In various combinations, we chose two values for true rates of increase in the base and source populations: (1) 7.3 %/year, which is the median rate of increase obtained by Zerbini et al. (2010, Approach A) from the means of observed parameter values from different populations of humpback whales worldwide; and (2) 9.6 %/year, which is intermediate between the average and the 11.8 %/year “maximum” rate of increase given by Zerbini et al. (2010).

We explored twelve scenarios involving these two rates of increase as well as different incremental immigration rates of 1, 2 and 3 %, where the increased proportion of individuals migrating from the source to the base population was additive over time (e.g., for the 1 % example, the immigration rate from source to base was 1 % in 1987, 2 % in 1988, 3 % in 1989 and so on). We wanted to examine a range of possibilities, including some that are behaviorally more or less plausible. The initial size of the base population in 1987 is approximately 879 individuals, corresponding to the estimated size of the eastern Australia population in that year (Brown et al. 2003). The size of the source population was arbitrarily set at 500 individuals as the SAH hypothesis assumes that individuals are drawn from a smaller source population to the more populated base population breeding ground.

The simulation model structure is presented in Fig. 1. The base (eastern Australia) and the source (western Oceania) population dynamics in the breeding and feeding grounds were simulated as follows:

Initial population sizes

$$N_{\text{base},1987}^{\text{FG}} = 879$$

$$N_{\text{source},1987}^{\text{FG}} = 500$$

Number of immigrants

$$I_{\text{source} \rightarrow \text{base},t} = N_{\text{source},t}^{\text{FG}} \cdot \alpha \cdot (t - 1986)$$

$$I_{\text{base} \rightarrow \text{source},t} = N_{\text{base},t}^{\text{BG}} \cdot \alpha \cdot (t - 1986)$$

Abundances

$$N_{\text{base},t}^{\text{MC}} = N_{\text{base},t}^{\text{FG}} + I_{\text{source} \rightarrow \text{base},t}$$

$$N_{\text{base},t}^{\text{BG}} = \left(N_{\text{base},t}^{\text{FG}} \cdot \lambda_{\text{base}} \right) + \left(I_{\text{source} \rightarrow \text{base},t} \cdot \lambda_{\text{source}} \right)$$

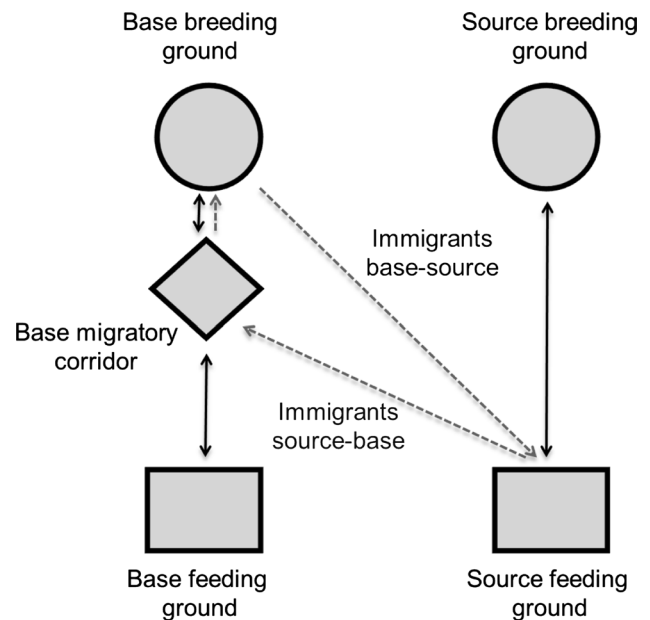

Fig. 1 Model structure to simulate the dynamics of the base and source populations to assess the SAH

$$N_{\text{source},t}^{\text{BG}} = (N_{\text{source},t}^{\text{FG}} - I_{\text{source} \rightarrow \text{base},t}) \cdot \lambda_{\text{source}}$$

$$N_{\text{base},t+1}^{\text{FG}} = N_{\text{base},t}^{\text{BG}} - I_{\text{base} \rightarrow \text{source},t}$$

$$N_{\text{source},t+1}^{\text{FG}} = N_{\text{source},t}^{\text{BG}} + I_{\text{base} \rightarrow \text{source},t}$$

where:

- $N_{\text{base},1987}^{\text{FG}}$ and $N_{\text{source},1987}^{\text{FG}}$ are the initial population sizes for the source and base population in the feeding grounds in 1987
- $I_{\text{source} \rightarrow \text{base},t}$ is the number of immigrants moving from the source population feeding grounds to the base population in year t ,
- $I_{\text{base} \rightarrow \text{source},t}$ is the number of immigrants returning from the base to the source population feeding grounds in year t ,
- $N_{\text{base},t}^{\text{MC}}$ is the abundance in year t in the migratory corridor (MC) of the base population (equivalent to the observed population migrating past east Australia)
- $N_{\text{base},t}^{\text{BG}}$ is the abundance in year t in the breeding grounds of the base population
- $N_{\text{source},t}^{\text{BG}}$ is the abundance in year t in the breeding grounds of the source population (western Oceania)
- $N_{\text{base},t+1}^{\text{FG}}$ is the abundance in year $t + 1$ in the feeding grounds of the base population

Table 1 Simulation scenarios, rates of population change (ROC in %/year) of the source population on the breeding grounds/migratory routes of the base population, as well as the proportion of animals from the source population migrating to the base by 2015

Scenario	α (%)	λ source	λ base	Average observed ROC _{source, BG}	Average observed ROC _{base, MC}	Proportion of migrants to base in 2015
1	1	7.3	7.3	6.2	7.9	29
2	1	7.3	9.6	6.2	10	29
3	1	9.6	7.3	8.7	8.3	29
4	1	9.6	9.6	8.7	10.2	29
5	2	7.3	7.3	4.2	8.4	58
6	2	7.3	9.6	4.2	10.2	58
7	2	9.6	7.3	6.6	9.3	58
8	2	9.6	9.6	6.6	10.7	58
9	3	7.3	7.3	−0.1	8.8	87
10	3	7.3	9.6	−0.1	10.5	87
11	3	9.6	7.3	2.2	9.7	87
12	3	9.6	9.6	2.2	11.2	87

The initial size of the base population is set at 879 individuals, which corresponds to the estimated size of the eastern Australia population in 1987 (Brown et al. 2003)

- $N_{\text{source}, t+1}^{\text{FG}}$ is the abundance in year $t + 1$ in the feeding grounds of the source population
- α = temporary immigration rate,
- λ = is the population-specific (source or base) finite intrinsic rate of increase (7.3 %/year or 9.6 %/year in the scenarios simulated in this study).

The observed (or apparent) rates of change (ROC) in abundance in the period from 1987 to 2015 for the population in the base migratory corridor ($N_{t, \text{base MC}}$) and the source population breeding grounds ($N_{t, \text{source, BG}}$) were computed as the average annual rate of change in the abundance. The proportion of migrants moving from the source to the base population at the end of the simulation period (2015) was also calculated.

The simulation model presented above assumes an exponential rate of population growth under the assumption that the populations were too small (relative to carrying capacity) for density dependence to have a significant impact on growth during the time frame of the simulation (1987–2015). This model is equivalent to log-linear regression methods typically applied to compute population growth rates from time series of humpback whale abundance estimates (Bannister and Hedley 2001; Stevick et al. 2003; Zerbini et al. 2006; Noad et al. 2011a, b) and is consistent with the growth rate patterns of recovering endangered whales within the time frame examined here.

There is of course an almost endless set of scenarios which could be tested in this work. However, our aim is not to conduct an exhaustive exploration of all options but rather to test the possible validity of the SAH. We wish to assess how, under a range of values, this phenomenon

would be manifest if real, and whether high apparent rates of increase in a base population could be maintained over extended periods by temporary immigration from another stock.

Results

The results of the simulation are shown in Table 1 and Fig. 2. The results show that in some scenarios (2, 4, 6, 8, 10 and 12), relatively high rates of increase (10–11 %/year) in the observed base population migratory route can be maintained. These scenarios typically require the higher λ values among the two that we selected for the simulation work for the base (larger) or both populations. Higher rates (e.g., >10.4 %/year) are observed only in scenarios 8, 10 and 12, which require an annual increment of 2–3 % of individuals from the source population immigrating to the base population. Except for scenarios 2 and 4, where the observed ROCs are around 10 %/year, higher ROCs require a relatively large number of individuals (58–87 %) immigrating from the source population to the base population at the end of the simulation (in 2015). In scenarios 10 and 12, the source population numbers decline in the breeding grounds (Fig. 2) because a large number of individuals moving toward the base population is needed in order to maintain the relatively high observed rates of increase observed on the base population's migratory routes.

In scenarios where λ values are lower (7.3 %/year) for both source and base populations or when a higher λ is assigned to the source (smaller population), ROCs above 10 % are not possible irrespective of the proportion

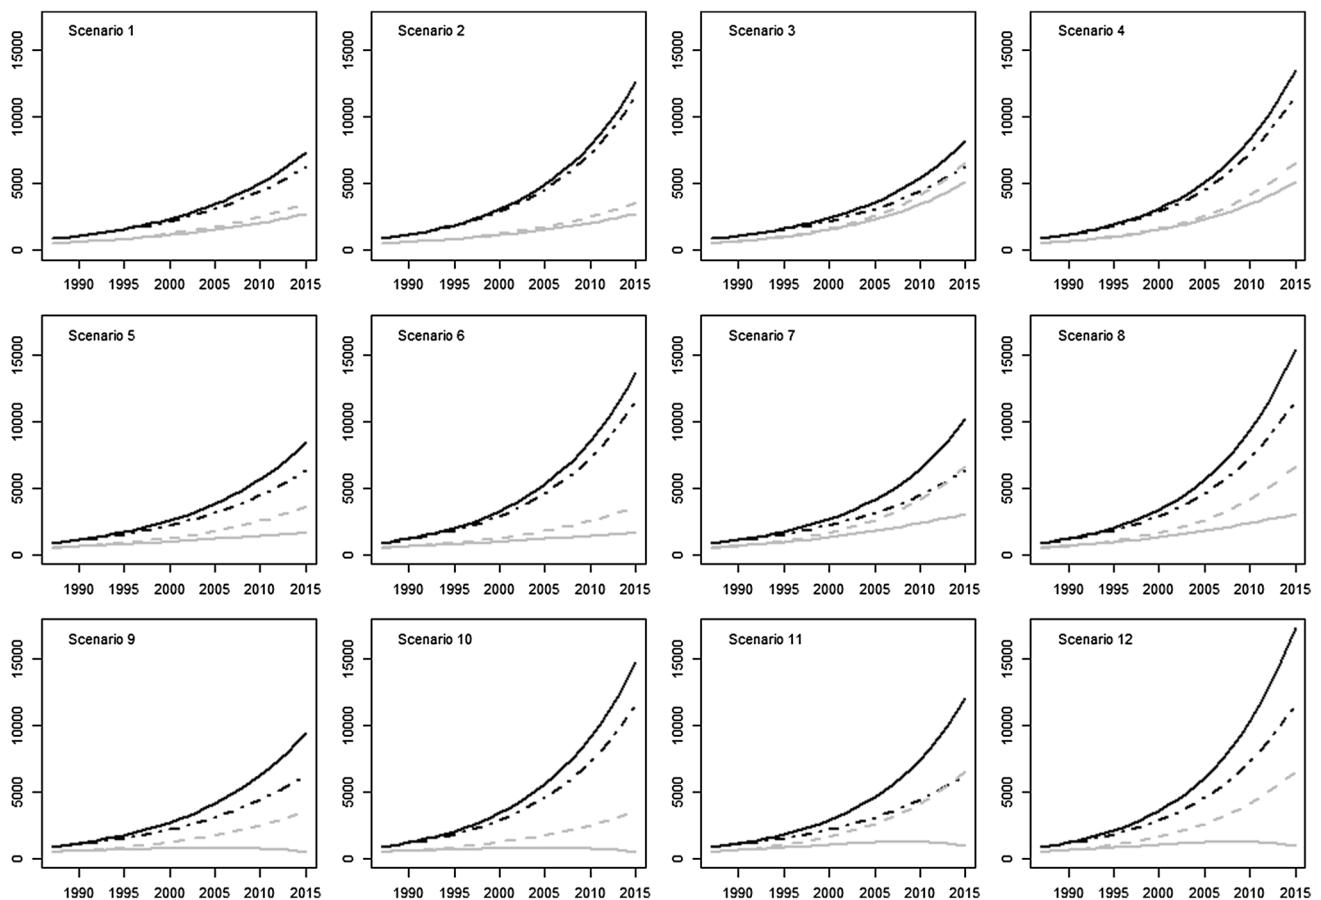

Fig. 2 Simulated population trajectories of humpback whales under twelve scenarios of varying rates of increase and temporary immigration rates. Gray and black lines correspond to the “source” and “base” population, respectively. Dotted and continuous lines

represent, respectively, the true population (feeding ground) and “observed” population (migratory corridor for base and breeding ground for source)

of migrants visiting the breeding grounds of the base population.

Discussion

We undertook this exercise to assess whether, at least in theory, temporary immigrants from a depleted population drawn into (for them) a new breeding area could artificially inflate apparent observed rates of increase in that area. The modeling exercise conducted here shows that in order to maintain the same rate of high growth observed off eastern Australia (or any other population), the contribution to that rate by immigration from a source population would have to represent an increasingly larger proportion of the source stock each year. The demand for immigrants would eventually exceed the supply and exhaust the source population, but the simulations demonstrated that high increase rates can be sustained over extended periods (well over 20 years). From this, we conclude that, at least

theoretically, the SAH could account for observed high rates of increase such as those reported since 1987 for the eastern Australia component of Breeding Stock E. However, in other scenarios (e.g., 9–12 here), it cannot.

It is possible that any population large enough to support a protracted high apparent rate of increase in the base stock would form its own centers of aggregation in historically important habitats rather than seeking social centers elsewhere. However, this might not be the case if the immigration trend began when the population was small (e.g., prior to surveys being conducted in the base) and then became a self-sustaining collective behavior which continued as the stock recovered, and/or if the cultural memory of the existence of historically important habitats was lost. It is probably pointless to speculate on the identity of such a population given that we do not know whether it even exists, but it is worth noting that the feeding grounds of Area VI were not exploited as heavily as those in Area V and might therefore have retained more animals than the latter. However, we know neither the pre- and post-whaling size of the Area

VI stock, nor whether the survivors would seek or find any connection to breeding area E.

In the scenarios investigated in this study, the proportion of the source population moving to the base population (the immigration rate) increased over time in order to maintain the relatively high apparent rate of increase estimated with the surveys. Additional scenarios, not included in this study, could assume that individuals move from the source to the base population at a constant rate. Under these circumstances, the most likely outcome is that the growth rate observed at the survey site corresponds to a combination of the growth rate of two populations, bounded by the rates observed for each individual population. For example, if the base and source populations are growing at the same rate, say 5 %/year, then the observed rate of increase should be 5 %/year irrespective of the size of either population and of the immigration rate from the source to the base population. If, by contrast, the base and source populations have different growth rates, say 7 % for the base and 4 % for the source population, then the observed rate must be a figure between 4 and 7 %. The actual observed rate will depend upon the size of both populations and the immigration rate.

It is interesting to note that estimates of growth rates reported for Oceania (Constantine et al. 2012) are consistent with those observed for the source population in their breeding grounds in some of the modeling scenarios presented here. For example, Constantine et al. (2012) estimated nonsignificant but positive growth rates of 4–7 %/year for the Oceania population with mark-recapture population models. The observed ROC for the source population breeding ground in scenario 8 is consistent with their estimates and still allows for the maintenance of an observed high (10.7 %/year) ROC in the base population.

Although we did not examine the dynamics involved, even more complicated scenarios can easily be envisaged involving more than one source population and more sophisticated models. Obviously, immigration from two (or more) source stocks would increase the time taken for demand in the base stock to exceed the combined supply from elsewhere. Nonetheless, given the results presented here, the SAH is likely to represent at best an incomplete explanation of the high rates of increase observed in some Southern Hemisphere humpback whale populations. Irrespective of what is mathematically plausible, it is difficult to believe that social aggregation would produce the remarkable consistency that has been observed in the rates of increase reported from eastern Australia.

Certainly, the highly social nature of humpback whales during their winter breeding season makes it unlikely that no temporary immigration into large aggregations occurs, notably in situations where commercial whaling essentially destroyed such assemblages in certain areas. It is clear that the large whaling catches of the late 1950s and early 1960s

so reduced some populations of whales that the remaining animals were small in number. For example, whales which formerly migrated past New Zealand and (presumably) on to Fiji would, in the post-whaling era, no longer have found the sizeable breeding aggregations which once existed in such places.

Similarly, the current relatively low density of whales in the southeastern Caribbean (the major West Indies whaling ground in the nineteenth century, Reeves et al. 2001; Swartz et al. 2003) might not be due to a lack of recovery but to whales changing their migratory destination to the much more populous Silver/Navidad Bank complex in the northern part of the Antillean arc.

The key point here is that, given what is known of the mating system, it is unrealistic to believe that humpback whales would continue to return to largely empty habitats if an alternative, more attractive destination was available to them. Song represents a potential means by which whales could be drawn into aggregation centers (Herman 1979; Reeves et al. 2001; Herman et al. 2013). Although even high densities of singers in shelf waters would not be audible over great distances due to transmission loss in shallow water, it is not necessary for a distant whale to initially detect the aggregation itself; rather, all that is required is for a whale to hear a few singers in the right direction, and then to pick up increasing numbers of singing males as it traveled closer and closer to the actual aggregation site.

There is evidence from both photo-identification resighting histories and analysis of mitochondrial DNA for long-term female fidelity to breeding areas, including in Oceania (Olavarría et al. 2007). Accordingly, it is possible that movement among breeding areas, if it occurs, is more likely to be undertaken by males seeking to increase opportunities for mating.

Although the high increase rates indicated by the point estimates from eastern Australia could be real, as noted above, they require values for survival, age at first parturition and calving rate that represent a combination of extreme values from among those observed elsewhere in the world (Zerbini et al. 2010). Accordingly, we conclude that some portion of these high growth rates is likely due to immigration, but we have no way of assessing the extent of this phenomenon without data on true growth rates, population structure and the movement rates of individuals among the base stock and any source population(s) elsewhere.

Although distributional shift by some animals may partly explain the low densities of whales today in Fiji, New Zealand and some other areas, and indeed the apparent delay in recovery of the Oceania population as a whole (Constantine et al. 2007), we cannot contradict the prevailing belief that these areas were host to one or more relatively discrete management units and that these populations

have failed to recover from the intensive whaling to which they were subject during the last century.

However, we believe that it is dangerous to dismiss the SAH idea completely. Although inevitably impossible to validate, we believe that—given what we know of the social ecology of humpback whales—it is entirely plausible that social aggregation has been a factor in determining the distribution and demographics of depleted populations of this endangered species as they attempt to recover from the damage inflicted by commercial whaling. Through whaling, humans may well have wrought major changes in the distribution and habitat use of humpback whales. There are currently not enough data to speculate on whether social aggregation following depletion by whaling would be manifest in other species of large whale. However, the principle potentially applies to any species with a population that is characterized by discrete hotspots of distribution during the mating season; as such, it might apply to at least right whales (*Eubalaena* spp.) and gray whales (*Eschrichtius robustus*).

More generally, population modeling for whales (and many other taxa) is invariably a numbers game in which estimates of abundance, trend and demographic parameters are examined and modeled; such exercises, and interpretations of model output, rarely attempt to incorporate knowledge regarding the social behavior or mating system of the species concerned. A major lesson from the modeling exercise conducted here is that changes in distribution caused by disruption of a species' social system could explain anomalously high rates of population growth, as well as unusually low rates observed in highly depleted source stocks. Whether or not that is actually what has occurred with humpback whales, we strongly caution that assessments of depleted animal populations that do not take into account the social ecology of the species concerned are missing a potentially vital component of the picture.

Acknowledgments We thank Nancy Friday, Barbara Taylor, Paul Wade and two anonymous referees for helpful discussions and reviews of this paper.

Taxonomy

Kingdom	Phylum	Class	Order	Family
Animalia	Chordata	Mammalia	Cetartiodactyla	Eschrichtiidae

Taxon Name: *Eschrichtius robustus* (western subpopulation) (Lilljeborg, 1861)

Parent Species: See [Eschrichtius robustus](#)

Common Name(s):

- English: Western Gray Whale

Taxonomic Notes:

This is a subpopulation of the Gray Whale, *Eschrichtius robustus*.

Assessment Information

Red List Category & Criteria: Endangered D [ver 3.1](#)

Year Published: 2018

Date Assessed: January 1, 2018

Justification:

The Gray Whales that summer in the western North Pacific, mainly off northeastern Sakhalin Island and the southeastern coast of Kamchatka, appear to be a genetically and demographically self-contained group and are therefore listed as a subpopulation, even though many of them migrate to wintering areas in the eastern North Pacific. The number of reproductive females is estimated to have been between 51 and 72 in 2016, hence the total number of mature individuals is well below 250, the threshold for Endangered under IUCN Red List criterion D. Historically Gray Whales migrated through Japanese and Korean waters to wintering grounds thought to be located in the South China Sea. Recent sightings and bycatches off Japan and China showed that some individuals, including at least two that were known to feed off Sakhalin Island, migrated through Asian waters in winter and spring. Although one recent record exists of a mother and calf migrating through Japanese waters in spring, it is unclear whether a specific wintering ground still exists in Asian waters. If the western subpopulation were defined to include only those whales that winter in the western North Pacific, then that subpopulation would be classified as Critically Endangered because the number of mature individuals in that group is most probably less than 50.

Geographic Range

Range Description:

The main known summering grounds of Gray Whales in the western Pacific are off the northeastern coast of Sakhalin Island (Russian Federation) in the Okhotsk Sea and in bays on the southeastern coast of the Kamchatka Peninsula. They also occur at least occasionally in other coastal waters of the northern Okhotsk Sea (Vladimirov 1994, Weller *et al.* 1999, Yakovlev *et al.* 2011). Historically there was a migration along both coasts of Japan (Sea of Japan and the Pacific Ocean side), the mainland coast of the Sea of Japan, and the Korean Peninsula (Nambu *et al.* 2010). At least 1,700 Gray Whales were taken by modern whaling during 1890-1966 in the Sea of Japan/East Sea, mainly off the coast of Korea, plus unknown numbers in the Yellow Sea (Kato and Kasuya 2002). The catches in the Jangjeon ground (= Changjin northeast Korea) had two peaks, in December and April, which reflect the southbound and northbound migrations, respectively, while the catches in the Ulsan ground (off southeast Korea) were concentrated in December and January.

Until recently, the Gray Whales summering off Sakhalin Island were thought to belong to the historical Asian Gray Whale subpopulation, hence the term "Korean-Okhotsk Gray Whale" used in the Russian literature (Blokhin *et al.* 1985), but evidence from tagged whales (Mate *et al.* 2015) and photographic and genetic matches with whales off Canada and the U.S. and in wintering lagoons along the coast of Baja California, Mexico (Weller *et al.* 2012) show that many of the Sakhalin and Kamchatka whales migrate to the eastern North Pacific in winter.

Although Bowen (1974) speculated that the Asian Gray Whale population was extinct after summarizing available negative findings, this idea was rebutted by Brownell and Chun (1977), who reported that Gray Whales were captured in Korean waters until 1967 and observed there in 1968 and also during research cruises in the Okhotsk Sea in 1967 and 1974. The last confirmed sighting in Korean waters was of two Gray Whales in January 1977 in the Sea of Japan /East Sea (Park 2001, Kim *et al.* 2013). Small numbers of gray whales were observed off Piltun, Sakhalin, in the 1980s (Blokhin *et al.* 1985). About 20 records were documented in Japan between 1990 and 2016, mainly on the Pacific coast (Kato *et al.* 2016). These include at least one female that moved between Sakhalin and Japan and one individual seen in successive years off Sakhalin in summer and off Japan in winter and spring (Weller *et al.* 2008, 2016; Nakamura *et al.* 2017). The last recorded living Gray Whale sighted in Chinese waters was around Wangjia Island, China (36°50'N, western Yellow Sea) in January 1979 (Wang 1984). A Gray Whale stranded near Zhuanghe (Korea Bay, northern Yellow Sea) in December 1996 and died soon after (Zhao 1997). A Gray Whale was caught in fishing gear in the Taiwan Strait (Fujian Province of China) in November 2011 (Wang *et al.* 2015). There are no confirmed records of Gray Whales from the coastal waters of Taiwan (excluding fossils). Two mother-calf pairs were caught in "spring" 1953 (month not stated) in the eastern Gulf of Tonkin off Leizhou Peninsula, Guangdong Province, China (Zhu 2002 cited in Nambu 2010). This is near the Hainan Strait where pre-modern whalers took Gray Whales in January and February in the 19th century (Henderson 1984). The westernmost record is a stranding in October 1994 on the island of Ngãc Vung, Viet Nam, in the western Gulf of Tonkin. The specimen was misidentified at the time as a Fin Whale (*Balaenoptera physalus*), but the skeleton was placed in the Quãng Ninh Historical Museum where it was recently confirmed to be a Gray Whale (Pham *et al.* 2014). Therefore, it appears that at least some of the Gray Whales that feed in the Okhotsk Sea migrate through Japanese waters in winter and spring. These may be a remnant of the historical Asian population, but it is not known whether any calving and nursery aggregations still exist in the west as

they do in the east (Baja California, Mexico).

Country Occurrence:

Native: Canada (British Columbia); China; Japan; Mexico (Baja California); Russian Federation (Central Asian Russia); United States (Alaska, California, Oregon, Washington)

Possibly extinct: Korea, Democratic People's Republic of; Korea, Republic of

FAO Marine Fishing Areas:

Native: Pacific - northwest, Pacific - eastern central, Pacific - northeast

Population

Gray Whales were hunted in the western North Pacific in prehistoric times both in Korea (Park 1995, Lee and Robineau 2004) and in the Okhotsk Sea (Krupnik 1984), but to an unknown extent. They were taken by Japanese hand-harpoon whalers in the Sea of Japan starting at least in the 17th century, and in larger numbers by Japanese net whalers in the Sea of Japan and East China Sea, on the Pacific coast of Japan, and along the Korean Peninsula from 1675 to 1890 (Omura 1984, 1988). Gray Whales were also taken by European and American whalers in the Okhotsk Sea from the late 1840s to perhaps the start of the 20th century (Henderson 1984, Reeves *et al.* 2008), and by Russian steam whalers on the southern coast of the Russian Far East and then by Norwegian steam whalers off the Korean Peninsula in the early years of the 20th century (Andrews 1914, Weller *et al.* 2002). Quantitative information is scarce, but it is possible that the western subpopulation was already depleted by the start of modern whaling at the end of the 19th century. During 1890-1966 an estimated 1,800–2,000 Gray Whales were taken off the Korean Peninsula and Japan (Kato and Kasuya 2002). Nearly 85% of these whales were killed off southeastern Korea (Ulsan) while the remainder came primarily from northeastern Korea (Jangjeon, Sinpo and Yujin) with a small number of whales also taken in Japanese waters and the Yellow Sea in the early part of the 20th century. Occasional catches are recorded from China during 1916-1958 (Nambu *et al.* 2010). It is not known whether any Gray Whales have been taken since 1945 in the waters of the Democratic People's Republic of Korea. The Gray Whale population off Sakhalin and Kamchatka has been increasing at a rate of 3.4-4.8% per year, albeit with some fluctuations, over the period 2006-2016 (Cooke 2017). The population in 2016 was estimated at 271-311 whales, excluding calves, of which 175-192 whales were considered predominantly Sakhalin-feeding individuals. The number of breeding females was estimated at 51-72. The nominal number of mature individuals for the purpose of Red List assessment is taken to be twice the number of mature females (102-144 mature individuals). Some of the whales are known through tagging (Mate *et al.* 2015) and photographic matches (Weller *et al.* 2012) to migrate to the eastern North Pacific in winter, including to the wintering lagoons in Baja California, Mexico. While some have been observed to migrate to the western North Pacific (Weller *et al.* 2016), the analysis by Cooke (2017) indicates that the number doing so is 100 or less.

Based on analyses of individual identification data including mother-calf pairs, and the results of paternity analysis of genetic samples (Lang 2010), Cooke *et al.* (2017) concluded that the Gray Whales that summer off Sakhalin and southeastern Kamchatka may constitute a demographically self-contained subpopulation where mating occurs at least preferentially, and possibly exclusively, within the subpopulation. Significant genetic differences between Gray Whales sampled off Sakhalin and those sampled in the eastern North Pacific have been found in both mitochondrial and nuclear DNA (Le Duc *et al.* 2002, Lang *et al.* 2011). However, another genetic study involving 28 Gray Whales sampled off Sakhalin Island and one sampled in the eastern North Pacific concluded that the putatively 'eastern' individual was no more or less related to the whales sampled in the west than would be expected by chance alone (DeWoody *et al.* 2017).

Current Population Trend: Increasing

Habitat and Ecology (see Appendix for additional information)

Gray Whales are predominantly benthic feeders. The best-studied and apparently main feeding habitat of this subpopulation is the shallow (5-15 m depth) shelf off northeastern Sakhalin Island, particularly off the mouth of Piltun Lagoon, where the main prey species appear to be amphipods and isopods

(Weller *et al.* 1999, Demchenko *et al.* 2016). Mother-calf pairs appear to feed exclusively in the shallow water but other individuals also use an offshore feeding ground in 30-50 m depths southeast of Chayvo Bay where benthic amphipods and possibly cumaceans are apparently the main prey species (Demchenko *et al.* 2016). The prey composition in other Gray Whale feeding areas in the Okhotsk Sea and off Kamchatka is unknown. Historically, Gray Whales were observed to feed during their northbound migration in the East Korean Bay (North Korea; formerly known in English as Broughton Bay) between the two Japanese land stations Sinpo and Yujin in the early 20th century (Andrews 1914, Tago 1922).

Systems: Marine

Threats (see Appendix for additional information)

Three female Gray Whales, including a mother-calf pair, were fatally entangled in net-traps on the Pacific coast of Japan in 2005 (Kato *et al.* 2006). Based on projections, this level of mortality, if continued, would result in a high probability of decline towards extinction (Cooke *et al.* 2006). Following the deaths of two further females, at least one of which was fishery-related, in northern Japan in 2007, the western subpopulation was classified on the IUCN Red List in 2008 as Critically Endangered under criteria C2a(ii) and E (Reilly *et al.* 2008). From 2008, the deliberate killing and marketing of the species was prohibited in Japan (Kato *et al.* 2008), and no fishery-related deaths have been documented there since then. One of the Gray Whales found entrapped in a set net in May 2005 and a Gray Whale carcass that stranded in April 2016 at Ito City (35°N) on the Pacific coast of Japan both exhibited spinal pathologies severe enough in at least the first case to visibly impair mobility (Yamada *et al.* 2016). Since 2013, trap nets for Pacific Salmon have been deployed in the Western Gray Whale feeding ground off northeastern Sakhalin, resulting in two observed entanglements and at least one probable entanglement death (Lowry *et al.* submitted). Based on analysis of photographs, approximately 20% of Gray Whales observed off Sakhalin during 1995-2005 showed evidence of scarring from past entanglements (Bradford *et al.* 2009), but it is not known where the scars were acquired. Lowry *et al.* (submitted) conclude that the coastal salmon set net fishery operating at northeastern Sakhalin, and to a lesser extent elsewhere in the Russian Far East, poses a high risk of entangling Gray Whales from the western subpopulation. They also conclude that bottom-set gillnet, demersal longline, snurrewad, and trap and pot fisheries overlap substantially with Gray Whale distribution in the Russian Far East, and bycatch in those fisheries is possible. One Gray Whale was caught and died in fishing gear off China in the Taiwan Strait in 2011 (Wang *et al.* 2015). In addition to fishery-related hazards, the substantial nearshore industrialization and shipping congestion throughout the migratory corridors of those Gray Whales that migrate through Asian waters in fall, winter and spring increases the likelihood of exposure to ship strikes, chemical pollution, and general disturbance (Weller *et al.* 2002). Offshore gas and oil development in the Okhotsk Sea within 20 km of the primary feeding ground for mother-calf pairs off northeastern Sakhalin Island also represents a potential threat. Potentially harmful activities include geophysical seismic surveying, vessel traffic, and disturbance from construction work (IUCN 2017). However, the continued increase in the numbers of Gray Whales summering off Sakhalin implies that the impacts to date have been sustainable.

Conservation Actions (see Appendix for additional information)

Gray Whales have been legally protected from commercial whaling by the 1946 International Convention for the Regulation of Whaling (ICRW) since its entry into force in 1948, and by its

predecessor convention, the Convention for the Regulation of Whaling, since 1935, to which U.S.A., Canada, and Mexico were parties. The ICRW came into effect for the U.S.A., Canada, and the USSR in 1948, Mexico in 1949, Japan in 1951, Republic of Korea in 1978, and China in 1980. Canada withdrew from the ICRW in 1981 but Gray Whales remain protected under Canadian law. Gray Whales have a measure of legal protection in Russian waters through inclusion in the Russian Federation Red Book of Threatened Species: the Korean-Okhotsk population is listed as "Endangered" while the eastern North Pacific population, which occurs in Russian waters in summer, is listed as "Recovery and Restoration". The Gray Whale has been legally protected in Japan since 2008, and deliberate killing and commercial utilization are prohibited. The species is listed in Appendix I of Convention on International Trade in Endangered Species. Western Gray Whales are listed as endangered under the U.S. Endangered Species Act and are considered depleted and strategic under the U.S. Marine Mammal Protection Act. Five range states – Japan, Russian Federation, Republic of Korea, U.S.A. and Mexico – have signed a Memorandum of Cooperation Concerning Conservation Measures for the Western Gray Whale Population. A stakeholders' workshop to develop a conservation plan is planned for 2018 or 2019.

Population Assessment of the Sakhalin Gray Whale Aggregation

Justin G. Cooke^{1,2}, David W. Weller³, Amanda L. Bradford⁴, Olya Sychenko⁵, Alexander M. Burdin⁵
and Robert L. Brownell, Jr.³

ABSTRACT

A population assessment of the Sakhalin feeding aggregation of gray whales (*Eschrichtius robustus*) was conducted using photo-identification data collected on their summer feeding ground off Sakhalin Island from 1994 to 2011, fitted to an individually-based population model. This is an update of the assessments by Reeves *et al.* (2005) and Cooke *et al.* (2006; 2008). For this assessment, the model has been extended to incorporate the following additional factors: individual heterogeneity in sampling probability; time lags in the effects of environmental variability on population parameters; an explicit age-specific maturation ogive; and immigration. As in previous assessments, the sampling probability is found to be significantly stage-dependent and is lowest for immature animals. Allowing, additionally, for individual heterogeneity in sampling probability results in a very substantial improvement in model fit but has only a small effect on estimates of population size and demographic parameters. There is found to be significant inter-annual variability in both calving rates and “calf” survival rates, but no evidence of net trend in these parameters. For these data, “calf” survival represents survival from the first summer season (~6-8mo age) to the second summer season (~18-20 mo age). The best fit to the data is obtained by introducing a 2-year time lag in the correlation between calving rates and calf survival rates: *i.e.* a low (high) calf survival rate from year t to year $t+1$ tends to be associated with a low (high) calving rate in year $t+2$. There is little evidence for immigration: the level of immigration is estimated to be zero or negligible in recent years, but immigration early in the period cannot be excluded. Estimates of key population parameters from the best-fitting model are 0.975 (± 0.005) for the non-calf annual survival rate; 0.67 (± 0.07) for the average calf survival rate; 11.5 yr (± 1.1 yr) for the mean age at first parturition. 3.3% *per annum* ($\pm 0.5\%$) for the estimated realised average annual rate of population increase over the last 10 years (2002-2012); 140 (± 6) whales for the 1+ (non-calf) population size in 2012 and 36 (± 2) mature females in 2012. These estimates are insensitive to the choice of model. Forward projections of the population model to 2020, assuming no additional mortality or deterioration in environmental conditions, indicate a high probability ($>95\%$) of continued population increase. The results suggest that the Sakhalin feeding aggregation has been demographically self-contained, at least in recent years, in the sense that the only new recruits are calves born to mothers within the group, even though tagging results show that Sakhalin gray whales migrate to common gray whale breeding grounds in the eastern North Pacific.

1. INTRODUCTION

Gray whales (*Eschrichtius robustus*) have been regularly reported during the summer months (June to October) off northeastern Sakhalin Island since the early 1980's (Brownell *et al.* 1997) and have been intensively studied there since 1997 (Burdin *et al.* 2013). Initially the Sakhalin gray whales were assumed to be a remnant of the western gray whale population formerly hunted in Korean and southern Japanese waters until the 1960s. The timing of gray whales catches in the Korean grounds was suggestive of a migration to a wintering ground in Asian waters. However, a whale (“Flex”) tagged off Sakhalin in 2010 was followed to the waters of Oregon State, USA (Mate *et al.* 2011). Further tagging results and photo-id and genetic matches have shown that (at least some of) the Sakhalin gray whales migrate to breeding grounds in Mexican waters along with the bulk of the eastern North Pacific gray whale population (Weller *et al.* 2012). Whether a gray whale breeding ground in Asian waters still exists, and if so, whether any whales seen off Sakhalin migrate to an Asian

breeding ground is, at the time of writing, unknown but cannot be excluded on current evidence (Weller and Brownell, 2012).

An ongoing annual summer photo-identification study was initiated in 1995 as part of the Marine Mammal Project under Area V: Protection of Nature and the Organization of Reserves within the Russia-U.S. Agreement on Cooperation in the Field of Environmental Protection. This study has been continued since 2009 by the Kamchatka Branch of the Pacific Institute of Geography (Burdin *et al.* 2013). The photo-identification data (supplemented by genetic sex determinations from biopsies) from this study are used in this paper to conduct a population assessment.

A parallel vessel-based photo-id study sponsored by the petroleum industry has been conducted off Sakhalin since 2002 by the Institute of Marine Biology, Vladivostok (Tyurneva *et al.* 2013). Individuals identified off Sakhalin in both these studies have also been identified off eastern Kamchatka in summer (Tyurneva *et al.* 2013) and in Mexican waters in winter (Weller *et al.* 2012; Urbán *et al.* 2012).

On the assumption that Sakhalin whales constituted a separate population, Reeves *et al.* (2005) conducted a population assessment using photo-id data collected through 2003. This assessment was subsequently updated by Cooke *et al.* (2006 and 2008).

The model developed by Reeves *et al.* was an individually-based model in which each individual in each year is in a given stage (such as calves, immature whales of various ages, adult males, calving females and resting females). The transition probabilities between stages, and their variation over time, are modelled and estimated. The model was fitted to the photo-id data in an annual capture-recapture framework, where capture (i.e. photo-sampling) probabilities vary over time and between stages. It was used to estimate population size, survival, reproductive and population growth rates, and to project the population forward under various scenarios.

For this analysis, the model has been developed further to incorporate the following additional processes:

- individual heterogeneity in sampling probability (in addition to the stage-specific differences)
- time lags in the effects of environmental variability on population parameters;
- an explicit age-specific maturation ogive (to improve estimation of the mean age at first reproduction) ;
- immigration (i.e. the possibility for new whales to enter the aggregation in addition to those born to mothers within the group)

The latter issue is potentially important for the question of whether the Sakhalin whales constitute a demographically self-contained group and whether they should be managed as a unit, despite sharing breeding grounds with other gray whales.

2. MATERIAL AND METHODS

2.1. Photoidentification and sex-determination data

Photo-identification data have been collected in the summer season (June to September) in the Piltun area of north-eastern Sakhalin by the joint Russia-US programme from 1997 to the present, with some data also collected in 1994 and 1995. Since 2009 the programme has been continued by the Kamchatka branch of the Pacific Geography Institute (Burdin *et al.* 2013). Data from the seasons up to and including 2011 were available for this analysis. A total of 205 distinct individual whales had been catalogued as of 2011. The catalogue has been published and annually updated since 2006 (Weller *et al.* 2006).

Calves of the year (age approx 6-9 months, assuming births occur during December-January) were identified as such using the criteria specified by Bradford (2009). Associations between mothers and calves were recorded. Many of the catalogued whales have also been biopsied, enabling their sex to be determined genetically, and for apparent mother-calf relationships to be cross-checked genetically.

The following information on each identified whale was used for this analysis:

- the year first seen, and whether first seen as an accompanied calf, as an unaccompanied calf, or as a non-calf;
- the subsequent years in which the individual was seen, and the subset of years in which it was seen with a calf;
- sex, where known (determined genetically from biopsies)

Genetic sex determinations from biopsy were available for 141 whales (58 females and 83 males) for this analysis, including all but one of the whales seen with an accompanying calf. Further biopsy samples are awaiting analysis.

A total of 101 calves have been identified. Of these calves, 87 could be linked to an identified mother (in all but one case by observed association, the remaining case genetically). Of the 101 observed calves, 63 have been sexed genetically: 22 female and 41 male. Of these 63 calves, 54 were biopsied in the year that they were a calf : 18 female and 36 male.

While the observed sex ratio of non-calves may be subject to an availability bias, we assume that calves of each sex are equally available and that the sex ratio of calves, when sampled as calves, reflects the true sex ratio amongst calves. The sex ratio of these 54 calves is significantly biased towards males ($\chi^2 = 6.0$; d.f. = 1; $p < 0.01$). Therefore, we included the sex ratio of calves as a parameter in the model, instead of assuming that was 50:50.

Twenty-nine (29) individual females, have been observed with a calf. Two of these had originally been observed as calves and are hence of known age (age 9 and 10 respectively).

A total of 58 apparent inter-birth intervals have been observed, including 31 two-year intervals, 16 three-year intervals, 5 four-year intervals, and 6 longer intervals. Because no 1-year intervals were observed, we assume that all 2- and 3-year intervals were real inter-calf intervals, but that intervals of 4-years or longer may in some cases have spanned missed calvings.

The parallel vessel-based photo-id programme has been conducted off Sakhalin since 2002 by the Institute of Marine Biology had, of 2011, also identified 205 distinct individuals. A comparison of the two photo-id catalogues showed that 187 whales were common to both catalogues (IUCN, 2013). These data were not used in this analysis (but see further comments in the Discussion).

2.2. Population model

The population model is an individually-based stage-structured population model with stages and their transitions shown in Fig. 1. The model is discrete time with a time step of one year.

The breeding females are divided into three stages: pregnant, lactating, and resting. Females are assumed not to be simultaneously pregnant and lactating. A female can become pregnant immediately following lactation, resulting in a 2-year calving interval (the minimum observed). Optionally, a female can enter the resting phase for one or more years, resulting in a 3-year or longer calving interval.

These stages are to be interpreted schematically rather than literally. “Lactating” females include all females that lactated in the given year: some may have already weaned their calf if encountered later in the season. The “Pregnant” stage includes only those whales which will actually give birth and bring a live calf to the feeding ground the following summer. Pregnancies which fail or where the calf is lost before arrival on the summer feeding grounds cannot be separately identified by the data used and are subsumed into the “Resting” stage. The age at first pregnancy is assumed to range from 7 to 12 years (i.e. first calving from 8 to 12 years of age).

Males are arbitrarily placed into an “adult” class from age 8. The adult males play no explicit role in this model. There are assumed to be more than enough males available for mating, and furthermore the females are under no obligation to choose a mate from within the Sakhalin population. The only reason for separating adult from immature males in the model is to allow the model to account for the differential availability of immature and adult animals in the study area.

The basic version of the model contains a total of 24 living stages: calves (2 stages); immature males (7 stages); adult males (1 stage); immature females (11 stages); and adult females (3 stages). In addition, there is an unborn stage and a dead stage, making a total of 26 stages.

Where there are multiple options for transition to the next stage, these are modelled as successive binary choices, starting with the choice survive/not survive. The probability p for the first option in each binary choice is modelled as a logit function $p = e^z / (1 + e^z)$ of a linear predictor z . The model for z contains, in each case, an intercept term plus zero or more optional factors as indicated below. The probability for the second option in the binary choice is $1 - p$.

Transition to the dead stage (not shown in Fig. 1.) represents mortality. If any permanent emigration occurs, this would be subsumed into the mortality rate as far as this model is concerned. There is no explicit transition probability from the unborn stage to a calf stage. Births are treated as a life choice of the mother, not of the calf. For each birth, the mother selects an unborn animal randomly from an inexhaustible pool of unborns. Sex is assigned randomly at birth: the sex ratio at birth is a parameter of the model.

Individual (as opposed to stage-related) heterogeneity in sampling probability is modelled by assigning each individual with equal probability to one of three availability strata: low, medium and high. The sampling probability is allowed to be stratum-dependent. While each individual has an equal prior probability of belonging to each stratum, the posterior probabilities that a given individual belongs to each of the three strata will depend on the data. When such heterogeneity is included, there are 3×24 live stages, to make a total of 74 stages.

The model parameters and the factors on which they depend (or may depend) are summarised in Table 1.

Table 1. Models used for each parameter

		Core terms in linear model	Optional terms
<i>Transition probabilities</i>			
<i>From</i>	<i>To</i>		
Female aged a ($j = 6, \dots, 11$)	Pregnant	intercept; age (linear)	year
Lactating	Pregnant	intercept	year
Resting	Pregnant	intercept	year
<i>Survival probabilities</i>			
Calves		intercept	year
Others		intercept	year
<i>Other parameters</i>			
Sex ratio at birth	female proportion	intercept	stage group; availability class
Sampling probability		intercept; year	
Initial population size		intercept	
Immigration		intercept; year (linear)	
Sex ratio of immigrants	female proportion	intercept	
Weaned probability		intercept	

The year effect in each case is modelled as a series of annual random effects, plus (optionally) a linear trend.

The transition probabilities to the pregnant state are referred to loosely as calving probabilities, because in this model the pregnant state includes only successful pregnancies

Immigration is optionally allowed. An “immigrant” is defined as an individual whose mother was not a member of the population. The number of immigrants is assumed to follow a Poisson distribution with an exponential trend. Immigrants are assumed to be immature animals. The sex ratio of immigrants is a parameter of the model.

To complete the model, we require a means to specify the initial numbers in each stage at the start of the modelled period. To reduce the sensitivity of the results to the initial conditions, we start the model in 1980, well before the first data in 1994. We take the 1980 population size (total across live stages) as a parameter to be estimated, while the stage distribution in 1980 is drawn randomly with replacement from the stable stage distribution implied by the deterministic version of the model (with all random effects set to zero). Sensitivity tests showed that taking the initial year further back had negligible effect on the results.

2.3. Sampling model

An animal is ‘sampled’ in a given year when it is photographed in that year, and the photographs have been processed and assigned to an existing known whale in the catalogue, or to a new whale which is added to the catalogue.

The sampling probability includes a year effect (to account for varying research effort over time), and, optionally, a stage effect and an “availability stratum” effect.

For the stage effect, the stages are grouped as follows: calves; immature animals; ‘adult’ males; lactating females; pregnant and resting females.

To allow for the fact that some lactating females of the year have already separated from their calf when encountered, a ‘weaned probability’ parameter, w , is included in the model to represent that probability that mother and calf have separated before they are first encountered in the season. Letting p_L and p_C denote the sampling probabilities for lactating females and unaccompanied calves in a given year and stratum: the probability that a lactating whale and its calf will be seen together is: wp_L ; the probability that a calf will be seen alone is wp_C ; and the total probability that the calf will be seen in that year is: $(1-w)p_L + wp_C$.

The data consist of the matrix of sampling histories H , where an entry H_{it} denotes the sampling result for history i in year t . The sampling result of each history in each year takes one of the following five values: (0) not seen; (1) mother with calf; (2) accompanied calf; (3) unaccompanied calf; (4) other whale. Each sighting history has an associated sex datum that takes one of three values: male; female; or unknown. The index i runs from 0 through n , where 0 denotes the null history (animals which have never been seen, and which remain unknown) and observed histories 1 through n where n is the number of individuals in the photo-id catalogue. The index t runs across all years for which there are data (they are not necessarily consecutive).

The sampling model enables us to calculate the array $P(j,t,k)$ of probabilities that an animal in stage j in year t will have sampling result k .

2.4. Fitting the model

2.4.1 Maximum likelihood estimation

Each individual in the population (whether observed or not) has a (hypothetical) biography, which consists of the true stage of the individual in each year. In the matrix of biographies, the entry B_{it} refers to the stage of biography i in year t .

Using the array P from sampling model of the previous section, we calculate the matrix Q defined by:

$$Q_{il} = \prod_t P(B_{it}, t, H_{lt})$$

where each entry contains the probability that an individual with biography i gets a sampling history l . The index i ranges over the set \mathcal{B} of all possible biographies.

Given an expression for b_i , the prior probability (given the population model and parameters, prior to the fit to the data) for biography i , the likelihood of sighting history l is given by:

$$L_l = \sum_{i \in \mathcal{B}} b_i Q_{il}$$

We avoid calculating explicitly the probability of all possible biographies (there would be too many), and instead use the standard forward-backwards algorithm for Markovian state space models. This obtains mathematically the same result by sequentially evaluating the posterior probability distribution of the stage probability distribution for each individual in each year.

The overall likelihood of the data is customarily taken as the product of the likelihoods of the individual histories. Strictly speaking, this is not a correct procedure because births are occurring and some known individuals were born from other known individuals. Thus, even if the sampling of each individual is independent, the production of each individual is not. Any potential biases arising from ignoring this dependence are overcome in the sampling of the Bayesian posterior distribution as described in the next section.

The overall log likelihood is taken as the sum of the sampling histories log likelihood and the residual log likelihood of the random effects, if any. The AIC (Akaike Information Criterion) is used for model comparison and selection. The effective number of parameters for the purpose of calculating the AIC is fractional when random effects are included.

Estimation standard errors for basic model parameters were determined from the variance-covariance matrix obtained by inverting the Hessian matrix at the point of best fit. Estimation standard errors for functions of model parameters were estimated using the linear approximation:

$$\text{var}(f(\mathbf{p})) \approx \left(\frac{\partial f}{\partial \mathbf{p}} \right) \mathbf{V}(\mathbf{p}) \left(\frac{\partial f}{\partial \mathbf{p}} \right)^T$$

where \mathbf{p} is the vector of basic parameters and \mathbf{V} is its variance-covariance matrix. For parameters subject to annual random effects, the process variance (sigma) of functions of the parameter is estimated using the linear approximation:

$$\hat{\sigma}[f(p)] \approx |df/dp| \hat{\sigma}_p \quad \text{where } \sigma_p \text{ is the process variance (sigma) of the parameter } p.$$

2.4.2. Estimation of the Bayesian posterior distribution

Once a model has been selected using AIC, the Bayesian posterior distribution of simulations of the population can be sampled. For this purpose, the population model is simulated explicitly on an individual basis, including all births and deaths. The dependence between individual biographies mentioned above is thereby automatically accounted for. The maximum likelihood estimates, obtained as described in the previous section, are used here only as an aid to efficient sampling of the posterior: the likelihood of each simulation is calculated separately. Each simulation was started in 1980 and run forward to 2020. Percentiles of key population parameters were generated.

For all parameters representing probabilities (survival and transition probabilities, and sex ratios), the prior distribution was taken to be uniform $U(0,1)$. For all random effect variances, the prior distribution of $\log \sigma^2$ was taken to be normal $N(0,1)$.

Prior distributions for positive quantities (initial population size and immigration rate) were taken as uniform on a log scale (improper priors). Priors for trends were taken as normal $N(0,1)$ after scaling to the length of the data series. Trends in parameters were not extrapolated beyond the data series.

3. Results

Table 2 shows the results of fitting various models in a sequential process, along with estimates of selected parameters of interest. The estimates of population parameters shown in Table 2 are fairly insensitive to the choice of model, especially once heterogeneity has been accounted for.

Case 1 represents the minimal reasonable model. The inclusion of stage-specific availability factors (case 2) substantially improves the fit ($\Delta AIC = -15.6$) and was therefore retained in all subsequent cases. Inclusion of individual heterogeneity in availability (case 3) further substantially improved the fit ($\Delta AIC = -61.0$) and was retained in all subsequent cases.

Allowing variability in the calving rate (case 4) results in a further significant improvement in fit ($\Delta AIC = 10.1$) and is retained in subsequent cases. Allowing, additionally, for independent variability in “calf” survival rate (case 5) produces only a modest improvement in fit ($\Delta AIC = -2.7$). Having the two parameters vary in unison (through sharing the same sequence of annual random effects) (case 6) substantially worsens the fit relative to either keeping calf mortality constant or allowing it to vary independently ($\Delta AIC = +7.3$ and $+10.0$ respectively). However, the fit is considerably improved if we introduce a time lag in the correlation between calving rates and calf survival rate. The best-fitting time lag is 2 years (case 8) ($\Delta AIC = -16.4$ relative to no time lag (case 6), or -6.4 relative to no correlation (case 5)). Other time lags fit less well than 2yr lag, although a 3yr lag is less strongly rejected ($\Delta AIC = +2.8$ relative to a 2yr lag) than other lags. Even if we adjust the AIC by $+2$ to allow for the fact that we are in effect treating the time lag as an additional parameter, the results still strongly reject both the unison and uncorrelated models relative to a 2yr lag. The 2yr lag was retained in subsequent fits. Allowing, additionally, an overall trend in the annual effects (case 11) does not improve the fit ($\Delta AIC = +0.1$).

Allowing for immigration (case 12) produced a slight improvement in fit ($\Delta AIC = -1.9$). However the estimates of immigration by year (Fig. 2b) show that immigration has been zero or negligible in recent years. For the earlier years, the data are consistent with immigration ranging from zero to a level comparable to the number of calves. It is in the nature of photo-id data that they cannot exclude immigration in the early years of a study, because new whales of all ages are encountered in the early years with no means to determine their origin. Because the results indicate that immigration has been zero or negligible at least over the most recent 10 years, and the evidence for earlier immigration is weak, we select both case 8 (no immigration) and case 12 (with immigration) into the shortlist of preferred models.

Estimates of further parameters of interest with their standard errors, and where applicable, their process standard deviations are listed in Table 3 for the two preferred models. The results show that the estimation errors are less than the process standard deviations where the latter can be estimated: the remaining uncertainty is therefore dominated by the latter variance.

Figs 2a-b shows the estimated historical time trends from 1994 to 2012 of four population components of interest: calves; immigrants (where applicable); mature females and the total age 1+ population (*i.e.* the non-calf population, including mature females).

Figs 3a-b show various percentiles of the population trajectories of the 1+ and mature female population size from a sample of 1,000 simulations of the Bayesian posterior distribution of population simulations, projected forward to 2020, for the case (a) without immigration and (b) with immigration. Although there is estimated to be no immigration in recent times, allowing for the possibility of earlier immigration slightly increases the uncertainty in future projections, because it reduces the precision of estimates of population parameters, and ascribes some of the strong apparent growth in the early years to immigration. However in both cases there is a high ($>95\%$) estimated probability of continued population increase forward to 2020.

4. Discussion

The results show that there is substantial heterogeneity in detection probability, both stage-related and individual-related, but it has a relatively minor impact on parameter estimates. There is compelling evidence of annual variability in both pregnancy and calf survival rates, and that these are correlated with a time lag of 2 years. The evidence is against any significant immigration in recent years, but is neutral to, or weakly in favour of, some immigration in earlier years. The estimate of “adult” (non-calf) annual survival rate at $0.975 (\pm 0.005)$ implies a mortality rate of $0.025 (\pm 0.005)$. Since this parameter would reflect any permanent immigration in addition to actual mortality, its value implies that the extent of emigration, if any, is small.

The finding that variations in “calf” survival rate (from the first to the second summer season, *i.e.* between about age 8-18 months) and calving rates are correlated with a 2-yr time lag may throw light on the question of when in the reproductive process the impacts of external factors are most strongly felt. The 2yr lag implies that when calf survival from summer 20xx

to $20xx+1$ is low, calf production, as recorded in summer $20xx+2$ tends also to be low. It may be that if feeding conditions are poor in summer $20xx$, calves of the year have trouble surviving to $20xx+1$, and also that the mother switches from a 2yr to a 3yr breeding cycle, so that her next calf is “born” in $20xx+3$ instead of in $20xx+2$. (*Note: we define the birth year as the year of the January: a calf born in December $20xx$ is assigned a birth year of $20xx+1$*). Analysis of the correlation between these parameters and time series of ecological factors known to affect gray whale survival and/or reproduction could throw further light on the question.

The estimates of small or zero immigration levels in recent years suggest that the Sakhalin gray whale population is demographically self-contained, in the sense that new entrants are almost exclusively calves of mothers from within the population.

However, the population is known, as a result of tagging, photo-identification matches and genetic matches, to share breeding grounds in the eastern North Pacific with other gray whales (Weller et al. 2012). These findings are not mutually inconsistent if there is a high degree of maternally directed feeding site fidelity. Such fidelity would also be broadly consistent with genetic information which shows a lower level of haplotypic diversity among Sakhalin whales (with 95 out of 142 animals belonging to just 2 haplotypes) than in North Pacific gray whales as a whole (Lang et al. 2011). The Sakhalin population is estimated in this assessment to have contained only 30 ± 4 age 1+ females in 1994. Projecting back the observed growth rates to the end of commercial whaling for gray whales in the mid-1960s would imply a possible bottleneck population of less than 10 females. The presence of greater haplotypic diversity among males (Lang et al. 2011) could suggest that, if immigration has occurred, it was predominantly of males.

Given its apparent demographic discreteness, the Sakhalin population may continue to merit treatment as a management unit or “unit to conserve” as defined by the IWC Subcommittee on Stock Definition (Jackson and Pampouille, 2012). Given the current estimate of 35 breeding females, the Sakhalin population would merit continued listing as Critically Endangered on the IUCN Red List under criterion D in conjunction with Definition 3 (IUCN, 2001). It would not appear to qualify as a subpopulation under the 2001 criteria if there is male-mediated genetic exchange with other gray whales, but Guideline 4.2 (IUCN 2013b) suggests that it could nevertheless qualify as a subpopulation if there is found to be substantial fidelity to both feeding and breeding grounds.

For completeness we note here that an analysis of the data from the parallel photo-id team of the Vladivostok Institute of Marine Biology was presented to the May 2013 meeting of the Western Gray Whale Advisory Panel, using a slightly earlier version of the model used here (IUCN, 2013c *in prep.*). This resulted in a less optimistic population projection, with a high probability of future decline. Until the reasons for the apparent difference in results from the two datasets have been elucidated, this difference should be treated as a potential caveat to the assessment results presented in this paper.

ACKNOWLEDGEMENTS

We acknowledge the numerous field scientists who have worked on the project in past and recent years, including many students and volunteers, who helped to produce the valuable dataset analysed in this paper. The International Fund for Animal Welfare (IFAW) and the Ocean Park Conservation Foundation Hong Kong have provided regular grants in support of this research.

ABSTRACT

The population assessment of gray whales *Eschrichtius robustus* feeding off Sakhalin and Kamchatka is updated, using a population model that allows for multiple feeding and breeding areas. The model is fit to photo-id data collected of Sakhalin during 1995-2015 (Burdin *et al.* 2015), tracking of whales from Sakhalin to the eastern North Pacific (Mate *et al.* 2015), photo-id matches of gray whales between the Sakhalin and Mexico catalogues (Urbán *et al.* 2013) and reported photo-id results from Kamchatka collected during 2004-12 (Yakovlev *et al.* 2013). The results show that the Sakhalin and Kamchatka feeding populations have been increasing at 2-5% per year over the 10 or 20 years to 2015. The number of non-calf whales in 2016 is estimated to be 320–410, of which 130–170 are predominantly Sakhalin-feeding whales or 180–220 are whales that feed at least occasionally off Sakhalin. A test of the population model output against the results of a paternity analysis by Lang (2010) just rejects the hypothesis of genetic closure of the Sakhalin feeding population ($p < 0.05$) but does not reject the hypothesis of genetic closure of the Sakhalin and Kamchatka feeding populations combined.

Of the predominantly Sakhalin-feeding whales, an estimated 0-50 belong to a possible relict western North Pacific breeding population (which may or may not be genetically closed). Using the IUCN Red List criteria, the Sakhalin and Kamchatka populations, if assessed as a subpopulation, either separately or together, would be classified as Endangered, on the basis of there being between 50 and 250 mature individuals (i.e. ~100-500 individuals when juveniles but not calves are included). If the relict western North Pacific breeding population were assessed as a subpopulation, it would be classified as Critically Endangered, on the basis of there being less than 50 mature individuals.

1. INTRODUCTION

Gray whales (*Eschrichtius robustus*) have been regularly reported during the summer months (June to October) off northeastern Sakhalin Island since the early 1980's (Brownell *et al.* 1997) and have been intensively studied there every year since 1995 (Burdin *et al.* 2015). Initially the Sakhalin gray whales were assumed to be a remnant of the western gray whale population formerly hunted in Korean and southern Japanese waters until the 1960s. The timing of gray whales catches in the Korean grounds was suggestive of a migration to a wintering ground in Asian waters (Kato and Kasuya 2002). However, tagging results and photo-id and genetic matches have shown that at least some of the Sakhalin gray whales migrate to breeding grounds in Mexican waters along with the bulk of the eastern North Pacific gray whale population (Mate *et al.* 2015; Weller *et al.* 2012). Many individuals observed off SE Kamchatka during 2006-11 have been matched with those off Sakhalin (Yakovlev *et al.* 2013, 2014) and some have been matched with whales seen in Mexico.

In an analysis of the data on movement between Sakhalin and the eastern North Pacific, including data from satellite tagging of individuals and photo-id matches between Sakhalin and Mexico, Cooke (2016)

³Protected Species Division, Pacific Islands Fisheries Science Center, National Marine Fisheries Service, National Oceanic and Atmospheric Administration, Honolulu, HI, USA

⁴Kamchatka Branch of Pacific Institute of Geography, Russian Academy of Sciences, Far East Division, Petropavlovsk, Kamchatka 683000, Russia

concluded that 30-100% of Sakhalin whales migrate in winter to the eastern North Pacific. Thus, those data alone could not confirm or exclude the possibility of a western breeding migration.

However, sightings of Sakhalin-matched gray whale of the Pacific coast of Japan in spring are suggestive of the possibility that at least some of the gray whales seen off Sakhalin undertake a western North Pacific migration that may lead to a western North Pacific breeding area whose location is unknown (Weller *et al.* 2016).

On the assumption that Sakhalin whales constituted a separate population, Cooke *et al.* (2016), using photo-id and biopsy data from the Russian Gray Whale Project (Burdin *et al.* 2015), estimated that the feeding aggregation off Sakhalin contained about 175 non-calf individuals by 2016 (although not all of these would be present every year), and had been growing at 2-4% per year.

In this note, the previous assessment is expanded to include additional information, including satellite tag data (Mate *et al.*, 2015), photo-id data collected off Kamchatka, as reported by Yakovlev *et al.* (2013, 2014), and matches between Sakhalin and Mexico (Urbán *et al.*, 2012). The results of the assessment are also compared with the results of a paternity analysis by Lang (2010), to test the hypothesis of genetic closure of the separate or combined feeding populations.

2. MATERIAL AND METHODS

2.1. Data

2.1.1 Photoidentification and sex-determination data

Photo-identification data from the Russian Gray Whale Project were available for each summer season (June to September) from the Piltun area of north-eastern Sakhalin from 1997 to 2015, with some data also collected in 1994 and 1995. A total of 248 distinct individual whales had been catalogued as of 2015. The catalogue has been published and annually updated since 2006 (Weller *et al.* 2006). Yakovlev *et al.* (2012, 2013) list a total of 155 distinct whales identified off SE Kamchatka, of which 85 were matched with whales seen off Sakhalin.

Genetic sex determinations from biopsy were available for 179 whales (89 males and 67 females) for this analysis. A total of 132 calves have been identified. Of these calves, 117 could be linked to an identified mother (in all but one case by observed association, the remaining case genetically). Of the 132 observed calves, 76 have been sexed genetically: 30 female and 46 male.

2.1.2 Tracking and long-range matching data

The three records of known whales successfully satellite-tracked from Sakhalin to the eastern North Pacific (Mate *et al.* 2015) were used.

17 matches between the Sakhalin catalogues and the San Ignacio lagoon catalogue for the years 2006-12 were found (Urbán *et al.* 2013). Of these, 15 were known to be alive as of 2011, of which 13 were known to be born in 2000 or earlier. Because of the low rate of matching of other whales, only whales satisfying these age criteria (born before 2000) and survival not satisfying these age and survival criteria (alive in 2011) were treated as candidates for matching with Mexico.

2.1.3 Paternity

A paternity analysis by Lang (2010) used genotypes collected from 57 mother-calf pairs up to 2007 and compared these with the genotypes of up to 83 males (of which some could be excluded as being too young to sire a calf) to establish paternity. Depending on the criteria used to determine paternity, 26-30 paternities were assigned to known genotyped animals, comprising 17-18 distinct fathers. These data were not used in the model of this paper, because paternity does not directly affect population dynamics, but the estimated population trajectories were compared with the results of Lang's paternity analysis to test the hypothesis of genetic closure.

2.2. Model structure

2.2.1 Basic (single-stock) population model

The core population model is as used by Cooke *et al.* (2016). It is an individually-based stage-structured population model, working in discrete time with a time step of one year.

The reproductive females are divided into three stages: pregnant, lactating, and resting. Females are assumed not to be simultaneously pregnant and lactating. A female can become pregnant immediately following lactation, resulting in a 2-year calving interval (the minimum observed). Optionally, a female can enter the resting phase for one or more years, resulting in a 3-year or longer calving interval. The minimum age at first (successful) pregnancy is 7 years; thereafter, the probability of becoming pregnant is assumed to increase as a logistic function of age, reaching a plateau at age 12.

Immigration is optionally allowed. An “immigrant” is defined as an individual whose mother was not a member of the population. A random number of immigrants enter the population independently each year. Immigrants are assumed to be immature animals. The sex ratio of immigrants is a parameter of the model.

The basic version of the model contains a total of 24 living stages: calves (2 stages: male and female); immature and maturing males (11 stages); adult males (1 stage); immature and maturing females (11 stages); and adult females (3 stages). In addition, there is an unborn stage, a “freshly dead” stage (where a carcass might be found and identified), and a “dead and buried” stage (no further possibility of being found), making a total of 27 stages in the core set.

2.2.2 Multi-stock population model

The main new feature of this analysis is the introduction of multiple feeding and breeding populations.

The “Sakhalin” feeding population is defined to consist of the whales that feed predominantly off Sakhalin but may also be seen off Kamchatka, and possibly in other areas. The “Kamchatka” feeding population is defined as whales that feed predominantly off SE Kamchatka but may also be seen off Sakhalin or in other areas. The two feeding populations are modelled by allowing individuals to have differing probabilities of being encountered in the two areas. These probabilities are determined by the parameters of the sampling model (see below) that are estimated by the data. Many individuals have been seen in both feeding areas, so the two feeding populations are not completely separate. The degree of separation is estimated by the model.

Two breeding populations are assumed: western North Pacific (WNP) and an eastern North Pacific (ENP). The Sakhalin feeding area is assumed to contain a mix of ENP and WNP whales, while the Kamchatka feeding area is assumed to contain only ENP whales. The population is divided into three feeding/breeding subpopulations: (1) WNP breeding population, feeding off Sakhalin; (2) ENP breeders that feed predominantly off Sakhalin; and (3) ENP breeders that feed predominantly off Kamchatka. In each year, whales in each of the three subpopulations can be in any of the above 27 stages, which results in 81 possible states for each whale. The relative abundance of ENP and WNP whales, and of Sakhalin and Kamchatka feeders, are parameters of the model.

The meaning of “predominantly” is not fixed in advance. The sampling probabilities of whales in each group in each area are parameters of the model, as are the relative numbers of whales in each group. Individuals are not assigned definitively to either group, but the posterior likelihood of each whale belonging to each group depends in its sampling history, and is estimated together with all the parameters of the model.

The possibility that some Kamchatka-feeding whales belong to the WNP breeding population was not considered in this analysis, although in principle this would be possible.

2.2.3 Sampling model

2.2.3.1 Photo-id sampling

An animal is ‘sampled’ in a given year when it is photographed in that year, and the photographs have been processed and assigned to an existing known whale in the catalogue, or to a new whale which is added to the catalogue. A lactating (or post-lactation) female may be sampled alone or with its calf; likewise, a calf may be sampled alone or with its mother. The probability that a mother-calf pair has separated before it is recorded is a parameter of the model.

An animal may be sampled off Sakhalin, off Kamchatka or off Mexico. The sampling probabilities off Sakhalin and Kamchatka are parameters of the model allowed to vary by year, location, stage and individual. Individual (as opposed to stage-related) heterogeneity in sampling probability is modelled by assigning each individual with equal probability to one of a number of availability strata. The sampling probability may also depend on various interactions between the above factors, as determined by the model-selection process.

The required number of strata is determined by the model-selection process (see below). When there are m strata, each whale can be in a total of $81m$ different states.

The sampling probability for Mexico was estimated externally by Cooke (2016). The sampling probability of an “adult” whale (i.e. one meeting the age criteria defined above) in the Mexican breeding grounds was estimated at 0.054 per year, or 0.32 in total for the years 2006-12 combined. There may be scope for refining this estimate.

2.2.3.2 Satellite tracking

We assume that the tracking success probability is independent of breeding location. That is, we assume that if the three whales tracked from Sakhalin to the eastern North Pacific had instead migrated south in the western North Pacific, they would have been tracked there too. With this assumption, we condition on the actual number and identity of whales successfully tracked, and do not need to model the tracking probability.

This approach implies a qualitative difference in the evidentiary value of satellite-tracked animals versus long-range photo-id matches: for photo-id, the relevant sampling probability must be known or estimated, but this is not necessary for tracked animals.

2.3. Likelihood, model fitting and model selection

Table 1 lists the factors/terms included in each of the alternative models fitted. Each model was first fitted by maximum likelihood (REML) to produce estimates of model parameters and of the population trajectory. The factors/terms to include in the model were selected using the AIC criterion, to identify a preferred model. The Bayesian posterior distribution of the population trajectory was sampled for the preferred model. Full details of the model and fitting procedure are given by Cooke *et al.* (2016).

In summary, each individual has a range of potential biographies, each of which consist of a time series of its putative true state in each year. Some aspects of the state are assumed to remain constant over its lifetime, such as sex and membership of a feeding and/or breeding group. Other aspects, such as age, reproductive status, live vs. dead, change from year to year according to the transition probabilities.

In addition, each individual has an observed history. The observed history may be null for some individuals (i.e. individuals that exist but have not yet been sampled). The likelihood is calculated by comparing each putative biography with the observed history. Some aspects of the comparison are probabilistic. For example, whether an individual is sampled in a given area in a given year: the likelihood depends on the relevant sampling probabilities. Other aspects, such as sex or membership of a breeding stock, are of an either/or nature. For example, if a whale is tracked to the eastern North Pacific, all its potential biographies that involve it being a western breeder get assigned a zero likelihood. Likewise, if a whale is determined through genetic sampling to be male, all the potential biographies that involve it being female get assigned a zero likelihood.

2.4. Testing genetic closure

No paternity data were used in the model-fitting process, because paternity is assumed not to affect population dynamics. However, the output of the preferred model was used to compute the expected distribution of number of identified paternities under the assumption that all paternities were from within the population (genetic closure) and there is random mating. This was compared with the observed number of identified paternities in order to test the genetic closure hypothesis. A range of 7-12 years was assumed for the age of effective reproductive maturity for males.

Two genetic closure hypotheses were tested: (i) paternities are within each feeding population; (ii) paternities are not necessarily within each feeding population, but are within the two feeding populations combined.

For each hypothesis, the comparison was performed by generating a random sample of 500 realizations from the posterior distribution of the individually-based population trajectories. In each realization, the father of each calf included in Lang's paternity analysis was selected randomly from the pool of potential fathers under the given hypothesis (i.e. reproductively mature males alive in the given population in the year of conception of the calf – assumed to be 1 year before the birth year). The size of the subset of these assigned fathers that were included in the genetic sample used in Lang's analysis was recorded for each realization. This produces a posterior distribution for the predicted number of known paternities, which can be compared with the observed number.

3. RESULTS

3.1. Model selection

Table 1 shows the results of fitting various models sequentially. Case A represents the minimal reasonable model, because the sampling probability is a function of the effort expended in each area by year. The inclusion of separate feeding populations differentially sampled in the two areas (case B) improves the fit very substantially ($\Delta AIC = -701$) and shows that the two areas (Sakhalin and Kamchatka) cannot be treated as an homogenous unit. Including stage-specific availability factors (case C) improves the fit ($\Delta AIC = -8.3$) and this factor was retained. Allowing for interaction between location and stage (case D) improves the fit substantially ($\Delta AIC = -147$). Allowing for individual heterogeneity in the sampling probability by location and population using 5 strata (case E) substantially improved the fit further ($\Delta AIC = -151$). Allowing for the pregnancy rate to vary by year (case F) also improved the fit ($\Delta AIC = -18.7$), and this factor was retained. Including annual variation in calf mortality (case G) worsened the fit ($\Delta AIC > 0$); this factor was not retained. Reducing (case H) or increasing (case I) the number of strata led to a worse fit in each case ($\Delta AIC > 0$). The original choice of 5 strata for modelling individual heterogeneity was therefore retained. Allowing for immigration (whales born to mothers outside the population) into the two populations (case J) worsened the fit ($\Delta AIC > 0$).

Table 1. Results of fitting various models in a sequential process.

Case	Model	AIC
A	Sampling:Location.Year	5 027.4
B	A + Sampling:Location.Population	4 326.1
C	B + Sampling:Stage	4 317.9
D	C + Sampling:Location.Population.Stage	4 170.8
E	D + Sampling:Location.Population.Stratum(5)	4 019.9
F	E + Pregnancy:Year	4 001.2
G	F + CalfSurvival:Year	4 029.7
H	F with 3 strata	4 019.4
I	F with 8 strata	4 044.6
J	F + Immigration:Population	4 020.3

The preferred model was, therefore, case F, where the sampling probability depends on interactions between location, feeding population and stage and between location, feeding population and stratum, and there is annual variability in pregnancy rate, but no annual variability in calf survival, and no immigration.

3.2. Population size and trajectories

A random sample of 50 trajectories from the posterior distribution of population trajectories is shown in Fig. 1 for (a) the aged 1+ population and (b) reproductive females only. In each plot the trajectories are shown for (i) the entire Sakhalin and Kamchatka feeding population; (ii) the Sakhalin feeding population only; and (iii) the western North Pacific breeding subset of the Sakhalin feeding population.

In contrast to the results of Cooke *et al.* (2016) no annual variability in the calf survival rate was found. The cause of the difference appears to be inclusion of data from Kamchatka: some of the calves which went “missing” from Sakhalin and would have been presumed dead in the analysis of Cooke *et al.* (2016), were sighted alive in Kamchatka. The “pregnancy rate” (strictly, the production rate of live calves that survive their first migration to the feeding grounds) was, as before, found to show significant annual variability.

The results show that the Sakhalin and Kamchatka feeding populations have been increasing at 3-5% p.a. over the 10 (or 20) years to 2015. The total aged 1+ (non-calf) population for the combined is estimated at 321–412 whales in 2016 (95% confidence interval). The exclusively and predominantly Sakhalin-feeding population is estimated at 133–168 non-calf whales in 2016.

The new estimate for the Sakhalin feeding population is slightly lower than the estimate of 158–193 by Cooke *et al.* (2016) but the earlier analysis defined the Sakhalin population to include all whales that visit Sakhalin at some time in their lives, including those who visit only occasionally. The new estimate is for predominantly Sakhalin-feeding whales. Using the previous definition, the new estimate for the Sakhalin population in 2016 would be 182–222.

These estimates for Sakhalin whales include both eastern and western North Pacific breeders, if there are any. If the Sakhalin whales contain a subgroup that breeds in the western North Pacific, this part is estimated to have contained up to 50 whales in 2016 (95% CI 2–47). Because the model input contains no definite records of a western breeder, the posterior distribution for the number of western breeders essentially runs from zero to a (probabilistic) upper bound determined by the number of definite eastern breeders that have been observed.

3.3. Genetic closure

The predicted number of paternities was found to be insensitive to the choice of male age at first reproduction, varying by only about 1 paternity across the range 7-12 for male age at first reproduction. This uncertainty was subsumed into the confidence intervals for each hypothesis.

On the assumption that mating occurs only within each feeding population, the population model predicts, with 95% probability, 31–47 identified paternities on Lang’s (2010) sample; if mating is random across the two feeding populations combined, the model predicts 14–27 identified paternities.

The observed value of 26–30 lies between the above two ranges. The result suggests that there is preferential, but not exclusive, mating within the Sakhalin feeding aggregation. The hypothesis of mating exclusively within the Sakhalin feeding population is just rejected ($p < 0.05$). We conclude that the Sakhalin feeding aggregation is probably not genetically closed but that the Sakhalin and Kamchatka feeding aggregations, taken together, may be genetically closed. However, genetic data from Kamchatka would be required to confirm this.

4. DISCUSSION

If these population estimates were used to update the IUCN Red List status, and either just Sakhalin or Sakhalin and Kamchatka whales are considered to constitute a distinct subpopulation, then their status would be Endangered, on the basis of there being more than 50 but less than 250 mature animals (mature animals make up about half the population). If there is a distinct western North Pacific breeding stock, this

would be classified as Critically Endangered, because the range of estimates for the number of mature animals is well below 50. Obtaining further information on the existence, nature and status of the relict western North Pacific breeding population is clearly a high priority.

ACKNOWLEDGEMENTS

We would like to acknowledge the work of all the volunteer biologists over the years who have assisted with data collection. We are also grateful to the International Fund for Animal Welfare (Marine Conservation Program) which has provided full or partial funding for each of the last 15 field seasons at Piltun Bay.

Abundance estimates for western North Pacific gray whales for use with stock structure hypotheses of the Range-wide Review of the Population Structure and Status of North Pacific gray whales

Justin G. Cooke¹

ABSTRACT

Abundance estimates are derived for western North Pacific gray whales *Eschrichtius robustus* that correspond to the various stock structure hypotheses developed by the IWC Scientific Committee's Range-wide Review of the Population Structure and Status of North Pacific gray whales (IWC 2018a), by fitting an individually-based population model to photo-id data and other data collected off Sakhalin, Kamchatka and Mexico. Abundance estimates are presented for the putative Western Feeding Group and Western Breeding Stock in 1995 and 2015. Abundance estimates for the Western Feeding Group in 2015 range from about 130 to about 300 whales (aged 1 yr and over) depending on stock structure hypothesis, while abundance estimates for the putative Western Breeding Stock are all less than 100.

1 INTRODUCTION

This paper presents abundance estimates for gray whales in the western North Pacific that correspond to the various stock structure hypotheses developed by the IWC Rangewide Workshops on North Pacific Gray Whales (IWC 2018a). Estimates corresponding to some further plausible stock structure hypotheses are also presented.

To derive the estimates, an individually-based model is fitted to photo-id data collected during 1995-2016 from Sakhalin Island and Kamchatka Peninsula (Burdin et al. 2017; Yakovlev et al. 2013, 2017), supplemented with sex determinations from biopsies (Lang 2010), photographic matches with wintering grounds in Mexico during 2006-12 (Urbán *et al.* 2012; 2013), and satellite tracking of some tagged individuals from Sakhalin towards their wintering grounds (Mate et al. 2015).

The generic individually-based population model structure and the method of fitting to data is specified in Appendix I. The specific implementation choices used for western North Pacific gray whales are described in the Methods section.

2 METHODS

2.1 Stock structure hypotheses

The stock structure hypotheses developed by the 4th IWC Rangewide Workshop on North Pacific Gray Whales (IWC 2018a) which were still under consideration for consideration after the 5th Workshop (IWC 2018b) are hypotheses 3a, 3b, 3c, 3e, 5a, 6b listed in Table 6 (JCRM 19(Suppl.):528).

The hypotheses posit the existence of up to two breeding stocks: an eastern breeding stock (EBS) which winters off Mexico, and possibly a western breeding stock (WBS) which winters at one or more locations in Asian waters. The hypotheses also posit the existence within the eastern breeding stock of a western feeding group (WFG) which visits Sakhalin and Kamchatka in summer, and a northern feeding group (NFG) which feeds in the Bering and Chuckchi Seas and possibly also off SE Kamchatka.

Of these, hypotheses 3a, 3c, 3e posit only a single breeding stock, and are mutually indistinguishable with respect to the data collected on western North Pacific gray whales.

Hypothesis 6b posits a western breeding stock (WBS) but it only occurs in areas for which no data are available, and is therefore effectively invisible with respect to the available datasets. With regard to observed whales in the western North Pacific, 6b is indistinguishable from the hypotheses with just one breeding stock (3a/3c/3e).

¹ Centre for Ecosystem Management Studies, Höllenbergstr. 7, 79312 Emmendingen, Germany. Email: jgc@cems.de.

In order to implement the hypotheses, whales occurring off Sakhalin and Kamchatka were divided into four subgroups, whose numbers are to be estimated from the data:

Table 1. feeding subgroups defined for the purpose of implementing stock structure hypotheses

Subgroup	Description
S	Whales that visit Sakhalin but not Kamchatka
SK	Whales that visit Sakhalin and occasionally Kamchatka
KS	Whales that visit Kamchatka and occasionally Sakhalin
K	Whales that visit Kamchatka but not Sakhalin

The hypotheses and their definitions are listed in Table 2. In all the hypotheses considered by IWC (2018), whales seen off Sakhalin include WFG whales and possibly also WBS whales. Whales seen off SE Kamchatka include WFG whales and possibly also WBS and NFG whales. The hypotheses considered by IWC (2018) do not allow for the possibility that all whales seen off Kamchatka belong to the WFG. In view of the lack of evidence that any Kamchatka whales belong to the NFG, two further hypotheses were added (8 and 9) in which there are no NFG whales off Kamchatka.

Table 2. Definitions of stock structure hypotheses in terms of affiliations of feeding subgroups

Hypothesis	Description	WBS	WFG	NFG
3a/3c/3e	One breeding stock, some NFG in K		S, SK, KS	K
3b	Two breeding stocks, WBS in K	K	S, SK, KS	
5a	Two breeding stocks, some NFG in K	S, SK	S, SK, KS	K
8	One breeding stock, no NFG in K		S, SK, KS, K	
9	Two breeding stocks, no NFG in K	S, SK	S, SK, KS, K	

In each case, the initial population sizes of each feeding subgroup/breeding stock combination were modelled using a log-linear model with one intercept parameter with a uniform prior, plus a random effect term for the feeding subgroup/breeding stock combination.

2.2 Data

2.2.1 Photo identification

Sampling with photo-identification was conducted in the summer feeding grounds off NE Sakhalin during 1995-2016 and off SE Kamchatka during 2004-12. There were two research teams working off Sakhalin and one off Kamchatka. Off Sakhalin, the Russian Gray Whale Project (RGWP, Pacific Geography Institute, Petropavlovsk, Kamchatka; a continuation of the former Russia-US project) has been collecting data since 1995 ((Burdin et al. 2017), and the Marine Biology National Research Center, (MBNRC, Vladivostok; formerly Institute of Marine Biology, IBM) has been collecting data since 2002 and cross-matched the results with photos from Kamchatka (Yakovlev et al. 2013, 2017).

A total of 287 distinct whales had been identified through the 2011 season, based on cross-matching of the individuals observed by each team. During 2012-2016, a further 56 whales were seen by the RGWP team and 73 whales by the MBNRC and Kamchatka teams, which have not been cross-matched.

Sampling also occurred in the wintering grounds off Baja California, Mexico. Because these grounds are shared with the more numerous eastern North Pacific gray whales, only individuals matched with the western North Pacific were included in the analysis. Cross-matching was conducted between whales identified in Mexico during 2006-12 and all whales in the Sakhalin and Kamchatka catalogues up to 2011 (Urbán et al. 2012, 2013).

Because the matching rate in Mexico appeared to be strongly age-specific, only animals known to be at least 6yr old were considered as potentially samplable in Mexico, and only matches from those animals were used, for the reasons explained by Cooke (2016). Of 17 whales matched between Sakhalin and Mexico, 16 met this criterion. Of a further 4 whales matched between Kamchatka and Mexico, 2 met this criterion.

2.2.2 Additional features recorded

The additional features recorded for at least some identified animals were: sex; mother/calf status; breeding stock affiliation.

Sex. Sex was determined by biopsy for a total of 167 whales, including 156 by the RGWP project, 23 by the MBNRC project, and 12 by both projects. Of the 12 individuals sexed by both projects, 11 agreed with respect to sex. The one

whale without agreement was deemed to be female, because it had been biopsied as female by the RGWP project on four separate occasions. Sex determination is assumed for modelling purposes to be 100% accurate.

Cow/calf status. Of 3,602 encounters of living whales off Sakhalin and Kamchatka (where “encounter” means an individual identified at least once by a team in a season) 205 were of cow-calf pairs and 71 were unaccompanied calves. It is assumed that all cow-calf pairs and accompanied calves were correctly identified by the RGWP team from 1995 and by the MBNRC team from 2003. The mother/calf status was not recorded by the MBNRC team in 2002. It is assumed that all unaccompanied calves were correctly identified by the RGWP team from 1995 and by the MBNRC team from 2007, which used the same criteria from this date. For the years 2003-06, MBNRC unaccompanied calf identifications were not used (they were treated as indistinguishable from other whales).

Of the 23 matching identifications from Mexico that were used in this analysis, 8 were of cows accompanied by calves, but the calf identifications were not available for this analysis.

Breeding stock affiliation

Three individuals sighted off Sakhalin were successfully tagged and tracked to the eastern North Pacific (Mace et al. 2015). It is assumed that the successful long-term tracking of an individual reveals its breeding stock affiliation (eastern or western). Individuals sighted in Mexico are also assumed to belong to the Eastern Breeding Stock (EBS).

2.3 Population model

The structure of the generic population model structure and the method of fitting to data is specified in the Appendix. The specific implementation choices used for western North Pacific gray whales are described here.

2.3.1 State space

The following attributes are represented in the state space:

- Life stage (sex, age and reproductive status, mortality status)
- Feeding subgroup affiliation
- Breeding stock affiliation
- Sampling availability (reflection of individual heterogeneity in capture probability)

The life stages and the possible transitions are shown in Table 3. Animals in any of these stages can die by entering a “carcass” state, where they have a (typically small) probability of being recovered and identified. From the following year they are assumed to be unobservable (“buried”).

Table 3. List of living stages in the gray whale model

The youngest allowed age for a pregnant whale is 7 years and the youngest age for a lactating whale is 8 years. In the summer season, the “Age x ” stage contains animals aged approximately $x + \frac{1}{2}$.

Feeding group and breeding stock affiliations are assumed to be maternally inherited and to remain constant throughout life.

Individual heterogeneity in availability was modelled using 1, 3 or 5 availability classes. Each whale is born into a random class with equal probability. The individual availability class is assumed to be retained throughout life but not to be heritable. The purpose of including these classes is to reduce the bias in abundance estimation arising from capture probability heterogeneity.

2.3.2 *Reproduction, mortality and other transitions*

Each animal in the lactating stage has exactly one calf, assumed to be male or female with equal probability.

The calf mortality is modelled as a constant plus an optional annual random effect. The non-calf mortality rate is assumed to be constant.

The transition probability to the maturing class is assumed to be constant. The transition probability to the pregnant stage depends on the source stage (maturing, lactating or resting) plus an optional annual random effect.

2.4 Sampling model

2.4.1 *Primary and secondary sampling occasions*

The sampling in a season by a research team is treated as sampling occasion. Up to and including the 2011 season, each season of sampling by each team off Sakhalin and Kamchatka is treated as a primary sampling occasion (see Appendix section 2.1 for the definition). From 2012, two options were considered: (i) RGWAP team as primary team throughout, MBNEC and Kamchatka teams secondary from 2012; (ii) MBNRC and Kamchatka teams are primary throughout, RGWAP secondary from 2012.

Individuals sighted up to 2011 by a non-primary team only were treated as “identity lost” (see Appendix section 2.4) from 2012 onwards, because they might, unknown to the analysis, match whales seen by the primary team for the first time in 2012 or later. Sampling occasions in Mexico during 2006-12 are treated as secondary, because only whales matched with Sakhalin or Kamchatka were used.

2.4.2 *Capture probability models*

The capture probability model for the summer sampling includes a free parameter for each sampling occasion (team by year), and a parameter for each combination of feeding subgroup and location, where “location” means Sakhalin or Kamchatka. That is, each feeding subgroup may be differentially catchable in each location.

The summer capture probability model also contains optional random-effect terms for life stage, life stage \times team interaction, and availability class. The life stages for this purposes were summarized into five stages: calves, subadults, lactating mothers, other mature females, and mature males.

The capture probability for the Mexican wintering grounds was estimated externally of this model, because the great majority of the animals there are eastern North Pacific gray whales. The average annual capture probability was estimated to be 0.054 (Cooke 2016).

Because only three identified carcasses were observed, a single value for the capture probability of carcasses was estimated. Unidentified carcasses were not used: each year, the observation of carcasses is treated as a secondary sampling occasion.

2.4.3 *Additional features recorded*

The additional features enter the likelihood through the Q factor in expression (A.13).

Sex is treated as a deterministically observed feature ($Q = 0$ or 1). Any gender bias present in the sampling of individuals is modelled through the capture probability model, which allows for sex-biased sampling.

The probability ($0 < Q < 1$) that a calf of the year was still with its mother when first sampled by a team in a season was modelled as a team-specific parameter, because the MBNRC team tended to observe the animals later in the season than the RGWP team, after more calves had been weaned.

Identifications of calves were assumed to be deterministic ($Q = 0$ or 1) in all years in which they were used (see above).

Individuals sighted in Mexico are automatically assigned belong to the eastern breeding stock (EBS), in the sense that the probability of sighting an animal from the western breeding stock (WBS) in Mexico is assumed to be zero ($Q = 0$).

Three individuals were successfully tagged and tracked to the eastern North Pacific were likewise assigned to EBS. It is assumed that, conditional on the location where they were originally sampled and tagged (in this case, Sakhalin) the probability of successfully tagging and tracking a sampled animal is independent of their breeding stock affiliation (that is, had the individuals been western breeding stock animals, this would have been verified).

2.5 Model selection

Model selection for the purpose of determining which nuisance covariates need to be included was performed with the AIC criterion applied to the large population approximation to the parameter likelihood (see Appendix, section 2.6.2). For this purpose, stock structure hypothesis 3a was used.

3 RESULTS

3.1 Model selection

The results of fitting various models are listed in Table 4 with the AIC criterion from the approximate parameter likelihood. The preferred model (F) includes the following factors: annual variability in calf survival and pregnancy rate; capture probability depends on: team/year interaction, stage effect and team/stage interaction, subgroup/location interaction and availability class (3 levels). Increasing the number of availability classes to 5 increased the AIC.

Fig 1 shows a comparison of the mean population trajectory using (a) the RGWP data; (b) the MBNRC data as the primary data set for the years 2012-16 (when no cross-matching was conducted). The difference in trajectories is seen to be negligible, and the RGWP data were treated as the primary data set for all other model fits.

3.2 Abundance and trends

Population trajectories for the aged 1+ population size for the WFG, the WBS and their sum, were extracted from the posterior distributions of the individual-based population trajectories for each stock structure hypothesis. The estimates of abundance for 1995 and 2015, and of the annual trend, are shown in Table 5. The reason for selecting years near the beginning and end of the data series is that the estimates for the two years have low covariance and together summarize the fitted population trajectories well. The mean abundance estimates for the western feeding group (WFG) in 2015 range from 132 to 287 depending on the stock structure hypothesis. The estimates for the western breeding stock (WBS) are all below 100. The estimate annual rate of increase from 1995-2015 is about 0.05 in all cases. Figs 2a-e show samples of population trajectories from the posterior distributions for each hypothesis.

Table 4. Results of model selection

Case	LogLike	Rank	AIC	Calf mortality	Pregnancy	Capture probability
A	-3806.9	60.0	7733.7	Constant	Stage	Team.Year + Subgroup.Location
B	-3773.9	64.1	7676.1	Constant	Stage	Team.Year + Subgroup.Location + Stage
C	-3697.2	71.6	7537.7	Constant	Stage	Team.Year + Subgroup.Location + Stage + Stage.Team
D	-3653.9	73.3	7454.2	Constant	Stage	Team.Year + Subgroup.Location + Stage + Stage.Team + AvailabilityClass
E	-3640.2	83.1	7446.5	Constant	Stage + Annual	Team.Year + Subgroup.Location + Stage + Stage.Team + AvailabilityClass
F	-3635.5	87.7	7446.4	Annual	Stage + Annual	Team.Year + Subgroup.Location + Stage + Stage.Team + AvailabilityClass

Table 5. Estimates of abundances and trends by stock structure hypothesis

Year	Hypothesis	Group	Abundance estimates (aged 1+)		
			Mean	SD	CV
1995	3a	WFG	74	4	0.05
1995	3b	WBS	33	6	0.17
1995	3b	WFG	75	4	0.06
1995	5a	WBS	27	6	0.24
1995	5a	WFG	47	7	0.16
1995	5a	WFG+WBS	74	4	0.05
1995	8	WFG	106	8	0.07
1995	9	WBS	27	6	0.24
1995	9	WFG	78	10	0.12
1995	9	WFG+WBS	105	7	0.07
2015	3a	WFG	200	6	0.03
2015	3b	WBS	86	11	0.13
2015	3b	WFG	202	5	0.03
2015	5a	WBS	67	14	0.20
2015	5a	WFG	132	14	0.11
2015	5a	WFG+WBS	199	6	0.03
2015	8	WFG	287	12	0.04
2015	9	WBS	67	14	0.20
2015	9	WFG	218	19	0.09
2015	9	WFG+WBS	285	14	0.05

Appendix

Specification of the generic individually-based population model

This Appendix specifies the generic individually-based population model, applicable to any mammal population with seasonal breeding and litter size 1. The implementation choices for the specific application are noted in the main text. The generic model consists of a biological model and a sampling model.

1 BIOLOGICAL MODEL

1.1 State space representation

The biological model is a stochastic, individual-based model with a fixed time step, usually 1 year. At each time step, each individual is in one of n possible states. There are up to N individuals in total, where N is chosen large enough to accommodate any individual alive at any time during the era of interest, which runs from time $t = 0$ to t_{\max} .

Each row of the $N \times n$ matrix S represents an individual biography, where S_{it} is the state of individual i in year t ($i = 1, \dots, N$; $t = 0, \dots, t_{\max}$). The matrix S as a whole represents the individual-based population trajectory.

If the state of an individual is characterized by r attributes, and the j th attribute can take n_j values, then the number of possible states is up to $\prod_{j=1}^r n_j$ but may be less if not all combinations of attribute levels are allowed.

The attributes reflected in the range of individual states include those that are relevant for the population dynamics (such as age, sex, health and reproductive status) and those that are relevant for the sampling process, such as migration habits, behavior etc. These two categories of attributes typically overlap. The attributes of an individual that define its state may or may not correspond to observable features of the individual. Some attributes remain fixed throughout life, such as sex, while others, such as reproductive status, may change each year.

The possible states of an individual include live states, dead states, and the unborn state (individuals which have not yet entered the population).

Because an unborn animal cannot be observed, only one unborn state need be recognized. All attributes of an individual, including inherited attributes, can, without loss of generality, be deemed to be acquired at birth or on entry into the population. The unborns include not only individuals which are literally unborn, but also immigrants prior to their immigration. All individuals count as unborn prior to $t = 0$.

Post-mortem states can be divided into one or more freshly dead “carcass” states where there is still some chance that the animal will be found and identified, and a terminal “buried” state where the animal has, for the purpose of the analysis, become permanently unobservable.

In order to limit the number of parameters to be estimated, individual variation in an attribute, such as migration behavior or reproductive output, is modelled by allowing individuals to belong to a fixed number of notional classes with respect to that attribute. The number of such classes is deemed sufficient when further subdivision has negligible effect on the results.

Some of the individuals will be individually identified at some point during the era of interest. Individuals which are identified at any time during the era of interest are termed “known”, while those which are never identified are termed “unknown”. At any given time t , individuals identified prior to that time are termed “identified” otherwise “unidentified”.

The value of N need not be fixed in advance. Only those individuals which are alive and/or identified at some time within the era of interest need be represented explicitly in the model. Unknown individuals remain mutually indistinguishable with respect to the model until they are born. Whenever an unknown individual is born or otherwise enters the population, it can be taken from a presumed unlimited source of unborn unknowns, and the value of N incremented by 1. Where a distinction is required, N denotes the number of individuals alive at some point during the era of interest, N^+ denotes the indefinitely large number of potential individuals, and N^- denotes the number of known individuals.

The description of the population trajectory is completed by defining a vector of parents π , such that π_i is the parent (mother) of individual i . By convention, π_i is set to 0 (parentage unspecified) for individuals which are already alive at time $t = 0$, or which enter the population other than by birth to a member of the population, such as by immigration.

1.2 Aggregate population trajectory

The aggregate population trajectory is given by the matrix P where P_{kt} is the number of individuals in state k in year t . The aggregate population trajectory is related to the individual-based population trajectory by:

$$P_{kt} = \sum_{i=1}^N I(S_{it} = k) \quad (\text{A.1})$$

I is the indicator function (1 for true, 0 for false) according to the equality of its arguments.

To fit a population trajectory to individually-based data, such as photographic or genetic identification of individuals, the full individual-based trajectory is required. To fit to aggregate data, such as abundance and trends, where individuals are not distinguished, the aggregate trajectory is sufficient. Many different individual-based trajectories share the same aggregate trajectory.

1.3 Population aggregates

Arbitrary linear population aggregates are defined as required. The value of the j th population aggregate in year t is a weighted sum of individuals by state:

$$A_{jt} = \sum_k W_{jk} P_{kt} \quad (\text{A.2})$$

where the weight matrix W defines the population aggregates. Population aggregates can serve as explanatory variables for density-dependent effects.

1.4 Dynamics

The dynamics of the population are determined by two (time-varying) matrices, the transition matrix T and the reproduction matrix R .

For $j > 0$, the transition matrix entry T_{jkt} is the probability that an individual in state j at time t transitions to state k at time $t+1$. Some of the entries of T are constants, while others depend on unknown parameters, whose values are to be estimated. Entries of T that correspond to inadmissible transitions, such as sex change, are zero.

For any given source state $j > 0$, the set of allowed direct destination states (the set of values of k for which the entries T_{jkt} are non-zero), is assumed to be time-invariant. Let n_j denote the number of possible destination states from source state j , and let the integer-valued matrix U_{jl} ($j=1, \dots, n$; $l=1, \dots, n_j$) denote the l th possible destination state from source state j . Let ϕ_{jlt} denote the transition probability from state j to state U_{jl} during time t to $t+1$, conditional on the individual not having transitioned to any of the states $U_{j,1}, \dots, U_{j,l-1}$. The ordering of the allowed destination states is significant and forms part of the model specification. By definition, $\phi(j, n_j, t) = 1$, because there are no further allowed destination states remaining.

Transition probabilities that depend on unknown parameters are modelled with a logit-linear model:

$$\phi_{jlt} = 1 / (1 + \exp(-\zeta_{jlt})) \quad (l = 1, \dots, n_j - 1) \quad (\text{A.3})$$

where the values of ζ are unconstrained (can take any values from $-\infty$ to $+\infty$) and are modelled as linear combinations of unknown parameters:

$$\zeta_{jlt} = \sum_k X_{jltk} \beta_k \quad (\text{A.4})$$

where β is the vector of parameters where the entries of the data matrix X are either constants or values of population aggregates.

The entries $T_{0,k,t}$, where $k > 0$, have a special meaning. $T_{0,k,t}$ represents the expected total number of individuals to enter the population in state k at time t , for example through birth or immigration. For convenience in formulae, $T_{0,0,0}$ is set to 1.

For $j > 0$ and $k > 0$, The reproduction matrix entry $R_{j,k,t}$ is the probability that a female in state j in year t bears a calf that is in state k . The entry $R_{j,0,t}$ is the probability that an animal in state j does not bear a calf in year t . Entries of R which depend on unknown parameters are modelled in a similar way to the entries of T .

The entry $R_{0,k,t}$ denotes the expected number of individuals that enter the population in state k at time t other than by birth to a member of the population, for example by immigration. Expected numbers of immigrants that depend on unknown parameters are modelled in the same way as the expected initial numbers by state.

From these definitions of T and R it follows that:

$$T_{0,k,t} = \sum_{i=0}^N R_{i,k,t} \quad (\text{A.5})$$

1.5 Initial conditions

The initial conditions for the population are handled by taking the initial time sufficiently far before the era of interest that the results are insensitive to the choice of initial conditions.

Expected initial numbers that depend on unknown parameters are modelled with a log-linear model:

$$T_{0,j,0} = R_{0,j,0} = \exp(\psi_j) \quad (\text{A.6})$$

where the values of ψ are unconstrained (can take any values from $-\infty$ to $+\infty$) and are modelled as linear combinations of unknown parameters:

$$\psi_j = \sum_l Z_{jl} \beta_l \quad (\text{A.7})$$

where β is the vector of parameters and the entries of the data matrix Z are constants.

2 SAMPLING MODEL

2.1 Sampling occasions

The sampling process involves a fixed number of sampling occasions. Each sampling occasion involves sampling individuals randomly, without replacement, with a probability that can depend on the state of the individual. Each sampling occasion is tied to a specific time step. Multiple sampling occasions associated with the same time step are treated for analysis purposes as occurring in a specified order, even if in reality they overlap in time.

Sampling occasions can be *primary* or *secondary*. All individuals encountered on a *primary* sampling occasion are eligible for use in the analysis, including individuals identified for the first time. Individuals encountered on a *secondary* sampling occasion are eligible only if they are previously identified. Secondary sampling occasions include, for example, samples taken in areas or at times where conspecifics of other populations (other than the populations of interest) are also present.

The matrix entry J_{ij} takes the value 1 if individual i is eligible for sampling on sampling occasion j , 0 otherwise.

2.2 Sampling probability

Let p_{jk} denote the probability that an eligible individual in state k is sampled on sampling occasion j . The entries p_{jk} typically depend on unknown parameters, whose values are to be estimated. Sampling probabilities that depend on unknown parameters are modelled using a complementary log-log-linear model:

$$p_{jk} = 1 - \exp\left(-\exp(\eta_{jk})\right) \quad (\text{A.8})$$

where the values of η are unconstrained (can take any values from $-\infty$ to $+\infty$) and are modelled as linear combinations of unknown parameters:

$$\eta_{jk} = \sum_l D_{jkl} \beta_l \quad (\text{A.9})$$

where the entries of the data matrix D are constants, usually 0 or 1.

2.3 Observed features

When an individual is sampled, features of the individual may be observed, depending on the nature of the sampling occasion. They are called *features* to distinguish them from the *attributes* defined in section 1.1. The observation of features is conditional on the sampling of the individual.

Some features may be observed deterministically. For example, with genetic capture-recapture, the gender may be determined with effectively 100% certainty once the genetic sample has been analyzed. Any gender bias that may exist in the chance of being sampled would be modelled through the sampling probabilities p .

The observation of some features may depend on probabilities. For example, if an animal is suckling a calf, the probability of seeing the calf when the animal is sampled may be appreciably less than 100%.

Let Q_{fjkl} denote the probability that feature f of an individual in state k sampled on occasion j is observed to have level l . For each f, j, k we require $\sum_l Q_{fjkl} = 1$. For deterministically observed features, the corresponding entries of Q are 0 or 1. Where the probability Q depends on unknown parameters, a normalized log-linear model is used for Q :

$$Q_{fjkl} = \frac{\exp(\theta_{fjkl})}{\sum_l \exp(\theta_{fjkl})} \quad (\text{A.10})$$

where the values θ_{fjkl} are unconstrained (can take any values from $-\infty$ to $+\infty$) and are modelled as linear combinations of unknown parameters:

$$\theta_{fjkl} = \sum_i G_{fjkl i} \beta_i \quad (\text{A.11})$$

where the entries of the data matrix G are constants, mostly 0 or 1. There is no explicit time-dependence in the entries of θ , but they may depend on sampling occasion and thereby on time.

2.4 Loss of identity

Loss of identity can occur if artificial or natural marks are lost. Effective loss of photographic or genetic identity can also occur if the study is continued by a new research group without the possibility for cross-matching with the previous records. Loss of identity of an individual is modelled by appearance of a new individual into the same state as the old individual (“cloning”), coupled with the simultaneous transition of the old individual into an unobservable “lost” state.

2.5 Data

The data consist of a list or catalogue of identified individuals and an associated sampling history of each individual. Associated with each occasion on which an individual was sampled is a list of observable features that were checked for that individual, and the recorded levels of each observed feature.

The meta-data include a list of sampling occasions and any relevant properties of those occasions, such as the time or the primary/secondary attribute, and the number and nature of observable features that were checked (for at least some sampled individuals) on that sampling occasion. Let \mathcal{T}_j denote the time of sampling occasion j , and m_j denote the maximum number of observable features checked on that occasion.

The sampling histories form a matrix Y where Y_{ij} is 0 or 1 according to whether individual i was sampled on occasion j . The entries in the array K_{ijf} are 0 or 1 according to whether feature f was checked for individual i on sampling occasion j . The matrix L_{ijf} specifies the observed level of feature f for individual i on sampling occasion j , when that feature is checked, otherwise 0.

2.6 Likelihood

We distinguish between the trajectory likelihood and the parameter likelihood. The trajectory likelihood is the likelihood of a single individually-based population trajectory. The parameter likelihood is the sum of the likelihoods all possible trajectories given those parameters.

2.6.1 Trajectory likelihood

The trajectory likelihood is the product of the simulation likelihood and the data likelihood. The simulation likelihood is given by:

$$\Lambda_S = \exp\left(-\sum_{t=0}^{t_{\max}} \sum_{j=1}^n R_{0,j,t}\right) \prod_{i=1}^N \left(\frac{R(S_{\pi_i, \tau_i}, S_{i, \tau_i}, \tau_i)}{R(S_{\pi_i, \tau_i}, 0, \tau_i)} \prod_{t=\tau_i}^{t_{\max}-1} R(S_{i,t}, 0, t) T(S_{i,t}, S_{i,t+1}, t) \right) \quad (\text{A.12})$$

where τ_i is the year of birth or entry into the population of individual i ,

The first factor accounts for the fact that N includes only individuals born or alive during the era of interest. The first sub-factor of the second factor ensures that the birth probability of each individual is included only once, even though it is an event in the life both of the parent and of the child.

The probability of the data collected on individual i at time t , given the state k of the individual at that time is given by:

$$\phi_{ikt} = \prod_{j: T_j=t} p_{jk}^{J_{ij}Y_{ij}} (1-p_{jk})^{J_{ij}(1-Y_{ij})} \prod_{f=1}^{m_j} Q(f, j, k, L_{ijf})^{J_{ij}K_{ijf}Y_{ij}} \quad (\text{A.13})$$

where the first product sign is over the sampling occasions that occur in time step t . The first factor contains the probabilities that individuals are seen (captured) or not seen on each sampling occasion, while the second factor contains the probabilities that various features are observed on the occasions on which an individual is seen.

The data likelihood is then given by:

$$\Lambda_D = \prod_{i=1}^N \prod_{t=0}^{t_{\max}} \phi(i, S_{i,t}, t) \quad (\text{A.14})$$

The trajectory likelihood is then given by: $\Lambda_T = \Lambda_S \cdot \Lambda_D$.

2.6.2 Parameter likelihood – large population approximation

The exact computation of the parameter likelihood as the integral of the trajectory likelihoods for the given parameter values is seemingly intractable. The model describes a hidden Markov process, which can, in principle, be solved by applying the forward-backward algorithm to the probability distribution over states (Eddy1996). However, the size of the population state space is approximately n^N , which is too large for computation of the probability distribution over states to be feasible.

An approximation to the parameter likelihood is obtained by computing the probability distribution over states separately by individual, on the assumption that population aggregates that affect the trajectory of an individual can be treated as independent of the state of the individual (the large population approximation). Population aggregates that affect an individual include, for example: (i) the breeding population, which drives the probability that an individual will be born in a given year; and (ii) the feeding population, which may have a density-dependent effect on the survival or reproduction probability of an individual.

Using the large population approximation, the probability distribution of the population state can be approximated by an independent distribution of each of N individuals over n states. This reduces the effective dimension of the state space from n^N to $n \times N$.

We take the notional individual $i = 0$ to represent unknown individuals, so that:

$$\phi_{0,j,t} = \prod_{l: T_l=t} (1-p_{lj}) \quad (\text{A.15})$$

We define the array Φ_{ijt} recursively as follows:

$$\Phi_{i,j,0} = T_{0,j,0} \quad (0 \leq i \leq N^- ; 0 \leq j \leq n) \quad (\text{A.16})$$

$$\Phi_{i,j,t+1} = \sum_{k=0}^n \Phi_{i,k,t} \phi_{i,k,t} T_{k,j,t} \quad (0 \leq t < t_{\max})$$

The probability of the observed data for a known individual i , summed over all possible trajectories consistent with those data is then given by:

$$\Psi_i = \sum_{j=1}^n \Phi_{i,j,t_{\max}} \quad (\text{A.17})$$

assuming that no data are available for time $t = t_{\max}$.

The approximate log-likelihood for all individuals is then obtained by summing the individual log-likelihoods, treating them as independent:

$$\log(\Lambda_P) = \sum_{i=1}^{N^-} \log \Psi_i - E(N^-) \quad (\text{A.18})$$

where the final term is the expected number of known individuals. It accounts for the large potential number of unknown individuals, each of which has a vanishingly small probability of being born and identified (Poisson limit of the binomial). The final term can be computed by:

$$E(N^-) = E(N) - \sum_{j=1}^n \Phi_{0,j,t_{\max}} \quad (\text{A.19})$$

where:

$$E(N) = \sum_{j=1}^n \sum_{t=0}^{t_{\max}} T_{0,j,t} \quad (\text{A.20})$$

2.7 Priors

Where probabilities are modelled using generalized linear models, each term in the model is an intercept term or a random effect term.

The prior for each parameter associated with an intercept term is chosen such that the prior for the corresponding probability would be uniform on $[0,1]$ if the model only included that intercept term. Thus, the prior for an intercept parameter in the transition probability model (A.3) is $\exp(\zeta) / (1 + \exp(\zeta))^2$. The prior for an intercept parameter in the sampling probability model (A.8) is $\exp(\eta - \exp(\eta))$.

The prior for an intercept in a feature observation model of the form (A.10) is $\exp(\theta) / (1 + \exp(\theta))^2$.

The prior for a random effect term is $N(0, \sigma^2)$ where σ^2 is either estimated or fixed at 1. If σ^2 is estimated, then $\log \sigma^2$ has an $N(0,1)$ prior.

The use of proper (normalized) priors ensures that the posterior distribution of each parameter is normalizable.

Typically, the model for sampling probabilities will have at least an intercept term for each sampling occasion, while the remaining terms, if any, are modelled as random effects.

2.8 Fitting the model and model outputs

The primary output of interest is the posterior distribution of individual-based population trajectories. From this posterior distribution, posterior distributions of any population parameters of interest can be calculated. The posterior distribution of individual-based population trajectories is obtained from the prior distributions of parameters and the trajectory likelihood in the usual way.

The validity of the resulting trajectory posterior does not depend on the large population approximation. However, in order to enable reasonably efficient sampling of the trajectory posterior, the parameter likelihood is maximized as a first step, and an approximate posterior distribution of the parameter values is obtained using a quadratic approximation the likelihood. This approximate parameter posterior is then used for importance sampling of the

trajectory posterior. A poor approximation to the parameter posterior would not invalidate the resulting trajectory posterior, but would reduce the efficiency with which it can be sampled.

The estimates of parameter values and their nominal variances obtained by maximizing the approximate parameter likelihood can also be used directly, but the interpretation of such parameter values is, in general, model-dependent. Furthermore, the nominal variances of parameter values derived from quadratic approximation to the likelihood can be rather inaccurate.

2.9 Model selection

Preliminary model selection proceeds using the large population approximation of the parameter likelihood. The model selection is based on the Akaike Information Criterion (AIC; Akaike 1973).

For model selection using the trajectory likelihood, the Widely Applicable Information Criterion (WAIC; Watanabe 2009) is used. The definition of the WAIC is:

$$\text{WAIC} = -2\bar{L} + \text{var}(L) \quad (\text{A.21})$$

where \bar{L} is the posterior mean of the log-likelihood and $\text{var}(L)$ is the posterior variance of the log-likelihood.

The WAIC does not depend on the notion of a parameter count, which is not well-defined for individual trajectories, because the discrete individual transitions do not correspond to continuous, real-valued parameters. The WAIC coincides with the AIC in cases where the latter is applicable (i.e. where all parameters are real-valued and unconstrained, and the log-likelihood function is quadratic). Although the formula for the WAIC is not explicitly dependent on the prior distributions of the parameters, the priors affect the posterior distribution of the log-likelihood and hence the value of the WAIC.

A disadvantage of the WAIC is that its computation is subject to sampling error, because it is computed from a finite sample of the posterior distribution of the likelihood. This can make it difficult to measure small differences in WAIC.

ABSTRACT

Molecular markers such as single nucleotide polymorphisms (SNPs) can reveal otherwise cryptic aspects of organismal ecology and evolution. Herein, we provide the first description of the gray whale genome and characterize a novel SNP panel that includes 88 gene-associated markers, two molecular sexing markers, and two mitochondrial markers. We sequenced the gray whale genome, repeatedly genotyped replicate whale biopsies at 92 SNP loci, then quantified genotyping error rates and variability at each marker. Mitochondrial DNA haplotyping and molecular sexing with SNPs was 100% concordant with conventional assays based on PCR and dideoxy sequencing or electrophoresis. Genotyping error rates, calculated across loci and across replicate samples, were very low (0.021%) and observed heterozygosity was 0.33 averaged over all autosomal markers. This level of variability across loci provides substantial discriminatory power, as evidenced by our genetic documentation of parent/offspring pairs. For example, the mean probability of identity was $<10^{-25}$ for unrelated individuals and the mean probability of exclusion was >0.9999 when neither parent was known. The characterization of the gray whale genome should enable comparative studies of natural selection in cetaceans and the SNP markers should be highly informative for future studies of gray whale population structure, demography, and relatedness.

INTRODUCTION

Gray whales (*Eschrichtius robustus*) were once common in both the North Pacific and North Atlantic Oceans but disappeared from the Atlantic by the early 1700s due to overhunting (Mead and Mitchell 1984). Contemporary gray whales are found only along the eastern and western coasts of the North Pacific Ocean (Andrews 1914; Rice and Wolman 1971). Herein, we follow the convention established by the International Union for Conservation of Nature (IUCN 2008; Reilly et al. 2013) and refer to an eastern gray whale (EGW) population and a western gray whale (WGW) population.

Like so many of the great whales, gray whale numbers crashed during the commercial whaling era (Mead and Mitchell 1984; Alter et al. 2012; Weller and Brownell 2012). Based on whaling records, Henderson (1984) estimated the size of the historic EGW population as 15,000 to 20,000 individuals prior to commercial hunting. Historically, the WGW population is thought to have been much smaller, numbering only 1,000 to 1,500 individuals prior to 1910 (Berzin and Vladimirov 1981). Although there is considerable uncertainty as to the historical size of the WGW population, its distribution was much larger than the contemporary WGW population that summers in the Sea of Okhotsk (Reeves et al. 2008).

The IUCN considers the extant WGW population to be critically endangered (IUCN 2008; Reilly et al. 2013), as there were only about 140 western gray whale adults in 2012 (Cooke et al. 2013) and the population was previously believed to be extinct (Bowen 1974; Weller et al. 2002). The EGW population was reduced to a low of approximately 2,000 individuals and has since made a strong recovery; the contemporary population numbers about 19,000 individuals (Laake et al. 2009).

Gray whales are occasionally sighted along the historical western migration corridor (Weller et al. 2008; Weller and Brownell 2012), which includes waters near Sakhalin Island (Russia), and some genetic studies have indicated that whales sampled near Sakhalin are differentiated from the EGW population (Lang et al. 2010; LeDuc et al. 2002; Alter et al. 2012; Meschersky et al. 2015). However, gray whales have the capacity to migrate among oceanic basins (>22,000 km; Scheinin et al. 2011; Shpak et al. 2013) and the gene pools of some other great whales are genetically homogenous across their range (e.g., sperm whales; Alexander et al. 2016). Geospatial and genetic data (e.g., Alter et al. 2015; Mate et al. 2015) suggest the extant WGW and EGW populations may be demographically linked and that contemporary signals of population differentiation may represent historical patterns. The development of additional, more powerful genetic assays would be a boon to gray whale conservation globally as the ability to identify individuals and family groups, confidently delineate populations, and track patterns of genetic diversity over space and time would result in more informed management decisions.

Suites of single nucleotide polymorphisms (SNPs) can be used to delineate breaks in genetic structure, but can also be used for definitive individual identifications (e.g., from biopsies) and for categorical assignment of parentage or relatedness (e.g., Ruegg et al. 2014; Doyle et al. 2016). We sought to develop a SNP panel from the gray whale genome in order to facilitate

genetic studies of population differentiation, parentage, and individual identity (e.g., comparing photographs to biopsy genotypes).

Herein we describe the genome sequence of the gray whale and use it to identify SNPs from genic and non-genic regions. We sequenced the genomes of two Sakhalin Island gray whales (a male and a female WGW) and a female EGW from Barrow Alaska. Subsequently, multi-locus SNP genotypes were generated for the single EGW (N=1) plus a set of WGW biopsy samples (N = 35) collected near Sakhalin Island to provide a preliminary estimate of genomic diversity in gray whales. The genome and genetic markers we describe herein will allow researchers to validate photographic or other means of individual identification and to demographically track individuals in space and time as has been done for other species of conservation concern (e.g., Nussberger et al. 2014).

METHODS

Sample collection

Biopsies of skin and blubber were obtained from WGWs (N=35) on their summer feeding grounds near Sakhalin Island using methods approved by the Scientific Committee of the International Whaling Commission. These include samples from six calves as well as adults. Biopsy samples were frozen and shipped to Purdue University processing. Skin samples from EGWs (N = 2) were cut from two dead gray whales that beached near Barrow, Alaska and then frozen until processing at Purdue University.

Genome sequencing, assembly, and annotation

DNA was extracted from two WGWs (male ER-14-168 and female ER-14-0147) and one EGW (female GFD-02). For the male WGW, we constructed one paired-end (PE) library without PCR amplification and one mate-paired (MP) no-gel library. For the two female gray whales (WGW and EGW) we only constructed PE libraries. In total, we sequenced 7 lanes of PE libraries and 1 lane of the MP library using an Illumina HiSeq (2x100).

We used FASTQC v0.11.2 to generate summary statistics for the sequencing data. TRIMMOMATIC v0.32 (Bolger *et al.* 2014) was used to remove adaptor sequences and low quality bases (Phred scores <20). Multiple genome assemblies were generated using ABySS version 1.9.0 (Simpson et al. 2009) with a variety of k-mer values (k-mer = 30, 40, 50, 60 and 70) to produce the most comprehensive assembly. We used the PE data during the contig-building steps and MP data during the scaffold-building steps. Genome annotation was based on the male WGW (ER-14-168) to include genes found on the Y-chromosome (Zfy) and the X-chromosome (Zfx). We used MAKER 2.28 (Cantarel et al. 2008) for annotation following Doyle et al. (2014). Briefly, we used SNAP (Korf 2004) to generate *ab initio* gene predictions. Gene predictions supported by expressed sequence tags, protein or InterProScan evidence were elevated to gene annotations. Eutherian protein data were downloaded from the UniProtKB database (www.uniprot.org) and EST evidence was derived from an assembled transcriptome of

an Alaskan bowhead whale (Keane et al. 2015). We used CEGMA to assess the completeness of our genome assemblies (Parra et al. 2007).

SNP identification and development

From published cetacean data, we generated a manually curated list of candidate genes potentially subject to strong natural selection. These include genes associated with osmoregulation, oxygen binding/delivery, and other aspects of marine life (referred to hereafter as “nonneutral” or “candidate” genes; see Kosiol et al. 2008). Using the MAKER transcripts from our genome annotation, we used BLAST 2.2.31+ to annotate these candidate genes in the gray whale genome. For SNP identification, we used BWA version 0.7.12 (Li and Durbin 2009) to map all PE reads to the male assembly. We used GATK 3.4 (DePristo et al. 2011; Van der Auwera et al. 2013) to 1) identify and realign reads around insertions/deletions (indels); 2) identify SNPs with a minimum Phred quality score of 30 and a minimum depth of 10 reads; and 3) disregard SNPs within 20 bp of each other. BEDOPS 2.0 (Neph et al. 2012) was used to identify variable sites (i.e., SNPs) within nonneutral genes. We used IGV version 2.3 to identify target SNPs with at least 60 nucleotides (nt) of high-quality flanking sequence upstream and downstream and GC content less than 65%. We deliberately minimized linkage disequilibrium (LD) by choosing only single SNPs from a given scaffold.

Ultimately, we developed and tested 92 autosomal nuclear markers from protein-coding genes specifically targeted because of evidence for selection in other marine mammals. Following preliminary population surveys via dideoxy sequencing (Alter and Palumbi 2009), we designed two mitochondrial DNA (mtDNA) markers for haplotyping. For sexing, we designed two redundant SNP assays to assess nucleotide variation in the *Zfx/Zfy* genes.

SNP genotyping, error rates, and variability

We genotyped 36 gray whale biopsy samples at 96 candidate SNP markers. Samples were genotyped using a Fluidigm Juno Genotyping System and a specific target amplification step was incorporated to facilitate genotyping of the low-quantity DNA samples that are typical of biopsies from endangered species. Individual SNP calls were visualized and edited using Fluidigm’s Genotyping Analysis Software; data from nuclear loci that did not produce obvious clusters of homozygotes and heterozygotes (Figure 1) were excluded from further analyses.

In theory, our 35 WGW biopsies could include whales that were inadvertently sampled more than once (e.g., in subsequent years). Individual biopsies were genotyped at the SNP panel

multiple times, and ultimately 78 samples were genotyped at ≥ 88 loci (only DNA samples and

Figure 1. An example of Fluidigm data from an autosomal whale SNP: clustering results for locus 11737172_20296. GG homozygotes are shown in green, heterozygotes in blue, and TT homozygotes in red. The negative control is shown as the black data point.

SNP loci with $<10\%$ missing data were included in this analysis). We used `allelematch` in R (Galpern et al. 2012; R Development Core Team 2008) to group replicate genotypes into unique records that represent individual whales, allowing for a maximum of 2 mismatches between replicates. All genotypes identified as replicates were subsequently confirmed visually.

Error rates were calculated using replicate DNA samples ($N = 69$ in total) from 27 individual gray whales. The plurality principle was used to determine a consensus sequence for each individual whale by utilizing SNP calls across replicate samples (see Doyle et al. 2016). The SNP typing error rate (e) was calculated according to the equation $e = m/[d(s)]$, where m represents the total number of mismatches between each replicate sample and the consensus sequence across multiple samples from the same individual; d represents the total number of loci per replicate sample; and s represents the total number of replicate samples. Both incorrect SNP calls (errors of commission) and instances where no amplification occurred (errors of omission) contributed to m .

We used GENALEX v6.5 (Peakall & Smouse 2012) to quantify observed (H_O) and expected heterozygosity (H_E), the mean probability of identity (P_I), and the mean probability of exclusion with neither-parent known (P_E). We tested for deviations from Hardy Weinberg Equilibrium (HWE) and for linkage disequilibrium (LD) after applying a sequential Bonferroni correction to account for multiple tests (Holm 1979). The inbreeding coefficient f (Weir & Cockerham 1984) was evaluated in GENODIVE v2.0b27 (Meirmans & Van Tienderen 2004) using 10^3 permutations.

Molecular sexing and haplotyping

For validation purposes, all samples were sexed using a traditional PCR/gel method (Bérubé and Palsboll 1996) and also by using our novel sexing SNPs. Similarly, mtDNA haplotypes were generated using both traditional dideoxy methods (Alter and Palumbi 2009) and novel SNP markers. We then compared the concordance among assays in an attempt to validate our novel markers.

Relatedness, genetic structure, and effective population size

Relatedness among individuals was estimated using RELATED v1.0 (Wang 2011; Pew et al. 2015), which implements five widely used moment-based relatedness estimators. In order to identify the estimator that performed best with our data, we used our empirical allele frequencies to simulate 100 datasets for four types of dyads: parent-offspring pairs (expected $r = 0.5$), full-siblings ($r = 0.5$), half-siblings ($r = 0.25$), and unrelated individuals ($r = 0.0$). Point estimates and 95% confidence intervals (CI) were estimated based on 100 bootstrap replicates and the best estimator was identified using Pearson's correlation coefficient. This estimator was used to compare the observed mean pairwise relatedness of each individual whale (r_{pw}) to the mean for the population (r_{pop}). Thus, r_{pw} represents the mean relatedness of a single individual whale to every other whale in the population whereas r_{pop} represents the mean relatedness of the population as a whole. By comparing r_{pw} to r_{pop} , individual whales were identified that were more or less related to the population than expected by chance alone. CERVUS version 3.0.7 (Marshall et al. 1998; Kalinowski et al. 2007) was used to assign parentage to calves, considering all sampled adults as candidate parents. The minimum allowable confidence level for which a parentage assignment was accepted was 95%.

We used GENALEX to perform a principal components analysis (PCA) of genetic variation among distantly related (i.e., second-degree or greater) gray whales to assess overall population structure. We also included both western ($N = 35$) and eastern ($N = 1$) samples in a STRUCTURE v2.3.4 (Pritchard et al. 2000) analysis. Samples identified by our relatedness analyses as biological replicates from the same individual (i.e., $r = 1$) were excluded from the PCA and STRUCTURE analyses so only individual genotypes were used. We used two different approaches: i) including all whales and ii) including only one representative from pairs identified as first-degree relatives (e.g., full-siblings or parent-offspring pairs). We used the 'admixture' model, which allows individuals to have inherited different parts of their genome

from ancestors in different relatedness clusters. For each value of K from 1–6, we performed five iterations, using a burn-in of 10^4 iterations followed by an MCMC of 10^5 iterations. The most likely number of clusters was identified using STRUCTURE HARVESTER v1.1.2 (Earl & vonHoldt 2012) using the ΔK method (Evanno et al. 2005). CLUMPP v1.1.2 (Jakobsson & Rosenberg 2007) was used to combine STRUCTURE output and results were displayed with DISTRUCT v1.1 (Rosenberg 2004).

To estimate contemporary effective population size (N_e) and effective number of breeders (N_{eb}) of the WGW population we populated NeESTIMATOR v2.01 (Do et al. 2014) with the unique multilocus genotypes that represent individual whales. The software implements two different methods for estimating N_e from a single-sample, based on i) linkage disequilibrium (Waples & Do 2008) and ii) heterozygosity excess (Zhdanova & Pudovkin 2008). A molecular co-ancestry approach (Nomura 2008)—also implemented in NeESTIMATOR— was used for estimating N_{eb} . Note these methods assume selectively neutral markers and closed populations, so these N_e and N_{eb} estimates may be biased. Moreover, the influence of selection and migration on such estimates are unknown as they have not been investigated in a thorough, systematic manner (Waples 2006).

RESULTS

Genome sequencing, assembly, and annotation

Our WGW sequencing results are compiled in Tables 1-2. We generated >2.5 billion reads (~2 billion high-quality reads after quality-control) that collectively span ~200 billion bases and contain near all of the core genes common to eukaryotes (Table 2). The N50, which represents the value where more than half of the assembly is contained in larger contiguous regions, was ~180,000 bp for the best assembly. We annotated roughly 22,000 genes, a number similar to other cetacean genomes (Supplementary Table 1).

Table 1. Sequencing statistics associated with the Western gray whale genome.

Sample name	Total reads	Total bases	Quality reads	Quality bases
Paired-end libraries				
ER-14-0147	1,331,820,280	134,513,848,280	988,439,854	97,099,230,094
ER-14-0168	1,254,676,990	126,722,375,990	974,126,824	95,896,562,771
Mate-paired libraries				
ER-14-0147	184,404,728	18,624,877,528	146,095,780	13,350,014,231
ER-14-0168	213,408,466	21,554,255,066	168,844,292	15,387,314,171

Table 2. Summary statistics generated by ABySS for the western gray whale genome assemblies. In both cases, a kmer length of 60 produced the best assemblies shown here. The N50, measured in bases, represents a midpoint whereby half of the assembled sequence is contained in contigs larger than the N50. The n:N50 column refers to the number of sequences of length N50 and longer. Comp% refers to the percentage of 248 ultraconserved core eukaryotic genes detected in the gray whale assembly (Parra et al. 2007).

Sample	Sequences	Bases	Min. Length	Max. Length	N50	n:N50	Comp%
ER-14-0147	60,534	3,082,450,012	500	1,943,192	180,882	4,539	95

SNP identification and development

We identified 2,057,254 candidate SNPs from the WGW, of which 1,474,749 passed quality filtering criteria. Of this high-quality subset, 8,413 SNPs were located in exons that were identified in the genome annotation. From these exonic SNPs, we designed and tested 96 SNPs for our genotyping assay. Four were ultimately excluded because they were monomorphic, clustered poorly, or were otherwise of insufficient quality. These novel SNP loci and flanking sequences are described in an associated Excel spreadsheet. The 92 informative loci include 88 gene-associated nuclear markers (which may be targets of selection), two mitochondrial markers, and two nuclear molecular-sexing markers (Supplementary Table 2).

SNP genotyping, variability, and error rates

The vast majority of markers amplified in each individual DNA sample (Figure 1). By genotyping 27 of the 36 biopsy samples multiple times, we calculated an overall genotyping error rate (e) of 0.021%. According to allelematch, the 36 biopsies represented a total of 29 unique multilocus genotypes that correspond to 29 individual gray whales (i.e., 7 whales were sampled twice; Table 4). Observed and expected heterozygosities at autosomal SNPs were 0.33 ± 0.18 (mean \pm SD) and 0.31 ± 0.15 , respectively, for all WGWs sampled (Supplementary Table 3). All autosomal SNP loci were in Hardy-Weinberg equilibrium following sequential Bonferroni correction. Male whales ($N = 14$) H_O and H_E averaged 0.30 ± 0.02 and 0.29 ± 0.02 , respectively, across all autosomal markers whereas female whales ($N = 21$) H_O and H_E averaged 0.35 ± 0.02 and 0.32 ± 0.02 . The mean inbreeding coefficient (f) was -0.05. The mean probability of identity (P_I ; Waits et al. 2001) was 1.6×10^{-25} and the mean probability of exclusion (P_E ; Jamieson and Taylor 1997) with neither parent known was >0.9999 .

Table 4. Pairwise relatedness estimates (r) among each possible pair of individual gray whale biopsies in our sample. Bold rows indicate pairs of samples from the same individual that were inadvertently sampled more than once. Italicized rows represent likely first-degree relatives (e.g., parent-offspring pairs or full-siblings). The table was arbitrarily truncated at mean $r = 0.30$ due to space constraints; see Supplementary Table 4 for smaller values.

Molecular sexing and haplotyping

Samples from the 29 individual gray whales were sexed using both our novel SNP assays and the traditional method using PCR and gel electrophoresis. The results of the two methods were in complete concordance with one another (see Figure 2), indicating that our samples were derived from 11 males and 18 females. These same samples were haplotyped using both our mtDNA SNP assays as well as traditional Sanger sequencing. Once again, the results of the two methods were in complete concordance (data not shown) and three distinct mitochondrial haplotypes were detected (Table 3).

Table 3. Haplotype and sex data. Genotypes for two mitochondrial (CR_82 and CR_104) and two sexing markers (ZFY_288 and ZFY_342). Missing genotypes are represented with a dash.

Relatedness, effective population size, and genetic structure

Mean pairwise relatedness (r_{pop}) observed among all 29 individual gray whales (including one eastern individual) was -0.032 and the 95% confidence interval ranged from -0.055 to -0.009. This analysis of pairwise relatedness confirmed the allelematch results in that 7 of our

biopsies were duplicate samples from the same individual, and many dyads were likely first-degree relatives (e.g., full siblings or parent-offspring pairs) as indicated in Table 4. The A.

B.

Figure 2. Concordance between A) traditional PCR/gel and B) our novel SNP sexing assays. Panel A demonstrates that the traditional method produces a single product in females (ZFX) and two products in males (ZFX and SRY); also shown are a no-template control and a size standard. Panel B demonstrates that males (blue) and females (red) can be distinguished from one another based on HEX and FAM intensity measured in normalized fluorescence units (NFU).

distribution of individual relatedness values (r_{pw}) is shown in Fig. 4. The CERVUS analyses identified two cow-calf pairs, one of which (ER14-0159/ER14-0173) confirmed a relationship suspected in the field whereas the other (ER14-0152/ER14-0172) overturned our field suppositions. No sires were identified in our sample but we identified two potential full sisters

(ER14-0162 and ER14-0173; pairwise $r = 0.483$). They apparently share the mother ER14-0174/ ER14-0159, $r = 0.631$ with ER14-0173 and $r = 0.469$ with ER14-0162; Table 4).

The N_e estimates of contemporary WGW were similar based on linkage disequilibrium (mean $N_e=14.1$; 95% CI from 12.1–16.7) and heterozygosity excess (mean $N_e=14.4$; 95% CI from 7.6–254.1). The effective number of breeders, based on individual coancestry, was only 1.3 (95% CI from 1.0–1.7).

Our analyses of population structure found the lone EGW in our survey to be genetically similar to the WGWs. The PCA revealed a single cluster of genotypes that include all the WGWs and the lone EGW; there was no differentiation between these two putative populations (Figure 3a). Our data contained signals of substructure in the gray whale gene pool and the most likely number of clusters was three ($K = 3$; $\Delta K = 27.00$; Figure 3b).

DISCUSSION

Genome sequencing, assembly, and annotation

The gray whale genome assemblies we describe consist of ~22,700 genes (Tables 1 and 2) and contain ~95% of the genes known to be highly conserved among eukaryotes (Parra et al. 2007). These assemblies are relatively complete and reveal that the gray whale genome is fairly typical of cetaceans in terms of genome size and gene complement, which likely reflects their shared ancestry. Foote et al. (2015) have recently argued that the genomes of marine mammals have evolved in a convergent fashion, and future research will determine what proportion of the gray whale genes we annotated (Supplementary Table 1) are orthologues of the 16,878 genes shared by killer whales, manatees, walrus, and bottlenose dolphin (Foote et al. 2015). We expect that all of these species have undergone similar selection with regard to genes involved in osmoregulation (e.g., adaptation to a saline environment), oxygen binding affinities, and other aspects of marine life.

SNP identification and development

From the genomic sequence data, we identified hundreds of thousands of SNPs that can be used in future population genetic surveys. Of these, we evaluated 96 and found that 92 of these were polymorphic, had low error rates, and could be multiplexed in a single assay. This small panel of markers should be sufficient for investigations of genetic parentage, relatedness, individuality, demographic turnover, and population structure. However, the much larger set of SNPs we identified could inform future genome scans based on RAD-seq (Miller et al. 2007) or other queries of anonymous SNPs that might also be informative for studies of natural selection and/or demographic history.

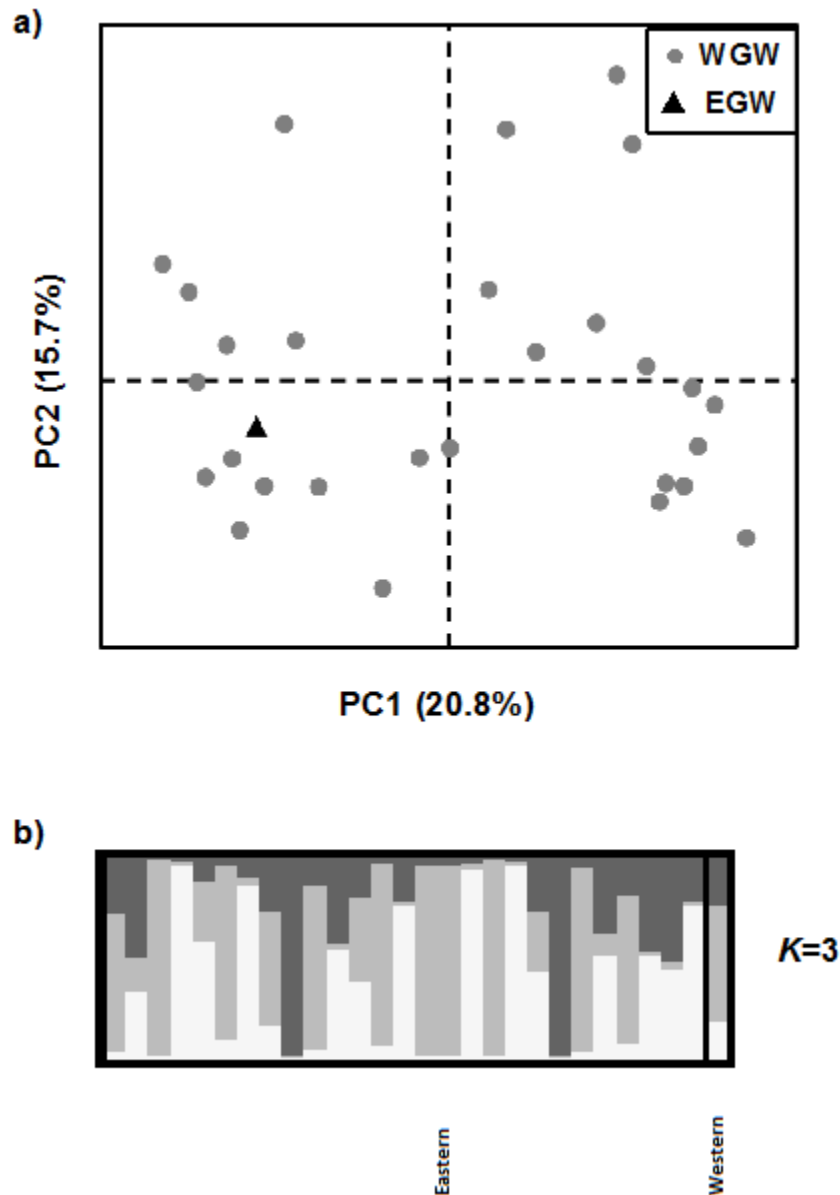

Figure 3. Gray whale population structure based on PCA (panel A) and Bayesian clustering (panel B). For panel B, each vertical bar represents an individual and its proportional ancestry one of $K=3$ clusters; this plot excludes first-degree relatives (including ‘parent-offspring’ and ‘full-siblings’ pairs; $r \geq 0.5$). A black line separates the eastern gray whale (EGW) from the western gray whale (WGW) samples.

SNP genotyping, variability, and error rates

The oligonucleotides we developed and the SNPs they query were assessed with the Fluidigm platform, but could instead be utilized with alternative genotyping technologies. Because these markers are polymorphic and have low error rates ($\sim 0.02\%$), we expect lab-to-lab variability should be low, as 99.98% of our replicate data were identical across independent genotyping runs. For example, a whale from the western Pacific that is genotyped with these SNPs could be identified as one also sampled in the eastern Pacific provided the genotypes are stored in a common database that could easily be queried by independent research groups (e.g., on the cloud).

From a large pool of candidates, genetic markers can be used to assign a) genotypes to individuals (e.g., forensic applications) and b) offspring to candidate parents (e.g., paternity). The power available for such analyses are captured by P_I and P_E , respectively. In our sample of whales, the mean $P_I = 1.6 \times 10^{-25}$. Thus trillions and trillions of whales would have to be sampled—far more than collectively ever roamed the oceans since the evolution of cetaceans—before two unrelated individuals would be expected to have the same multi-locus SNP genotype by chance alone. Indeed, our sampling yielded multiple biopsies from the same donor whales which were identified by their identical SNP genotypes (see below and Table 4). Similarly, a calf's unknown parentage could be determined among thousands of candidate parents with virtual certainty if all were genotyped with this SNP panel ($P_E > 0.9999$).

Molecular sexing and haplotyping

Our novel SNP sexing assays performed well (i.e., were corroborated by conventional molecular sexing), as did the SNP mtDNA haplotyping assay. Although our marker set queries only two mtDNA sites, this marker panel could easily be extended to other SNP sites known to be variable in gray whales; we provide herein the first proof-of-concept data. We include these markers along with our autosomal SNPs because data on sex and matriline may ultimately reveal different aspects of cetacean biology, such as the female philopatry and male-biased dispersal observed in sperm whales (Alexander et al. 2016).

Relatedness, effective population size, and genetic structure

The WGW is considered critically endangered by the IUCN, and although our sample consisted of only 28 WGW individuals, this is $\sim 20\%$ of the entire population (Cooke et al. 2013). Our relatedness analysis indicated that a number of our biopsies came from the same whales; seven pairs of samples were found to have identical SNP genotypes across all loci (Table 4). Given the paucity of WGWs, it is not entirely surprising that we sampled 7 individuals twice. Furthermore, a number of individual pairs were apparently derived from close relatives (Table 4; Figure 4) that may represent parent-offspring pairs, full-siblings, half-siblings, and other close relatives. We identified two distinct cow/calf pairs and one ostensible full-sibling pair. This point illustrates the power of genetic analyses in corroborating or overturning relationships suspected based on field work. All of our population inferences (i.e., genetic structure and N_e)

are preliminary, but we include them here because of the keen interest in the conservation of the critically endangered WGW population.

Whether the population near Sakhalin Island is comprised of western gray whales, eastern gray whales, or is a mixed aggregation of the two stocks is under study by the IWC (2015). The lone EGW we sampled was no more or less related to the WGW population than expected by chance alone (Figure 4). If the EGW was derived from an independent gene pool, it should be more distantly related to the WGW population. Furthermore, the relatedness analysis (based on the proportion of alleles shared among loci by two individuals) corroborates the STRUCTURE analysis (based on minimizing population deviations from Hardy-Weinberg equilibrium).

Figure 4. The distribution of individual relatedness values (r_{pw}) and their associated 95% confidence intervals (CI). The mean pairwise relatedness among all 29 individuals in the population (i.e., 406 pairwise comparisons where $r_{pop} = -0.032$) is shown as a solid black line and the 95% CI (from -0.055 to -0.009) is shown as a dashed line. For each individual, r_{pw} is indicated as a dot and the 95% CI is shown as a vertical bar. Note that GFD02, the lone EGW, is no more or less related to the population than expected based on chance alone.

STRUCTURE indicated the presence of three genetic groups within our sample set, but it seems unlikely that this differentiation is simply due to the presence of eastern and western gray whales in our sample because the single EGW we genotyped was genetically indistinguishable from the WGWs and appeared to be admixed from all three groups that STRUCTURE identified (Figure 3). Populations with small effective sizes diverge rapidly due to drift and inbreeding (Wang and Caballero 1999). Thus, our small estimates of gray whale N_e ($N_e \approx 14$ by both linkage disequilibrium and heterozygosity excess) are consistent with the idea of genetic structure in the gray whale and may explain, at least in part, the divergence between the samples we genotyped.

A panel of ~100 SNPs has substantial discriminatory power, even in a migratory species (e.g., Ruegg et al. 2014). The signals of genetic differentiation that we detected may be due to true population structure associated with divergent selection, genetic drift, and/or a lack of migration (gene flow) among gray whale populations. Alternatively, the structure may represent the presence of relatives within our sample of WGWs (Anderson and Dunham 2008; see Figure 3). Additional genotyping will be required to differentiate among these possibilities, but the genome sequence and the genotyping platform we describe herein should enable those efforts.

Conclusions

Herein, we describe the gray whale genome and the development of a gray whale genotyping assay that queries 92 autosomal nuclear SNPs (88 gene-associated markers), 2 mitochondrial markers, and 2 molecular-sexing markers. We validated these markers by repeated genotyping of 36 gray whale samples and determined that the error rates were low and the markers were polymorphic despite small effective population sizes. The single whale we sampled from the eastern population could not be genetically distinguished from the 28 gray whales we sampled near Sakhalin Island, but our markers provide a powerful platform for distinguishing among individuals and kin (e.g., identifying close relatives). Ultimately, the markers described herein should prove a valuable resource for biologists and for the broader conservation community given the difficulty and expense associated with sampling and identifying baleen whales, and the genome sequence will serve as a valuable resource for basic studies across a diversity of disciplines.

This study was funded by Exxon Neftegas Limited and Sakhalin Energy Investment Company. The content herein is solely the responsibility of the authors and does not necessarily represent the official views of the funding parties.

ACKNOWLEDGMENTS

We thank the International Whaling Commission (IWC) and Aimée Lang for curating the 2011 western gray whale samples provided via the IWC. Teri Rowles provided assistance to obtain the required permits (NMFS Office of Protected Resources' Marine Mammal Health and Stranding Response Program (MMHSRP) permit 932-1905-MA-009526 and CITES permit 13US082589/9). Vladimir Efremov and Mike Swindoll provided support in obtaining the biopsies and associated metadata. The Institute of Ecology and Evolution of the Russian Academy of Sciences, the A.V. Zhirmunsky Institute of Marine Biology Far Eastern Branch, and Oregon State University provided invaluable support for the collection of the western gray whale samples. We thank E. Srouf and A. Cardoso (Indiana University School of Medicine) for their laboratory assistance and support. Craig George and Robert Suydam (Department of Wildlife Management, North Slope Borough of Alaska) provided for samples of stranded eastern gray whales. We thank Y. Ji, M. Sundaram, and J. Willoughby for constructive comments. Thanks to Mike Scott, Azivy Aziz, and Lucie N'Guessan for the management of this project. Finally, we thank Koen Broker and Jennifer Dupont for discussions about gray whale biology and population structure, and for help in the early stages of the conceptual development of this project.

ABSTRACT

Paper SC/66b/DNA/04 reported the results of the genome sequences of 2 western gray whales from Sakhalin Island and 1 eastern gray whale from northern Alaska. A modified version of that paper has been accepted for publication in the journal Biological Bulletin. Herein we provide a summary of the paper, the links to the data archives, and a discussion of the ongoing research program.

INTRODUCTION

The following is the abstract of the paper: *Genetic and genomic approaches have much to offer in terms of ecology, evolution, and conservation. To help better understand the biology of the gray whale, we sequenced the genome and produced an assembly that contains ~95% of the genes known to be highly conserved among eukaryotes. From this assembly, we annotated 22,711 genes and identified 2,057,254 single nucleotide polymorphisms (SNPs). Using this assembly, we generated a curated list of candidate genes potentially subject to strong natural selection, including genes associated with osmoregulation, oxygen binding/delivery, and other aspects of marine life. From these candidate genes, we queried 88 autosomal protein-coding markers with a panel of 92 SNPs that also included two sexing and two mitochondrial markers. Genotyping error rates, calculated across loci and across 69 intentional replicate samples, were low (0.021%) and observed heterozygosity was 0.33 averaged over all autosomal markers. This level of variability provides substantial discriminatory power across loci (mean probability of identity of 1.6×10^{-25} and a mean probability of exclusion >0.999 with neither parent known), indicating that these markers provide a powerful means to assess parentage and relatedness in gray whales. We found 29 unique multilocus genotypes represented among our 36 biopsies (indicating that we inadvertently sampled 7 whales twice). In total, we compiled an individual dataset of 28 Western gray whales (WGSs) and 1 presumptive Eastern gray whale (EGW). The*

lone EGW we sampled was no more or less related to the WGWs than expected by chance alone. The gray whale genomes reported herein will enable comparative studies of natural selection in cetaceans and the SNP markers should be highly informative for future studies of gray whale evolution, population structure, demography, and relatedness.

AVAILABILITY OF THE GENOME SEQUENCES AND SNP DATA

Upon official publication of the paper, genome data will be available from NCBI and SNP data will be archived by the journal.

ONGOING STUDIES

Additional biopsies of western gray whales were collected as part of the Joint Program in 2015 and 2016. Those samples are currently being imported from Russia into the US to be analyzed for SNPs. In addition, we are collaborating with Jorge Urban to analyze SNPs from gray whales from the Mexican wintering lagoons, and with the North Slope Borough Department of Wildlife Management to analyze SNPs from stranded gray whales from northern Alaska. And a request for samples from gray whales from Japan is presently being proposed.

The genome sequence and SNP panel reported in this paper and the ongoing collection of a larger dataset of SNPs from western and eastern gray whales will provide a test of the hypotheses of gray whale stock structure currently being considered under the Rangewide Review of the Population Structure and Status of North Pacific Gray Whales. Other useful applications include genetic fingerprinting for the identification of individual whales from their biopsies, estimates of relatedness and other population genetics parameters that inform of structure, genetic diversity, and aspects of behavior and reproduction. The SNP panel will provide a useful platform for future studies of gray whales because the results are directly comparable from lab to lab and study to study.

Abstract. Genetic and genomic approaches have much to offer in terms of ecology, evolution, and conservation. To better understand the biology of the gray whale *Eschrichtius robustus* (Lilljeborg, 1861), we sequenced the genome and produced an assembly that contains ~95% of the genes known to be highly conserved among eukaryotes. From this assembly, we annotated 22,711 genes and identified 2,057,254 single-nucleotide polymorphisms (SNPs). Using this assembly, we generated a curated list of candidate genes potentially subject to strong natural selection, including genes associated with osmoregulation, oxygen binding and delivery, and other aspects of marine life. From these candidate genes, we queried 92 autosomal protein-coding markers with a panel of 96 SNPs that also included 2 sexing and 2 mitochondrial markers. Genotyp-

ing error rates, calculated across loci and across 69 intentional replicate samples, were low (0.021%), and observed heterozygosity was 0.33 averaged over all autosomal markers. This level of variability provides substantial discriminatory power across loci (mean probability of identity of 1.6×10^{-25} and mean probability of exclusion >0.999 with neither parent known), indicating that these markers provide a powerful means to assess parentage and relatedness in gray whales. We found 29 unique multilocus genotypes represented among our 36 biopsies (indicating that we inadvertently sampled 7 whales twice). In total, we compiled an individual data set of 28 western gray whales (WGSs) and 1 presumptive eastern gray whale (EGW). The lone EGW we sampled was no more or less related to the WGSs than expected by chance alone. The gray whale genomes reported here will enable comparative studies of natural selection in cetaceans, and the SNP markers should be highly informative for future studies of gray whale evolution, population structure, demography, and relatedness.

Introduction

The gray whale *Eschrichtius robustus* (Lilljeborg, 1861) was once common in both the North Pacific and the North

Atlantic Ocean but disappeared from the Atlantic by the early 1700s because of overhunting (Mead and Mitchell, 1984). Contemporary gray whales are found only along the eastern and western coasts of the North Pacific Ocean (Andrews, 1914; Rice and Wolman, 1971; Fig. 1). Here, we follow the convention established by the International Union for Conservation of Nature (IUCN, 2008; Reilly *et al.*, 2008) and refer to an eastern gray whale (EGW) population and a western gray whale (WGW) population. We use WGW to refer to the gray whales that feed in the western North Pacific off the coast of Sakhalin Island, Russia (Fig. 1). The IUCN considers the extant WGW population to be critically endangered (IUCN, 2008; Reilly *et al.*, 2008), as there were only about 140 WGW adults in 2012 (Cooke *et al.*, 2013), and the population was previously believed to be extinct (Bowen, 1974; Weller *et al.*, 2002). The EGW population was reduced to a low of about 2000 individuals and has since made a strong recovery; the contemporary population numbers about 19,000 individuals (Laake *et al.*, 2009; Durban *et al.*, 2015).

Like so many of the great whales, modern gray whale populations declined steeply during the commercial whaling era (Mead and Mitchell, 1984; Alter *et al.*, 2012). On the basis of whaling records, Henderson (1984) estimated the size of the EGW population at 15,000–20,000 individuals prior to commercial hunting. The prewhaling WGW population is thought to have been much smaller (see Berzin and Vladimirov, 1981), but they were apparently not as restricted in geographic range as they are today (Reeves *et al.*, 2008).

Gray whales are occasionally sighted along a historical western migration corridor that includes waters near Russia's Sakhalin Island in the Sea of Okhotsk (Weller *et al.*, 2008; Weller and Brownell, 2012; Fig. 1). Studies based on the maternally inherited mitochondrial DNA (mtDNA) genome have documented genetic differentiation between the WGWs sampled near Sakhalin and the EGW population (LeDuc *et al.*, 2002; Alter *et al.*, 2012; Meschersky *et al.*, 2015). Geospatial and genetic data (*e.g.*, Alter *et al.*, 2015; Mate *et al.*, 2015) suggest that the extant WGW and EGW populations have the potential to mix, and thus contemporary signals of population differentiation may represent historical patterns. Gray whales have great capacity to travel long distances (>22,000 km; Scheinin *et al.*, 2011; Shpak *et al.*, 2013), and in other great whales (*e.g.*, sperm whales; Alexander *et al.*, 2016) nuclear gene pools are nearly homogenous across vast geographic scales. The development of additional, more powerful genetic assays would be a boon to global gray whale conservation, as the ability to identify individuals and family groups, delineate populations, and track patterns of genetic diversity over space and time would result in more informed management decisions.

Suites of single-nucleotide polymorphisms (SNPs) can be used to delineate breaks in genetic structure, but they can also be used for definitive individual identifications (*e.g.*, from biopsies) and for categorical assignment of parentage or relatedness (*e.g.*, Ruegg *et al.*, 2014; Doyle *et al.*, 2016). Here, we developed a gray whale SNP panel to facilitate genetic stud-

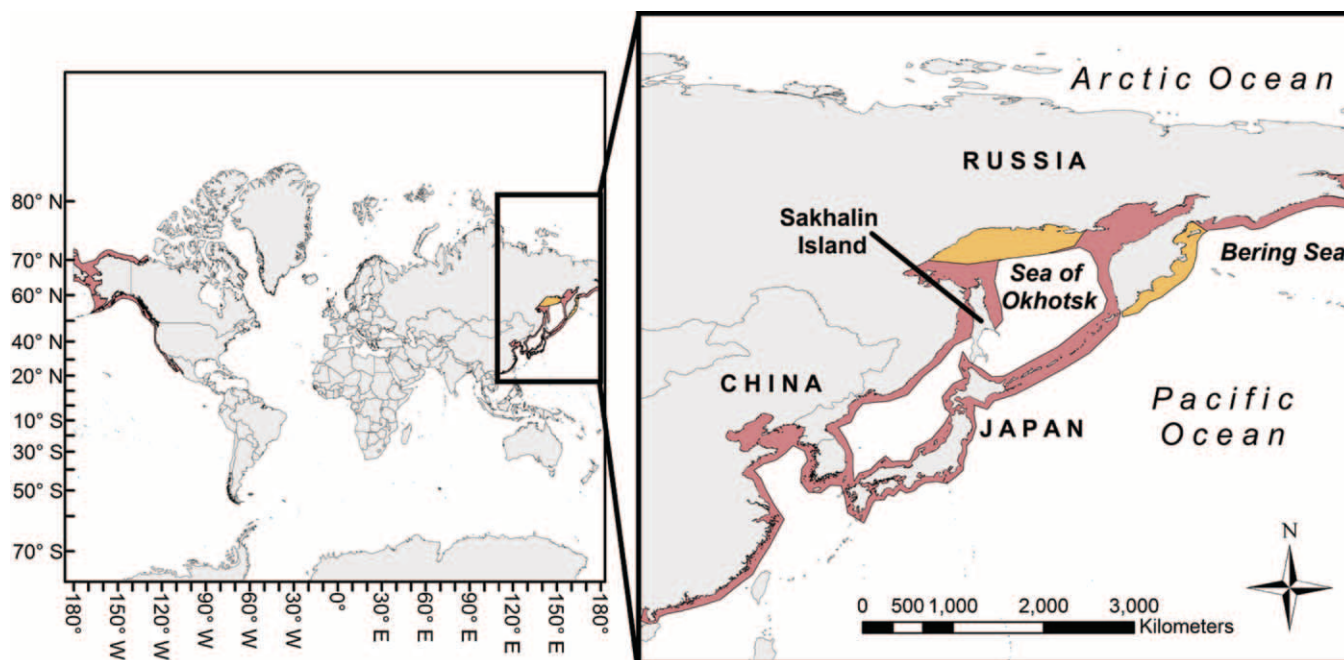

Figure 1. Range map of the gray whale according to 2008 International Union for Conservation of Nature (IUCN) data (which may not perfectly mirror the current range, particularly in the western Pacific). The red shading represents the “extant” portion of the range, and the orange shading represents the “probably extant” portion, according to the IUCN. *Inset:* presumptive range of the western gray whale.

ies of population differentiation, parentage, and individual identity. Instead of using anonymous SNP markers, we used SNPs from protein-coding genes thought to be targets of selection in other marine mammals because, in addition to providing a rich source of targets for future evolutionary genetic studies, they also have the potential to reveal subtle genetic differentiation sooner than neutral markers because of selection (Hoban *et al.*, 2016; Schweizer *et al.*, 2016).

To develop our SNP panel, we sequenced the genomes of two Sakhalin Island gray whales (a male and a female WGW) and a female EGW from Barrow, Alaska. Subsequently, multilocus SNP genotypes were generated for the single EGW plus a set of WGW biopsy samples ($n = 35$) collected near Sakhalin Island to provide a preliminary estimate of genomic diversity in gray whales. Our sample sizes are small despite three years of effort because these whales are rare and, like other baleen whales, difficult to sample because of both the expense involved and their extensive movements. However, the genome we describe here will allow researchers to explore evolutionary aspects of gray whales (*e.g.*, rates of nucleotide substitution) and perhaps identify genes and pathways unique to the species.

Materials and Methods

Sample collection and DNA extraction

Skin biopsies were obtained from WGWs on their summer feeding grounds near Sakhalin Island using methods approved by the Scientific Committee of the International Whaling Commission. These include samples from six calves as well as adults. Biopsy samples were frozen and shipped to Purdue University for processing. Skin samples from putative EGWs ($n = 2$) were cut from two dead gray whales that beached near Barrow, Alaska, and then frozen until processing at Purdue University. Genomic DNA was extracted using a standard potassium acetate protocol (Sambrook and Russell, 2001).

Genome sequencing, assembly, and annotation

The quality and quantity of DNA were greatest from the two WGWs (male ER-14-168 and female ER-14-0147), but we also sequenced one EGW (female GFD-02). For the male WGW, we constructed one paired-end (PE) library without polymerase chain reaction (PCR) amplification and one mate-paired (MP) no-gel library. For the two female gray whales (WGW and EGW), we constructed both MP and PE libraries. PE libraries were constructed per the instructions from the TruSeq DNA PCR-Free Library Preparation Kit (Illumina, San Diego, CA) using the 550-bp insert size method, whereas MP libraries were constructed per the instructions from the Nextera Mate Pair Library Preparation Kit (Illumina) using the “no gel size selection” method. In total, we sequenced 7 lanes of the PE libraries and 1 lane of the MP libraries using an Illumina HiSeq 2500 sequencing system (2×100).

We used FastQC software (ver. 0.11.2; Babraham Bioinformatics, 2016) to generate summary statistics for the sequencing data. Trimmomatic software (ver. 0.32; Bolger *et al.*, 2014) was used to remove adaptor sequences and low-quality bases (Phred scores <20). Multiple genome assemblies were generated using ABySS software (ver. 1.9.0; Simpson *et al.*, 2009) with a variety of k -mer values to produce the most comprehensive assemblies. We used the PE data during the contig-building steps and MP data during the scaffold-building steps.

Genome annotation was based on the male WGW to include genes found on the Y chromosome (*Zfy*) and the X chromosome (*Zfx*). We used the MAKER pipeline (ver. 2.28; Cantarel *et al.*, 2008) for annotation, following Doyle *et al.* (2014). Briefly, RepeatMasker software was used to identify and mask stretches of repetitive DNA. We subsequently used SNAP software (ver. 2013-02-16; Korf, 2004) to generate *ab initio* gene predictions. SNAP was trained (*i.e.*, gray whale gene models were generated) using cetacean protein sequences from the UniProtKB/Swiss-Prot database. SNAP gene predictions supported by expressed sequence tag (EST), protein, or InterProScan evidence were elevated to gene annotations. Cetacean protein data were downloaded from the UniProt Knowledgebase (Uniprot Consortium, 2017), and the manually annotated sequences were used with EST evidence derived from an assembled transcriptome of an Alaskan bowhead whale (Keane *et al.*, 2015). We used CEGMA software to assess the completeness of our genome assemblies (Parra *et al.*, 2007).

SNP identification and development

From published cetacean data, we generated a manually curated list of candidate genes potentially subject to strong natural selection. These include genes associated with osmoregulation, oxygen binding and delivery, and many other aspects of marine life (hereafter referred to as “nonneutral” or “candidate” genes; see Table S1 [available online], Table S2 [available online], and Kosiol *et al.*, 2008). We targeted SNPs from these genes because they can provide insights into adaptive divergence (Rico *et al.*, 2016), because they can help determine the biological significance of population genetic structure (Miller *et al.*, 2010), and because they can provide more power for population assignments (Freemo *et al.*, 2011; Helyar *et al.*, 2011). Using the MAKER transcripts from our genome annotation, we used BLAST software (ver. 2.2.31+) to annotate these candidate genes in the gray whale genome. For SNP identification, we used BWA software (ver. 0.7.12; Li and Durbin, 2009) to map all PE reads to the male assembly. We used GATK software (ver. 3.4; DePristo *et al.*, 2011; Van der Auwera *et al.*, 2013) to (1) identify and realign reads around insertions/deletions (indels), (2) identify SNPs with a minimum Phred quality score of 30 and a minimum depth of 10 reads, and (3) disregard SNPs within 20 bp of each other.

BEDOPS software (ver. 2.0; Neph *et al.*, 2012) was used to identify variable sites (*i.e.*, SNPs) within nonneutral genes. We used IGV software (ver. 2.3; Thorvaldsdóttir *et al.*, 2013) to identify target SNPs with at least 60 nucleotides (nt) of high-quality flanking sequence upstream and downstream and guanine and cytosine (GC) content less than 65%. We deliberately minimized linkage disequilibrium (LD) by choosing only single SNPs from a given scaffold.

Ultimately, we attempted to develop 92 autosomal nuclear markers from protein-coding genes specifically targeted because of evidence for selection in other marine mammals. Following preliminary population surveys *via* dideoxy sequencing (Alter and Palumbi 2009), we designed two mtDNA markers for haplotyping. For sexing, we designed two redundant SNP assays to assess differences in nucleotide sequence between the *Zfx* and *Zfy* genes, as reported in GenBank entries AF260789.1, AF260790.1, and AF260791.1.

SNP genotyping, error rates, and variability

We genotyped 36 gray whale biopsy samples at the 96 candidate SNP markers. Samples were genotyped using a Fluidigm Juno Genotyping System (Fluidigm, South San Francisco, CA), and a specific target amplification (STA) step was incorporated to facilitate genotyping of the low-quantity DNA samples that are often associated with endangered species. The STA step refers to Fluidigm's multiplex PCR, which uses a low molar concentration of each primer and limited thermal cycles to increase template material for downstream amplification. Individual SNP calls were visualized and edited using Fluidigm's genotyping analysis software; data from nuclear loci that did not produce obvious clusters of homozygotes and heterozygotes (see Fig. 2) were excluded from further analyses.

In theory, our 35 WGW biopsies could include whales that were inadvertently sampled more than once (*e.g.*, in subsequent years). We used allelematch in R software (Galpern *et al.*, 2012; R Development Core Team, 2008) to group replicate genotypes into unique records that represent individual whales, allowing for a maximum of two mismatches between replicates. Preliminary analyses conducted with the diagnostic function amUniqueProfile were used to determine the number of mismatches most appropriate for clustering replicate genotypes into groups (Galpern *et al.*, 2012). All genotypes identified as replicates were subsequently confirmed by manually evaluating the SNP calls.

Error rates were calculated using replicate DNA samples ($n = 69$ in total) from 27 individual gray whales. The plurality principle was used to determine a consensus genotype for each individual whale by using SNP calls across replicate samples (see Doyle *et al.*, 2016). The SNP typing error rate (e) was calculated according to the equation $e = m/[d(s)]$, where m represents the total number of mismatches between each replicate sample and the consensus sequence across mul-

Figure 2. Example of high-quality Fluidigm data from an autosomal whale single-nucleotide polymorphism: clustering results for locus 11737172_20296. GG homozygotes are shown in green, heterozygotes are shown in blue, and TT homozygotes are shown in red. The negative control is shown as the black data point. NFU, normalized fluorescence units.

tiples from the same individual, d represents the total number of loci per replicate sample, and s represents the total number of replicate samples. Both incorrect SNP calls (errors of commission) and instances where no amplification occurred (errors of omission) contributed to m .

We used GENALEX software (ver. 6.5; Peakall and Smouse, 2012) to quantify observed (H_O) and expected (H_E) heterozygosity, the mean probability of identity (P_I), and the mean probability of exclusion with neither parent known (P_E). We tested for deviations from Hardy-Weinberg equilibrium (HWE) and for LD after applying a sequential Bonferroni correction to account for multiple tests (Holm, 1979). The inbreeding coefficient f (Weir and Cockerham, 1984) was evaluated in GENODIVE software (ver. 2.0b27; Meirmans and Van Tienderen, 2004) using 10^3 permutations.

Molecular sexing and haplotyping

For validation purposes, all samples were sexed using a traditional PCR/gel method (Bérubé and Palsboll, 1996) as well as by using our novel sexing SNPs. Similarly, mtDNA haplotypes were generated using both traditional dideoxy methods (Alter and Palumbi, 2009) and novel SNP markers. We then compared the concordance among assays to validate our novel markers.

Relatedness and effective size

Relatedness among individuals was first estimated using RELATED software (ver. 1.0; Wang, 2011; Pew *et al.*, 2015), which implements five widely used moment-based related-

ness estimators. To identify the estimator that performed best with our data, we used our empirical allele frequencies to simulate 100 data sets for 4 types of dyads: parent-offspring pairs (expected $r = 0.5$), full siblings ($r = 0.5$), half siblings ($r = 0.25$), and unrelated individuals ($r = 0.0$). Point estimates and 95% confidence intervals (CIs) were estimated on the basis of 100 bootstrap replicates, and the best estimator was identified using Pearson's correlation coefficient. This estimator was used to compare the observed mean pairwise relatedness of each individual whale (r_{pw}) to the mean for the population (r_{pop}). Thus, r_{pw} represents the mean relatedness of a single individual whale to every other whale in the population, whereas r_{pop} represents the mean relatedness of the population as a whole. By comparing r_{pw} to r_{pop} , individual whales were identified that were more or less related to the population than expected by chance alone.

Because several commonly used relatedness estimators can be problematic when used with biallelic loci (Oliehoek *et al.*, 2006), we also calculated a pairwise genotypic similarity index following Blouin *et al.* (1996). The M_{xy} statistic quantifies the mean number of shared alleles (M_{xy}) among pairs of samples (in our case, 630 pairs). For each locus, the number of matching allelic positions (0, 1, or 2) between pairs of individuals was determined using only loci with no missing data among a given pair of whales. For each individual sample ($n = 36$), we calculated mean observed M_{xy} and 95% CI, which was compared with the population mean and 95% CI.

Conventional relatedness and allele-sharing approaches like those described above do not differentiate between relationship categories. For example, both parent-offspring pairs and full-sibling pairs are expected to have $r = 0.5$. CERVUS software (ver. 3.0.7; Marshall *et al.*, 1998; Kalinowski *et al.*, 2007) was used to assign parentage to calves. All adults identified in the field were considered candidate parents. Simulations included 100,000 replicate cycles with the number of candidate males and females set to 200 and the proportion of candidate males and females sampled set to 0.1. The proportion of loci mistyped was set to 0.0002, and the minimum allowable confidence level at which a parent assignment was accepted was 95%.

To provide preliminary estimates of contemporary effective population size (n_e) and effective number of breeders (n_{eb}) of the critically endangered GWG population, we used NeESTIMATOR software (ver. 2.01; Do *et al.*, 2014). The software implements two different methods for estimating n_e from a single sample, based on (1) LD (Waples and Do, 2008) and (2) heterozygosity excess (Zhdanova and Pudovkin, 2008). A molecular coancestry approach (Nomura, 2008)—also implemented in NeESTIMATOR—was used for estimating n_{eb} . Note that these methods assume selectively neutral markers and closed populations, so these n_e and n_{eb} estimates may be biased. Moreover, the influence of selection and migration on such estimates is unknown, as it has not been investigated in a thorough, systematic manner (Waples, 2006).

Results

Genome sequencing, assembly, and annotation

Our GWG sequencing results are compiled in Tables 1 and 2; the EGW genome yielded a poor-quality sequence and was not assembled. We generated >2.5 billion reads (~2 billion high-quality reads after quality control) that collectively span ~200 billion bases and contain nearly all of the core genes common to eukaryotes (Tables 1, 2). The scaffold N50, which represents the value where more than half of the assembly is contained in larger contiguous regions, was ~180,000 bp for the best assembly. We annotated roughly 22,700 genes, a number similar to other cetacean genome studies (Tables S1, S6, available online).

SNP identification and development

We identified 2,057,254 candidate SNPs from the GWGs, of which 1,474,749 passed quality-filtering criteria. Of this high-quality subset, 8413 SNPs were located in exons that were identified in the genome annotation. From these exonic SNPs, we designed and tested 96 SNPs for our genotyping assay. Four were ultimately excluded because they were monomorphic, clustered poorly, or were otherwise of insufficient quality. These novel SNP loci and flanking sequences are described in Table S5, available online. The 92 informative loci include 88 gene-associated nuclear markers, 2 mitochondrial markers, and 2 nuclear sexing markers (Table S2, available online).

SNP genotyping, variability, and error rates

The vast majority of markers amplified in each individual DNA sample. By genotyping 27 of the 36 biopsy samples multiple times, we calculated an overall genotyping error rate (e) of 0.021%. The mean probability of identity (P_i ; Waits *et al.*, 2001) was 1.6×10^{-25} , and the mean probability of exclusion (P_E ; Jamieson and Taylor, 1997) with neither parent known was >0.999. According to allelematch, the 36 biopsies represented a total of 29 unique multilocus genotypes that correspond to 29 individual gray whales (*i.e.*, we inadvertently sampled 7 whales twice). Observed and expected heterozygosities at autosomal SNPs were 0.32 ± 0.19 (mean \pm SD) and 0.31 ± 0.17 , respectively, for all GWGs sampled ($n = 28$). All autosomal SNP loci were in HWE following sequential Bonferroni correction (Table S3, available online). The H_O and H_E of male whales ($n = 11$) averaged 0.31 ± 0.02 and 0.29 ± 0.02 , respectively, across all autosomal markers, whereas the H_O and H_E of female whales ($n = 17$) averaged 0.33 ± 0.02 and 0.31 ± 0.02 , respectively. The mean inbreeding coefficient (f) was -0.05 .

Molecular sexing and haplotyping

Samples from the 29 individual gray whales were sexed using both our novel SNP assays and the traditional method

Table 1*Sequencing statistics associated with the western gray whale genome*

Sample name	Mean insert size (bp)	Mode insert size (bp)	Total reads	Total bases	Quality reads	Quality bases
Paired-end libraries						
ER-14-0147	471	481	1,331,820,280	134,513,848,280	988,439,854	97,099,230,094
ER-14-0168	497	506	1,254,676,990	126,722,375,990	974,126,824	95,896,562,771
Mate-paired libraries						
ER-14-0147	2223	1463	184,404,728	18,624,877,528	146,095,780	13,350,014,231
ER-14-0168	2363	1426	213,408,466	21,554,255,066	168,844,292	15,387,314,171

with PCR and gel electrophoresis (Table 3). The results of the 2 methods were in complete concordance with one another (see Fig. 3), indicating that our samples were derived from 11 males and 18 females. These same samples were haplotyped using both our mtDNA SNP assays as well as traditional Sanger sequencing. Although our marker set queries only two mtDNA sites, this marker panel could easily be extended to other SNP sites known to be variable in gray whales; we provide here the proof-of-concept data.

Relatedness and effective size

Mean pairwise relatedness (r_{pop}) observed among all 29 individual gray whales (including one EGW individual) was -0.032 , and the 95% CI ranged from -0.055 to -0.009 . In general, relatedness estimates based on r and on M_{xy} were qualitatively similar, so we focused on M_{xy} for reasons discussed in Oliehoek *et al.* (2006). Our analysis of pairwise relatedness confirmed the allelematch results in that 7 of our biopsies were duplicates. For example, the mean number of shared alleles (M_{xy}) ranged from 0.667 to 1.0 for all 630 pairwise comparisons (Fig. 4), including the 7 duplicate biopsy pairs identified by allelematch, all of which had $M_{xy} = 1.0$. Many dyads were likely first-degree relatives (*e.g.*, full siblings or parent-offspring pairs). The mean number of shared alleles for each of the 29 individual whales ranged from 0.768 to 0.851 (Fig. 5). The population mean $M_{xy(\text{pop})}$ was 0.834 (95% CI: 0.831–0.838; Fig. 5).

The CERVUS analyses were used to investigate suspected relationships among two ostensible cow-calf pairs. CERVUS confirmed one such relationship (ER14-0159/ER14-0173) on the basis of field observations but not the other (ER14-0152/ER14-0172). No sires were identified in our sample, but our relatedness analyses identified two potential full sisters (ER14-0162 and ER14-0173; pairwise $r = 0.483$). These two adult females apparently share the same mother (ER14-0174/ER14-0159).

The n_e estimates of contemporary GWG were similar based on LD (mean $n_e = 14.1$; 95% CI: 12.1–16.7) and heterozygosity excess (mean $n_e = 14.4$; 95% CI: 7.6–254.1). The effective number of breeders, based on individual co-ancestry, was 1.3 (95% CI: 1.0–1.7).

Discussion

Genome sequencing, assembly, and annotation

The gray whale genome assemblies we describe (Tables 1, 2) consist of ~22,700 genes and contain ~95% of the genes known to be highly conserved among eukaryotes (Parra *et al.*, 2007). These assemblies are relatively complete and reveal that the gray whale genome appears to be fairly typical of cetaceans in terms of genome size and gene complement (Table S1, available online). Foote *et al.* (2015) have argued that the genomes of marine mammals have evolved in a convergent fashion, and future research will determine what propor-

Table 2*Summary statistics generated by ABySS software for the western gray whale genome assemblies*

Sample	Contig N50	Scaffolds	Assembly size	Min. length	Max. length	Scaffold N50	$n : N50$	Comp%
ER-14-0147	8336	60,534	3,082,450,012	500	1,943,192	180,882	4539	95
ER-14-0168	8690	57,219	2,849,466,389	500	1,944,941	187,455	4089	96

In both cases, a k -mer length of 60 produced the best assemblies shown here. The contigs were created from the paired-end reads, and then the mate-paired reads were used to scaffold the final assembly. The N50, measured in bases, represents a midpoint whereby half of the assembled sequence is contained in contigs or scaffolds larger than the N50. “ $n : N50$ ” refers to the number of scaffolds of length N50 and longer. “Comp%” refers to the percentage of 248 ultraconserved core eukaryotic genes detected in the gray whale assembly (Parra *et al.*, 2007). Ultraconserved genes that were not identified in the gray whale assembly can be found in Table S4, available online.

Shown are genotypes for two mitochondrial (CR_82 and CR_104) and two sexing (ZFY_288 and ZFY_342) markers. A missing genotype is represented by an ellipsis.

tion of the gray whale genes we annotated (Table S1) are orthologues of the 16,878 genes shared by the killer whale, manatee, walrus, and bottlenose dolphin (Foote *et al.*, 2015) and what proportion are paralogues resulting from gene duplication. We expect that many of these species have faced similar selection pressures with regard to genes involved in processes such as osmoregulation (*e.g.*, adaptation to a saline environment), thermoregulation (*e.g.*, adipose deposition), and oxygen binding.

SNP identification and development

From the genomic sequence data, we identified hundreds of thousands of SNPs that could potentially be used in population genetic surveys. Of these, we evaluated 96 and found that 92 were polymorphic, had low error rates, and could be amplified in a single assay. This panel of markers should be sufficient for investigations of genetic parentage, relatedness, individuality (*i.e.*, DNA fingerprinting), demographic turnover, and population structure. However, the much larger set

of SNPs we identified could inform future genome scans based on restriction-site-associated DNA sequencing (Miller *et al.*, 2007) or other queries of anonymous SNPs that might also be informative for studies of natural selection and/or demographic history. We note that our markers are useful in the critically endangered GWs, so we expect them to be variable in the more plentiful EGWs. However, robust allele frequency estimates will be needed to assess their utility in EGWs (and to search for potential ascertainment biases).

SNP genotyping, variability, and error rates

The oligonucleotides we developed and the SNPs they query were assessed with the Fluidigm platform because it requires very little DNA. We note, however, that our markers could instead be assayed with alternative genotyping technologies. Because these markers are polymorphic and have low error rates (~0.02%), we expect laboratory-to-laboratory variability to be low, as 99.98% of our replicate data were identical across independent genotyping runs. For example,

Figure 3. Perfect concordance between (A) the traditional polymerase chain reaction/gel method and (B) our novel single-nucleotide polymorphism sexing assays. (A) demonstrates that the traditional method produces a single product in females (Zfx) and two products in males (Zfx and Sry); also shown are a no-template control and a size standard. (B) demonstrates that males (blue) and females (red) can be distinguished from one another based on HEX and FAM intensity measured in normalized fluorescence units (NFU).

a whale from the western Pacific that is genotyped with these SNPs could be identified as one also sampled in the eastern Pacific provided the genotypes are stored in a common database that could easily be queried by independent research groups (e.g., in a public database on the cloud).

The power available for individual identification and parentage is captured by P_I and P_E , respectively. In theory (based on allele frequencies in our small sample of WGWs), mean $P_I = 1.6 \times 10^{-25}$. In practice, our limited sampling revealed multiple biopsies from the same donor whales (see below). Similarly, a calf's unknown parentage could be determined among hundreds of candidate parents with virtual certainty if all were genotyped with this SNP panel ($P_E >$

0.999). For applications that require more power, our genome data include a large pool of additional SNPs that could serve as supplemental markers.

Relatedness and effective size

The WGW is critically endangered, and although our sample consisted of only 28 WGW individuals, this is ~20% of the estimated population (Cooke *et al.*, 2013). Our relatedness analysis indicated that a number of our biopsies came from the same whales; seven pairs of samples were found to have identical SNP genotypes across all loci. Given the paucity of WGWs, it is not entirely surprising that over multiple field seasons we (inadvertently) sampled seven individuals twice. Furthermore, a number of individual pairs were apparently derived from close relatives (Figs. 4, 5) that may represent parent-offspring pairs, full siblings, half siblings, and other close relatives. We identified two distinct cow/calf pairs and one ostensible full-sibling pair. Finally, the mean inbreeding coefficient is generally consistent with random mating within the WGW population. Overall, these results illustrate the power of genetic analyses for corroborating or overturning relationships suspected on the basis of fieldwork.

All of our population inferences are necessarily preliminary due to small sample sizes, but we include them here because of the keen interest in the conservation of the WGW population. Whether the population near Sakhalin Island is composed of WGWs, EGWs, or a mixed aggregation of the two stocks is under study by the International Whaling Commission (IWC, 2015). The putative EGW we sampled was no more or less related to the WGW population than expected by chance alone (Fig. 5). If the EGW was derived from an independent gene pool, it should have been more distantly related to the WGW population.

Populations with small effective sizes diverge rapidly due to drift and inbreeding (Wang and Caballero, 1999). Our small estimates of gray whale n_e ($n_e \approx 14$ by both LD and heterozygosity excess) are consistent with each other, with the idea that the extant WGW population is very small, and with published data indicating that the WGW population is genetically differentiated from the EGW population (e.g., LeDuc *et al.*, 2002; Alter *et al.*, 2012; Meschersky *et al.*, 2015). Such genetic differentiation may be due to population structure associated with divergent selection, genetic drift, and/or a lack of migration (gene flow) among gray whale populations. Additional sampling across the range of the gray whale will be required to differentiate among these possibilities, but the genome sequence and the genotyping platform we describe here should enable those efforts.

Conclusions

Here, we describe the gray whale genome and the development of a gray whale genotyping assay that queries 92 autosomal nuclear SNPs (88 gene-associated autosomal mark-

Figure 4. Distribution of average number of shared alleles (M_{xy}) among each possible pair ($n = 630$ pairwise comparisons) of gray whale biopsies ($n = 36$). Seven pairs of biopsies were inadvertently collected from the same individual whales, indicated by black dots clustered at the right tail of the distribution (*i.e.*, $M_{xy} = 1.0$).

ers, 2 mitochondrial markers, and 2 sex-chromosome markers). We validated these markers by repeated genotyping of 36 gray whale samples and determined that the error rates were low and the markers were polymorphic despite small effective population sizes. The single whale we sampled from the eastern population could not be genetically distinguished

from the 28 gray whales we sampled near Sakhalin Island, but our markers provide a powerful platform for distinguishing among individuals and kin (*e.g.*, identifying close relatives). Ultimately, these markers should prove a useful resource for biologists and for the broader conservation community given the difficulty and expense associated with sampling and iden-

Figure 5. Distribution of individual relatedness values (M_{xy}) and their associated 95% confidence intervals (CIs). The mean pairwise relatedness among all 29 individuals in the population (*i.e.*, 406 pairwise comparisons where mean $M_{xy} = 0.834$) is shown as a solid black line, and the 95% CI (0.831–0.838) is shown as dashed lines. For each individual, M_{xy} is indicated as a dot and the 95% CI is shown as a vertical bar. Note that GFD02, the lone eastern gray whale (EGW), is no more or less related to the population than expected on the basis of chance alone. This plot is based on Blouin *et al.*'s (1996) M_{xy} estimator, but Queller and Goodnight's (1989) estimator produced qualitatively similar results with regard to the lone EGW.

tifying baleen whales. Furthermore, the genome sequence will serve as a resource for basic studies across a diversity of disciplines.

Acknowledgments

We thank the International Whaling Commission (IWC) and Aimée Lang for curating the 2011 western gray whale samples provided *via* the IWC. This work was conducted under the National Marine Fisheries Service (NMFS) Office of Protected Resources' Marine Mammal Health and Stranding Response Program permits 932-1905-MA-009526 and 18786 and Convention on the International Trade in Endangered Species of Wild Fauna and Flora permit 13US082589/9. This work was supported by Exxon Neftegas Limited and the Sakhalin Energy Investment Company. Both collaborative agencies and funding parties received annual progress reports for the past several years. The content presented here is solely the responsibility of the authors and does not necessarily represent the official views of the funding parties. We also thank Teri Rowles (NMFS) for assistance with the project. A. Aziz, J. Dupont, M. Scott, and M. Swindoll provided support in obtaining the biopsies and associated metadata. The Institute of Ecology and Evolution of the Russian Academy of Sciences, the A. V. Zhirmunsky Institute of Marine Biology Far Eastern Branch, and Oregon State University provided invaluable support for the collection of the western gray whale samples. We thank E. Srour and A. Cardoso (Indiana University School of Medicine) for laboratory assistance and support. C. George and R. Suydam (Department of Wildlife Management, North Slope Borough of Alaska) provided the putative eastern gray whale samples. Finally, we thank S. Fears, Y. Ji, M. Sundaram, and J. Willoughby for constructive comments.

Data Accessibility

We have deposited the primary data underlying these analyses into the National Center for Biotechnology Information's Short Read Archive (study accession SRP105779; BioProject PRJNA384396), in the Dryad Digital Repository (DeWoody *et al.*, 2017), and in the associated online supplementary material (Tables S1–S6).

Lack of nuclear differentiation suggests reproductive connectivity between the ‘southern feeding group’ and the larger population of eastern North Pacific gray whales, despite previous detection of mitochondrial differences

ABSTRACT

During winter, eastern North Pacific gray whales migrate south to calving grounds in the lagoons of Baja California, and in spring they migrate north to their summer feeding grounds in the Chukchi and Beaufort Seas. Although the majority of the population makes this migration, a small subset of the population known as the ‘southern feeding group’ ends their northward migration early, spending summers feeding in waters ranging from northern California to southern Alaska. Previous analyses based on photo-ID and mtDNA data indicate that this seasonal substructuring results from maternally-directed site fidelity to different feeding grounds, and that this site fidelity and feeding ground preference is passed from mothers to their offspring. It is currently assumed, but not known, that the individuals of the southern feeding group mate with the rest of the population, and therefore that the eastern North Pacific gray whale represents one interbreeding population. Testing this assumption and understanding how these whales are related to the rest of the population, is key to making appropriate management decisions, which are particularly relevant given the recent increase in potential removals, or threats in the area such as the proposed resumption of aboriginal whaling, and increased oil pipeline development and subsequent vessel traffic. This paper analyses 15 nuclear microsatellite loci in 59 individuals from the southern feeding group and 40 individuals from the calving lagoons (representative of the larger population) to test the hypothesis that the eastern North Pacific gray whale represents one interbreeding population. No indication of population substructuring was found based on these nuclear loci, suggesting that all sampled whales do indeed represent one interbreeding population. Combined, these data from mitochondrial and nuclear markers therefore suggest one interbreeding population that is seasonally subdivided based on maternally-directed site fidelity to different feeding areas.

KEYWORDS: EASTERN NORTH PACIFIC; GRAY WHALE; REPRODUCTION; WHALING–ABORIGINAL; FEEDING GROUNDS; GENETICS; SITE FIDELITY; SEGREGATION

INTRODUCTION

The eastern North Pacific gray whale (*Eschrichtius robustus*) was extensively hunted from the mid-1800s through the early 1900s, reducing the population to just a fraction of its estimated pre-exploitation population size (Butterworth *et al.*, 2002; Henderson, 1984; Reilly, 1992). However, since gaining international protection, the population has steadily increased to roughly 20,000 individuals (Laake *et al.*, 2012; Rugh *et al.*, 2005; Sheldon and Laake, 2002). This recovery resulted in the removal of this population from the US Endangered Species List in 1994, and some data suggest it has recovered to its pre-exploitation population size (Alter *et al.*, 2007; Moore *et al.*, 2001; Rugh *et al.*, 2005; Wade, 2002). Despite this recovery, the population is still faced with numerous threats throughout its range, particularly in the area encompassing the Pacific northwest of the USA and the Pacific southwest of Canada (roughly Northern California through southeast Alaska). Here, there are several proposed activities where informed management will be critical. These include the proposed resumption of gray whale hunts by some aboriginal groups, the development of new oil pipelines off the British Columbia coast and the subsequent increase in tanker traffic for shipping oil to Asia.

One of the primary topics of relevance to management is population structure: how individuals are divided in space

and/or time such that some groups may be differentially affected by direct hunting or by non-intentional threats. If such structuring exists, then the different groups often require separate management/conservation consideration because the detrimental effects will not be spread evenly throughout the population, but instead will disproportionately affect the different groups (e.g. Hoelzel, 1998; Taylor, 2005; Wang, 2009). Such localised impacts on structured populations, if not considered, can nullify otherwise well-planned management/conservation initiatives. Indeed, there are several case studies where the effectiveness of conservation actions has been compromised because population structure was not taken into consideration (e.g. Daugherty *et al.*, 1990; Frankham *et al.*, 2002).

Previous studies have detected seasonal population substructuring in the eastern North Pacific gray whale in relation to summer feeding ground use (Frasier *et al.*, 2011). As with many other baleen whales, gray whales show a seasonal migration from low-latitude calving grounds in the winter to high-latitude feeding grounds in the summer. The winter calving grounds for this population are located in the lagoons of Baja California (Findley and Vidal, 2002; Swartz, 1986; Swartz *et al.*, 2006), whereas during the summer the majority of the population feeds in the Bering and Chukchi Seas (Moore and Ljungblad, 1984). However, there is a small

³Departamento de Biología Marina, Universidad Autónoma Baja California Sur, La Paz, BCS 23081, Mexico.

subset of the population—estimated at roughly 200 individuals (Calambokidis *et al.*, 2002) that spends the summer in lower-latitude feeding areas ranging from northern California to southeastern Alaska (Calambokidis *et al.*, 2002; Darling, 1984; Hatler and Darling, 1974; Pike, 1962; Swartz *et al.*, 2006). This group is often referred to as the ‘southern feeding group’, but is also referred to as the ‘Pacific coastal feeding group’ by the Scientific Committee of the International Whaling Commission (IWC, 2011; 2013a). Data from photo-ID and mitochondrial DNA (mtDNA) show that this seasonal population substructuring results from maternally-directed site fidelity to different feeding areas, and that this differential use of feeding areas is passed from mothers to offspring (Calambokidis *et al.*, 2002; Calambokidis *et al.*, 2010; Darling, 1984; Frasier *et al.*, 2011). This type of seasonal substructuring is common in baleen whales (e.g. Baker *et al.*, 1990; Malik *et al.*, 1999).

Despite this substructuring during the summer, it has always been assumed, but not known, that individuals from all feeding areas utilise the same mating area(s), and therefore represent one interbreeding population. Unfortunately, there is a lack of clarity regarding where fertilisation likely occurs, and hence where the mating grounds are. Sexual behaviour is frequently observed on the winter calving grounds (e.g. Swartz, 1986), and indeed these are often referred to as ‘breeding grounds’ (e.g. Alter *et al.*, 2009; Goerlitz *et al.*, 2003; Jones, 1990). However, the limited physiological data available actually suggest that fertilisation most often occurs during the southward migration, prior to arrival at the lagoons (Rice and Wolman, 1971). Thus, there is potential for differential feeding area use to also result in substructuring with respect to reproductive patterns.

There is also evidence that individuals show differential use of the calving grounds, with some females showing fidelity to particular lagoons (Jones, 1990; Goerlitz *et al.*, 2003; Alter *et al.*, 2009). Combined, there are enough questions regarding the timing and location of mating, as well as potential for differential habitat use of potential ‘breeding’ grounds, to warrant a full evaluation of the hypothesis of one interbreeding population. This paper uses data from nuclear microsatellite loci to compare genetic data from individuals of the southern feeding group to samples obtained from one of the calving lagoons (Laguna San Ignacio) used here as representatives of the larger population to test the hypothesis that individuals of the southern feeding group interbreed with individuals from the larger population. These data, in combination with previous information regarding structuring of mitochondrial haplotypes, can identify the degree of substructuring of the southern feeding group.

METHODS

Sample collection

Samples used for these analyses were collected over many years as part of other long-term research programmes on eastern North Pacific gray whales: off Vancouver Island, Canada by one of the authors (JDD); and off San Ignacio Bay, Mexico by another (JUR). Specifically, 86 samples from Vancouver Island (representing the southern feeding group, collected from 1996–2010) and 51 samples from San

Ignacio Bay (representing the larger population, collected from 1996–1997) were analysed. All samples were collected using a crossbow and a modified bolt, as is common for collecting small skin samples from free-ranging large whales (Lambertsen, 1987; Palsbøll *et al.*, 1991). This method of sample collection has been extensively scrutinised, has proven to be safe, and does not have any short- or long-term impacts on the whales, other than an immediate startle response (Best *et al.*, 2005; Brown *et al.*, 1991). All sample collection procedures were conducted under permits obtained from the relevant governmental agencies. The timing of sample collection overlaps between the two sample sets, as is appropriate for comparison. The longer time for sample collection off Vancouver Island should not bias the results because the long life span and generation time of gray whales suggest that substantial genetic change within this putative population would take longer than the time interval sampled here. Thus, both sample sets should represent comparable genetic pools for analysis.

Genetic analyses

DNA was extracted from ~40mg of tissue from all samples using standard phenol:chloroform procedures as commonly used for whale skin (e.g. Wang *et al.*, 2008). The quantity of DNA obtained from each sample was estimated based on spectrophotometry using a NanoDrop 2000 (Thermo Scientific Inc.). The quality of DNA obtained (i.e. the amount of DNA degradation) was assessed based on electrophoresis through 2.0% agarose gels stained with SYBR Green I (Invitrogen). Sex was determined for each sample based on PCR amplification of a region on the X and Y chromosomes using the primers described in Gilson *et al.* (1998).

To identify useful microsatellite markers for this study, 23 loci were screened for amplification and variability in gray whales (Table 1). These loci were chosen because previous experience showed that they amplify well, and are highly variable, across a wide range of whale species. Specifically, loci were initially tested based on the amplification of two gray whale samples (one from the southern feeding group and one from the larger population) using annealing temperatures of 50, 55 and 60°C. The reactions contained 10ng of template DNA, 1X PCR Buffer (20 mM Tris pH 8.4, 50 mM KCl), 1.5 mM MgCl₂, 0.05 U/μl *Taq* DNA polymerase (Invitrogen), 0.2 mM each dNTP (Invitrogen), 0.3 μM each primer, and 0.1 mg/ml of bovine serum albumin (BSA) (Invitrogen). The cycling conditions were as follows: an initial denaturing step of 94°C for 5 minutes; 30 cycles of 94°C for 30 seconds, annealing temperature for 1 minute, and 72°C for 1 minute; followed by a final extension step of 60°C for 45 minutes. All PCR was conducted on Veriti® 96-well thermal cyclers (Applied Biosystems). PCR products were then size-separated and visualised via electrophoresis through 1.5% agarose gels stained with ethidium bromide. Loci that showed a clean PCR product (without amplification of multiple regions) were selected for further development.

For primer pairs that amplified well, the forward primer was re-ordered with one of four fluorescent tags (6FAM-Blue, VIC-Green, PET-Red, or NED-Yellow). Each locus was then screened for variation by amplifying 10 samples using the optimal conditions that had previously been

determined. PCR amplification was carried out using the same conditions as described for testing annealing temperatures. PCR products were de-salted via ethanol precipitation (Irwin *et al.*, 2003), and size-separated and visualised on an ABI 3500xl capillary-based genetic analyser (Applied Biosystems).

Based on these amplification data (i.e. peak height and allele ranges) multiplex reactions where multiple loci are amplified simultaneously in the same PCR were developed through testing the amplification of different combinations of loci. These tests resulted in combinations of loci that minimised the number of reactions that were needed to amplify the variable loci. These protocols were then used to genotype all individuals. Alleles were scored using the GeneMarker software (SoftGenetics). Each 96-well plate of samples contained 2 individuals as ‘standards’, meaning that these same two individuals were present on all plates, to ensure consistency in genotyping across plates. All samples were scored by two individuals in a double-blind fashion to identify any potential scoring errors (Morin *et al.*, 2010).

Statistical analyses

Once genotypes for each sample had been obtained, the program CERVUS (Marshall *et al.*, 1998) was used to identify any duplicate genotypes (i.e. individuals that had unknowingly been sampled more than once). Based on these data, duplicate individuals were removed. CERVUS was also used to obtain estimates of allele frequencies and to estimate the frequency of null alleles for each locus. Loci were tested for deviations from linkage and Hardy-Weinberg Equilibrium (HWE) using exact tests as implemented in the program GENEPOP (Rousset, 2008).

Population structure was assessed using ‘classical’ approaches based on estimating differentiation of allele frequencies between pre-defined groups of individuals and Bayesian techniques. Classical methods have the benefit of

being far more powerful than available Bayesian methods but have the detriment of requiring pre-defined groups of individuals, which may or may not represent the real biological patterns (e.g. Waples and Gaggiotti, 2006). On the other hand, Bayesian methods allow for simultaneous assessment of the number of groups represented by the sampled individuals and the assignment of individuals to those groups (and therefore do not requiring pre-defined groupings) but suffer from lower power.

The classical assessment of population differentiation was conducted using the program GENEPOP. Here, individuals were categorised as representing either the southern feeding group or the larger population, based on sampling location. Specifically, samples collected off Vancouver Island were classified as the southern feeding group, while samples collected on the calving grounds off Baja California were classified as representing the larger population. Based on this division, estimates of F_{ST} were obtained and exact tests of population differentiation were conducted.

To assess the power to detect population structure using the methods implemented in GENEPOP (exact tests), the simulation program POWSIM (Ryman and Palm, 2006) was used. Specifically, conditions were simulated that would result in differing levels of differentiation ($F_{ST} = 0.001, 0.0025, 0.005, 0.01, 0.025, \text{ and } 0.05$), given the characteristics of the loci. There are two biologically realistic scenarios that can result in the same F_{ST} value. First, two populations that are not completely isolated will eventually reach an equilibrium F_{ST} value dependent upon the migration rate between populations (N_m). Second, if two populations have recently become reproductively isolated, they will drift apart, with F_{ST} values increasing with increasing time since divergence. POWSIM obtains desired F_{ST} values under the latter scenario by generating a single simulated population and then splitting it into equally sized populations with complete isolation once the split occurs. In this way, different F_{ST} values are obtained based on the number of generations that have passed since the split. Thus, users obtain estimates of the power to detect different degrees of differentiation by selecting combinations of N_e and t that result in the desired F_{ST} value, where $F_{ST} = 1 - (1 - 1/2N_e)^t$ (e.g. Nei, 1987, p.359). Due to uncertainty regarding N_e for the two putative gray whale populations, power to detect the different F_{ST} values (0.001, 0.0025, 0.005, 0.01, 0.02, 0.025, and 0.05) was estimated using N_e values spanning three orders of magnitude (500, 5,000, and 50,000) and using t values for each that would result in the appropriate F_{ST} value. Simulations for each scenario (N_e and F_{ST} value) were conducted 100 times and the proportion of iterations where significant differentiation was detected (using a critical α value of 0.05) was recorded.

Population structure was also assessed without making *a priori* assumptions about the nature of population structure (e.g. how many groups there are, and which individuals represent each group). These analyses were conducted in two different ways: using the programs STRUCTURE (Hubisz *et al.*, 2009; Pritchard *et al.*, 2000), and STRUCTURAMA (Huelsenbeck and Andolfatto, 2007). For the analyses in STRUCTURE, the number of groups, and the membership of individuals within those groups, were estimated based a run length of 1,000,000 Markov Chain Monte Carlo

(MCMC) steps, with 50,000 steps as the burn-in period. The program was run assuming that allele frequencies were correlated between groups, and allowing for admixture (i.e. allowing for individuals to have ancestry in more than one group). The program was run 16 times, testing for 1–4 populations ($K = 1-4$), with four iterations of each K . The average likelihood over the four iterations for each K was taken as the likelihood for that K .

The program STRUCTURAMA works in a similar manner as STRUCTURE but differs in how the user specifies the number of populations to be tested. With STRUCTURE, the user must explicitly specify the number of populations considered and then run the program independently for each hypothesised number, and subsequently compare the probabilities associated with each. With STRUCTURAMA the number of populations considered can be a random variable within the model (Pella and Masuda, 2006) and therefore the posterior probabilities associated with a range of values for the number of putative populations can be obtained within a single run, without requiring *a priori* specification by the user (Huelsenbeck and Andolfatto, 2007). STRUCTURAMA was run allowing the number of populations to be a random variable with a Dirichlet process prior. The alpha value (which determines the shape of Dirichlet prior, where smaller values result in individuals being distributed across fewer populations and larger values result in individuals being dispersed across more populations) was also treated as a random variable, following a gamma distribution. A shape parameter of 1.0001 and a scale parameter of 0.0001 were initially used, which result in a relatively flat distribution. However, to test the robustness of the subsequent posterior probabilities to the choice of shape and scale values, STRUCTURAMA was also run with the shape and scale values both set to 1, which results in an L-shaped distribution. Each scenario was run three times, to ensure consistency between runs under the same conditions. All analyses were run for 1,000,000 MCMC steps, with 10,000 steps used as the burn-in.

Finally, it has been argued that estimating migration rates between putative populations is more biologically meaningful than simply rejecting panmixia when trying to identify biologically independent 'units' for conservation (e.g. Palsbøll *et al.*, 2006). Estimating migration rates from genetic data is challenging, however, particularly when migration rates are high. This is because demographic independence can occur at migration rates that are high enough to genetically homogenise allele frequencies (e.g. Waples and Gaggiotti, 2006). Regardless, great progress has recently been made in the development of analytical techniques designed to address this issue and better infer biological processes from genetic data. For management, the parameter of interest is estimated contemporary migration rates. BayesAss has become the software commonly used for this purpose (Wilson and Rannala, 2003). However, the approach implemented therein is known to perform poorly when genetic differentiation is low (Faubet *et al.*, 2007). Our results suggest extremely low differentiation between the putative groups and perhaps none (see Results), therefore BayesAss was not appropriate for estimating migration rates for our data. Instead, the programs IMA and MIGRATE were used to jointly estimate migration rates in both directions, as

well as effective population sizes of each putative population (Beerli, 2006; Beerli and Felsenstein, 1999; 2001; Hey and Nielsen, 2004).

RESULTS

The average yield of DNA from the extraction process was 2.80 nanograms (ng) of DNA per milligram (mg) of tissue for the samples from Vancouver Island, and 0.42 ng/mg for the samples from San Ignacio Bay. This lower yield from the San Ignacio Bay samples likely results from the fact that these samples were stored in ethanol rather than DMSO, and DNA degradation is known to occur at a higher rate in ethanol than DMSO (e.g. Michaud and Foran, 2011).

The tests of microsatellite amplification and variability resulted in the identification of 15 loci that amplify well in gray whales, and are also variable. Multiplex reaction development resulted in all 15 loci being amplified in 5 reactions (Table 2), which were subsequently used for genotyping all samples.

No genotypes differed between the duplicate scoring personnel, indicating that allele calls were consistent across scorers. Genotypes were considered to be 'full' if individuals were missing data from 3 or fewer loci (i.e. they had data for at least 12 of the 15 loci). Full microsatellite profiles were not obtained for 14 samples, resulting in 123 genotyped samples that were used for subsequent analyses. Analysis of the genotypes identified 24 duplicate sampling events (23 off Vancouver Island, 1 from Laguna San Ignacio). All re-sampling events were from the same location (i.e. there were no cases where one individual was sampled in one location and re-sampled at the other). These duplicates were removed from the data set, resulting in genotype data for 99 individuals (59 from off Vancouver Island, 40 from Laguna San Ignacio). The genotypes did not show any significant deviations from Hardy-Weinberg Equilibrium expectations when analysed independently for each putative population, or when the data were combined into one 'population' (Table 3). Out of the 105 pairwise comparisons for assessing linkage between loci (considering all individuals together), six (5.7%) had p -values < 0.05 . However, none of these were significant after Bonferroni correction (Hochberg, 1988).

Table 2
Amplification information. Included is the locus name, fluorescent label, and reaction number for all loci. The annealing temperature for all reactions is 55°C.

No loci had estimates of null allele frequencies greater than 0.05.

Sex could be determined for 86 of the 99 individuals, with 38 males and 48 females. The DNA was too degraded from the remaining 13 individuals to obtain reliable sex information. Within each region, the sex ratios were 33 females: 24 males and 15 females: 14 males for Vancouver Island and Laguna San Ignacio, respectively.

The ‘classic’ tests (based on hypothesis testing of pre-defined groupings) did not show any significant signs of genetic differentiation between the genotypes of the southern feeding group and the larger population. Specifically, the F_{ST} estimate was -0.0010 , with a P -value estimate of 0.489. Simulation analysis showed that the power to detect structure, if it exists, was quite high. Specifically, given the sample sizes and the characteristics of the loci, we would expect to detect population structure over 70% of the time with an F_{ST} value as low as 0.005 (Fig. 1). The STRUCTURE analyses also did not detect any significant genetic differentiation within the data set, with one population ($K = 1$) having the highest probability (Table 4). Similar results were also obtained with STRUCTURAMA, with the scenario of the data representing one single population having a higher probability than scenarios with any other putative number of populations (Table 5).

Table 4

Results from STRUCTURE analysis. Shown is the estimated natural logarithm (\ln) of the probability of the data with the number of populations (K) ranging from one to four, and performing four iterations of each K . The bold value indicates the average K with the highest probability.

Iteration	K			
	1	2	3	4

Table 5

Results from STRUCTURAMA analysis. Shown are the estimated posterior probabilities of the data representing 1–3 populations. The top panel shows these probabilities calculated with the alpha value for the Dirichlet process being a random variable following a gamma distribution with a shape parameter of 1.0001, and a scale parameter of 0.0001. The second panel shows these probabilities calculated when the shape and scale value parameters were both set to 1.

Iteration	Number of populations		
	1	2	3
gamma(1.0001,0.0001)			
1	0.96	0.04	0
2	0.96	0.04	0
3	0.96	0.04	0
gamma(1,1)			
1	0.97	0.03	0
2	0.97	0.03	0
3	0.97	0.03	0

Fig. 1. Results from the POWSIM analyses. Shown is the power of the data (the proportion of simulations where population structure was detected (using a critical α value of 0.05)) under the different scenarios. The F_{ST} values tested were 0.05, 0.025, 0.02, 0.01, 0.005, 0.0025, and 0.001. These F_{ST} values were generated under three scenarios, $N_e = 500$, 5,000, and 50,000, with the time since divergence (t) varying to result in the desired F_{ST} values.

Despite testing a wide range of options with both IMA and MIGRATE, we were unable to get either program to converge on consistent estimates of migration rates. Our interpretation is that this inability is due to the lack of genetic differentiation of nuclear markers between the putative

groups. This interpretation, as opposed to a lack of information in the data, seems appropriate particularly because we have previously obtained consistent estimates from these same programs and the same individuals but based on mitochondrial data, which showed significant structuring and limited migration consistent with maternally-directed site fidelity (Frasier *et al.*, 2011).

DISCUSSION

The differential recovery of DNA from tissue stored in different solutions merits consideration for future sample storage. Several studies have compared the ability of different solutions (primarily ethanol and DMSO) to preserve DNA over long periods of time (e.g. Michaud and Foran, 2011; Seutin *et al.*, 1991). All such studies indicate that DMSO solutions preserve DNA at a higher quality, and over a longer period of time. However, many researchers and museum staff still use ethanol for the long-term preservation of tissue. The differential yields of DNA obtained here add to the growing amount of data suggesting that DMSO is the desirable storage solution for long-term storage of tissue that may be used as a source of DNA.

The results of all analyses of population structure lead to the same conclusion: a lack of differentiation of nuclear genotypes. The 'classical' tests did not detect significant differences in allele frequencies between whales of the southern feeding group and those sampled in Laguna San Ignacio, and both Bayesian approaches indicated that the probability that all samples originated from one single population was substantially higher than any other alternatives. These data suggest that the whales of the southern feeding group do indeed freely interbreed with whales that utilise other summer feeding grounds. Thus, from these data, it appears that the eastern North Pacific gray whale represents one interbreeding population.

One caveat of our study is that samples representing the larger population were all collected from whales in one of the lagoons Laguna San Ignacio (but spanning several years). Gray whales are not evenly distributed throughout the three known lagoons in winter. Instead, photo-ID data suggest that females show some site fidelity to different lagoons (e.g. Jones, 1990) and genetic data also suggest some structuring (Goerlitz *et al.*, 2003; Alter *et al.*, 2009). However, the patterns and degree of structuring between lagoons remains unclear. For example, Alter *et al.* (2009) did not find significant structuring of mitochondrial haplotypes between the lagoons, but found slight but statistically significant differentiation of microsatellite alleles between Laguna San Ignacio and Bahia Magdalena. The authors attribute this pattern to either a high contemporary migration rate, or perhaps to stronger patterns of structuring being erased by whaling and only beginning to accumulate and leave a detectable genetic signature today.

Our justification for using samples from Laguna San Ignacio as representative of the larger population, are three-fold. First, based on numbers of single individuals and mother-calf pairs, Laguna San Ignacio represents the second most populated lagoon, with numbers of whales that are vastly larger than the estimated size of the southern feeding group (Jones and Swartz, 1984; Urban *et al.*, 2003). Thus, Laguna San Ignacio is clearly used by a larger subset of the

population than the southern feeding group. Second, although there are data suggesting that some females show fidelity to specific lagoons, there is also an abundance of data showing that some individuals move freely between lagoons, and that average residence times within the lagoon (for non-mother-calf pairs) are less than a week (Jones and Swartz, 1984; Urbán *et al.*, 2003), suggesting that at least single whales move readily between lagoons. Moreover, some mothers are known to utilise different lagoons in different years (Swartz, 1986). Lastly, even if mothers do show fidelity to specific lagoons, this should not result in corresponding structuring of nuclear gene flow because fertilisation is thought to take place during the southward migration, prior to arrival at the lagoons (Rice and Wolman, 1971). Thus, although it would be ideal to have representative samples from all known lagoons, the available data provide no reason to doubt that the samples from Laguna San Ignacio are representative of the larger population.

These data based on nuclear markers add to previous photo-ID and mtDNA data to provide a more complete picture of the relationship between seasonal habitat use patterns and gene flow throughout the population. The photo-ID and mtDNA data indicate that, during the summer, whales of the southern feeding group represent a seasonal subpopulation, where this differential habitat use is driven by maternally-directed site fidelity to this feeding area that is then passed on to their offspring (Frasier *et al.*, 2011). However, the nuclear DNA data suggest that these whales breed with whales that show fidelity to other feeding grounds, and therefore are part of one interbreeding population. Thus, the combined picture is one of seasonal subdivision on summer feeding grounds, but with no such substructuring during the mating season, where all individuals in the eastern North Pacific represent one gene pool.

This result and interpretation is consistent with other data relating to known migration patterns and the timing of fertilisation. Briefly, it is thought that conceptions may occur in December, during the southern migration (Rice and Wolman, 1971). Whales that use the northern feeding grounds migrate through the areas occupied by the southern feeding group suggesting that whales from both known feeding grounds may migrate together the remainder of the way to the winter calving grounds (Darling, 1984). The peak time of migrants passing through the southern feeding area is mid-December to mid-January (Darling, 1984). Thus, the timing of fertilisation coincides with when whales from different feeding grounds become intermingled during their southern migration. This pattern indicates the strong potential for interbreeding regardless of any substructuring that may exist during the summer, or on the winter calving grounds.

Despite the presence of nuclear gene flow between whales from the southern feeding group and the rest of the population, this group still represents a separate management unit that warrants separate consideration with respect to the impacts of proposed threats, such as the resumption of traditional whaling and the impacts of oil distribution. This is the approach being used by the IWC Scientific Committee in examining the potential impacts of hunting (e.g. see IWC,

2013b). The presence of long-term site fidelity to this area that is passed on from mothers to offspring, indicates that these whales represent a seasonal subpopulation. Thus, detrimental impacts (e.g. ‘takes’) to these whales will not have a ‘random’ impact on the population at large, but will instead primarily impact these matrilineal specifically. The resulting effect on this local subpopulation could be far greater than would be expected under the assumption of a single, unstructured population. Potential impacts could include the loss of knowledge of these feeding areas from this population, and localised extirpation. For example, if the whales that currently show this site fidelity are removed, then this information will be lost, and thus these whales will not likely be replaced by others from the larger population, resulting in localised extirpation. Indeed, the recognition of such seasonal subpopulations as separate management units is recommended, and common, for baleen whales (e.g. Dizon *et al.*, 1997).

ACKNOWLEDGEMENTS

This work was funded by the Canadian Wildlife Foundation, the Faculty of Graduate Studies and Research at Saint Mary’s University, the Pacific Wildlife Foundation through donations from Remote Passages Marine Excursions, Jamie’s Whaling Station and Ocean Outfitters in Tofino BC, and a grant from Clayoquot Biosphere Trust. We would like to thank Drs. Barbara Taylor and Phillip Morin for reviewing earlier drafts of this manuscript and providing valuable comments.

METHODS AND COUNT DATA

This paper presents updated counts and abundance estimates for gray whales (*Eschrichtius robustus*) migrating southbound off the central California coast between December and February 2014/15 and 2015/16. Counting and analytical methods followed those described by Durban *et al.* (2015) for four previous abundance estimates between 2006/7 and 2011/12. Counts were made from a shore-based watch station at Granite Canyon, California, by teams of observer pairs rotating from a larger pool. A total of 16 observers were used over the two years, 10 in 2014/15 and 12 in 2015/16; six observers counted in both years. Only five of these 16 observers were not involved in the previous independent counting experiments when the detection models were parameterized; in these cases, observer effects were predicted (with uncertainty) from the hierarchical model for observer effects (Durban *et al.* 2015).

Data were the total counts of whales from each 1.5-hour watch period that had acceptable weather conditions (see Durban *et al.* 2015). These comprised 179 watch periods in 2014/15 and 151 in 2015/16, totaling 269 and 226 hours of watch effort over 39 and 37 days, respectively (Table 1). The result was 2978 and 2666 whales counted in each of these years, the former representing the highest count since our new watch protocol was started in 2006/2007 (Durban *et al.* 2015).

Table 1: The number of whales recorded during the southbound gray whale surveys in 2014/15 and 2015/16. Data are the total counts of whales, hours and distinct days for watches during acceptable observation conditions.

Migration	Dates	Hours	Days	Whales
2014/2015	30-Dec-14 to 13-Feb-15	269	39	2978
2015/2016	30-Dec-15 to 12-Feb-16	227	37	2666

ABUNDANCE ESTIMATES AND DISCUSSION

Bayesian Markov Chain Monte Carlo (MCMC) sampling was used to simultaneously rescale counts for detectability and also smooth to abundance changes over the course of each migration (Durban *et al.* 2015). These abundance changes were described using Bayesian model selection between a parametric model for a Normally distributed migration trend that borrowed strength across years and a semi-parametric model that estimated the time trends independently for each year; the resultant migration curve was a weighted compromise between models, allowing for key departures from the common trend. The total number of whales passing during each migration was then estimated by summing the expected value (along with associated uncertainty, see error bars in Fig 1) from the model-averaged number of whales passing each day from time 0 (01 December) to 90 days, and these estimates were then rescaled to account for the differential passage rate at night (see Durban *et al.* 2015).

Figure 1. Observed whale passage rates expressed as total counts per day / proportion of day observed (circles) and fitted migrations models (lines) for two gray whale migration counts in 2014/15 and 2015/16. The broken line represents the median estimates from a hierarchical Normal model for migration and the solid line represents a semi-parametric model of penalized splines (see Durban *et al.* 2015). The abundance estimate for each day (95% highest posterior density interval shown by vertical lines) is a model averaged compromise between the migration models, and these were summed to estimate the overall abundance for the migrations.

To sample the full extent of the uncertainty associated with model parameters, inference was based on each 10th iteration of the MCMC sampler to generate a sample of 30,000 iterations following a burn-in of 10,000. There was consistency between the model predictions and observed counts for both years, with Bayesian P-values of 0.49 and 0.54, respectively; values close to 0.5 would indicate that the data were consistent with replications under the model such that the distribution of the predicted count would symmetrically overlap the observed count (Gelman *et al.* 1996). However, daily and total abundance in 2014/15 were subject to considerable uncertainty, as shown by the large error bars associated with each of the daily estimates (Figure 1) and the large coefficient of variation (CV = posterior standard deviation / posterior median; $CV^{2015} = 0.13$). This is likely explained in part by the results of model fitting, as significant departures from the Normal migration model (probability of Normal model <0.25) were estimated in 18/90 days in 2014/2015 compared to only 9/90 days in 2015/16. These

departures, and the uncertainty associated with estimating an independent migration curve, constrained estimation of a precise migration curve. In contrast the $CV^{2016} = 0.05$ was consistent with previous estimates using this counting approach and model ($CV = 0.04$ - 0.06 for four previous estimates since 2006/2007), and this estimate was therefore more useful for interpreting in the context of the abundance time series. Differences in the CVs from the two years demonstrated the value of completing two counts and abundance estimates in back-to-back years, which provided a measure of redundancy.

The 2015/16 estimate of 26,960 (95% highest posterior density interval = 24,420-29,830) represented a 22% (5970 whales) increase in the five years since the 2010/11 estimate of 20,990. This is consistent with high estimates of calf production (Perryman *et al.* SC/67a), with a total of >6000 calves estimated during this period, including four of the highest years of calf production (>1000 calves per year) since our calf counts began in 1994. This increase in gray whale abundance also supports inference that gray whales have been experiencing a period of favorable feeding conditions in the Arctic due to a combination of expanding ice-free habitat (Moore 2016), increased primary production (Arrigo and Dijken 2015) and increased flow of nutrient-rich waters through the Bering Strait (Woodgate *et al.* 2012).

Figure 2: Gray whale abundance estimates for southbound migrations with an end year between 1967 and 2011 (open circles, with 95% confidence intervals; from Laake *et al.*, 2012 and Durban *et al.* 2015) together with the two recent migrations reported here for 2015 and 2016.

ABSTRACT: The eastern North Pacific gray whale *Eschrichtius robustus* was removed from the US Endangered Species List in 1994, and since then aboriginal groups in Washington (USA) and British Columbia (Canada) have discussed the resumption of traditional whaling. In particular, the Makah are pursuing legal permission to resume their hunt. Although the majority of whales in this population migrate to summer feeding grounds in the Bering, Chukchi, and Beaufort Seas, a small number of individuals (~200) spend the summers feeding in the waters ranging from northern California to southeast Alaska. The relationship of these 'southern feeding group' whales to the rest of the population is unknown. This information is key to making appropriate management decisions, because these whales inhabit the waters directly adjacent to the aboriginal communities interested in resuming whaling. We compared mitochondrial sequence data from 40 southern feeding group individuals to sequences from 105 individuals representing the larger population. We found significant differences in haplotype frequencies between the 2 groups, with an estimated long-term rate of exchange between the groups being $<1\%$. Moreover, estimates of Θ ($N_e\mu$ for mtDNA data, i.e. the probability of a mutation occurring within the population in each generation) were significantly different between the 2 groups, indicating that the maternal lineages of the southern feeding group represent a distinct seasonal subpopulation. Combined, these data show that the southern feeding group of gray whales qualifies as a separate management unit, which should be considered when making conservation decisions.

INTRODUCTION

The eastern North Pacific gray whale *Eschrichtius robustus* represents one of the few populations that have been removed from the US Endangered Species List, with the classification changing from 'endangered' to 'recovered' in 1994. Commercial whaling targeting gray whales in the eastern Pacific began in ~1845 (Henderson 1984) and reduced the population from an estimated 12 000–15 000 ind. to as low as

1500–1900 ind. by 1900 (Henderson 1984, Reilly 1992, Butterworth et al. 2002). International protection began in 1937, when the United States and Norway ended their gray whale hunts, but it was not until 1951 that all modern whaling countries agreed to stop hunting gray whales (Reeves 1984). Systematic surveys from 1967 to 1998 showed that the population increased at an annual rate of ~2.6%, reaching as many as 30 000 ind. (Shelden & Laake 2002, Rugh et al. 2005). Current estimates hover around 20 000 ind., and

*Email: timothy.frasier@smu.ca

there are even some suggestions that the population has reached carrying capacity (Moore et al. 2001, Wade 2002, Rugh et al. 2005, but see Alter et al. 2007 for an alternative perspective).

During the late fall and early winter, whales migrate to the lagoons of Baja California and the Gulf of California, which represent the winter calving grounds for this population (Swartz 1986, Findley & Vidal 2002, Swartz et al. 2006). During the spring, the majority of whales migrate to their northern feeding grounds in the Bering, Chukchi, and Beaufort Seas (Moore & Ljungblad 1984). However, a small subset of the population (~200 ind.) remains in more southerly feeding grounds ranging from northern California to southeast Alaska (Pike 1962, Hatler & Darling 1974, Darling 1984, Darling et al. 1998, Calambokidis et al. 2002, Swartz et al. 2006). These 2 subsets of the population will be referred to as the southern feeding group and the larger population, respectively.

Subdivision with respect to summer feeding ground use is common in baleen whales, and results from maternally directed site fidelity to different feeding grounds. For example, in humpback whales *Megaptera novaeangliae* and North Atlantic right whales *Eubalaena glacialis*, calves nurse for ~11 mo (and occasionally longer) and learn migration routes and the location of summer feeding grounds through cultural transmission from their mother (e.g. Baker et al. 1990, Malik et al. 1999). Thus, if there is differential use of feeding grounds by mothers, these preferences will be passed on to their offspring and result in substructuring with respect to summer feeding ground use. Gray whale calves nurse for a much shorter period of time (~6 mo; Swartz 1986). Although their length of lactation is still long enough to learn migratory routes and the location of summer feeding grounds, it is not yet clear whether gray whales show this maternally directed site fidelity. Because mitochondrial DNA (mtDNA) is maternally inherited, patterns of mtDNA diversity should reflect any maternally based patterns of movement and distribution. Therefore, analysis of mtDNA is ideal for testing hypotheses of maternally based site fidelity and subsequent population structure in baleen whales.

The relationship between the southern feeding group and the larger population is unknown. It is currently assumed that both of these groups use the same breeding ground, and therefore represent the same breeding population (e.g. Swartz et al. 2006). Given the known patterns in other baleen whale species, it seems likely that the southern feeding group and the larger population, and perhaps even smaller, as yet undefined subdivisions, result from maternally directed site fidelity to different feeding grounds by gray whale mothers. Photo-identification data are con-

sistent with this hypothesis, showing that the majority of whales sighted in the southern feeding areas are resighted there in subsequent years, and therefore show the expected site fidelity (Darling 1984, Calambokidis et al. 2002, 2010). For example, Calambokidis et al. (2002) found that between 70 and 100% of the whales photo-identified off British Columbia had been sighted there in previous years. Moreover, the majority (63%) of calves first sighted in the southern feeding area with their mothers are resighted there in subsequent years, suggesting that this differential use of feeding grounds is indeed the result of maternally directed site fidelity (Calambokidis et al. 2010). This resighting rate is high, given the numerous factors that can reduce the resighting rates of calves, including: (1) mortality of individuals between their calf and subsequent year (as this age class has the highest mortality rate in many mammalian populations; Caughley 1966); and (2) changes in physical features that prevent re-identification (Calambokidis et al. 2010). However, preliminary genetic analyses of population structure based on mtDNA were inconclusive (Steeves et al. 2001).

Understanding the relationship between the southern feeding group and the rest of the population is of increasing importance due to the intention of some aboriginal communities to resume hunting gray whales. Several aboriginal groups traditionally hunted gray whales, but voluntarily stopped hunting as whale numbers decreased and/or were required to stop when the population received international protection (O'Leary 1984, Russell 2004). The exception was off Chukotka, Russia, where whaling was allowed to continue. In 1998, the Makah (in Washington, USA) resumed whaling and caught/killed a whale in 1999, but have been prevented from continuing since 2000 by litigation. Specifically, the Makah were given the right to hunt gray whales at traditional sites under the Treaty of Neah Bay in 1855. However, a final court ruling in 2004 determined that in order to resume their hunt, they must follow the necessary procedures for obtaining a waiver under the Marine Mammal Protection Act (MMPA). The Makah have applied for this waiver, and this request is still being processed. The outcome of the Makah application will have large implications for the resumption of whaling by other aboriginal communities in the area as well (Russell 2004).

The relationship of these 'southern feeding group' whales to the rest of the population is unknown. This information is key to making appropriate management decisions, because these whales inhabit the waters directly adjacent to the aboriginal communities interested in resuming whaling. The negative consequences of ignoring potential population structure when making management decisions, such as the extinction of unrecognized populations and/or species,

are well known (e.g. Daugherty et al. 1990, Taylor 1997, Frankham et al. 2002). For the current gray whale situation, an understanding of population sub-structure in relation to known summer feeding ground use is required to infer how the whales in each feeding area, and the population as a whole, will respond to the removal of individuals through the proposed hunts. Therefore, if informed management decisions are to be made regarding resuming this hunt, it is first necessary to understand the relationship of this southern feeding group to the rest of the larger population. Here, we conducted analyses of the mitochondrial DNA of gray whales representing the southern feeding group, as well as the larger population, in order to better understand their relationship, and therefore inform management decisions.

MATERIALS AND METHODS

Sample collection. Skin samples were collected from whales representing the southern feeding group in Clayoquot Sound, British Columbia, from 1995 to 2006. Individuals of this group appear to move freely between specific feeding sites throughout this southern feeding range from northern California to southeast Alaska in summer (Calambokidis et al. 2002, 2010). Clayoquot Sound on central Vancouver Island is one such site (Darling 1984, Darling et al. 1998). Biopsy samples were collected using a crossbow and modified bolt (e.g. Lambertsen 1987, Palsbøll et al. 1991) or a pneumatic rifle biopsy system (Barrett-Lennard et al. 1996). The samples were collected in association with ongoing photo-identification research (e.g. Darling 1984), and the photo-identification data were used to ensure that individual whales were only represented once within the genetic data set. Moreover, the entire population migrates near this area on its northern and southern migrations. Therefore, samples were only used from whales sampled between 1 July and 15 November, i.e. the time period after which all northward migrants have passed and before which the first migrants start heading south (Darling 1984), to ensure that the sampled individuals actually represented the southern feeding group, as opposed to migratory animals. Tissue samples were stored in a 20% dimethyl sulfoxide (DMSO) solution (Seutin et al. 1991).

Genetic analysis. Approximately 40 mg from each sample was used for subsequent DNA extraction procedures. The skin was frozen in liquid nitrogen, ground to a fine powder, and transferred to a tube with 500 μ l of lysis buffer (4 M urea, 0.2 M NaCl, 0.5% *n*-lauroylsarcosine, 10 mM 1,2-cyclohexanediamine-tetraacetic acid, 100 mM Tris-HCl, pH 8.0). Samples were rotated in the lysis buffer at room temperature for

≥ 5 d, after which time they were subjected to 3 aliquots of Proteinase K, each at a concentration of 0.5 U mg^{-1} tissue. The addition of Proteinase K was as follows: after adding the first aliquot, samples were rotated at room temperature overnight; after adding the second aliquot, the samples were placed in a 65°C waterbath for 1 h, then transferred to a 37°C incubator for 1 h; after adding the third aliquot, the samples were rotated at room temperature overnight. Approximately 250 μ l of the tissue/lysis buffer solution was subsequently extracted using Qiagen DNeasy Tissue Extraction Kits. DNA quantity was estimated using PicoGreen (Singer et al. 1997). Extracted samples included those previously analyzed by Steeves et al. (2001), which were re-extracted and analyzed here, along with the newly collected samples.

A 345 bp portion of the mitochondrial DNA control region was amplified using the primers t-PRO and Primer-2 from Yoshida et al. (2001). PCR cycling conditions consisted of: (1) an initial denaturation step of 5 min at 94°C; (2) 30 cycles of 94°C for 30 s, 57°C for 1 min, and 72°C for 1 min; and (3) a final extension step of 60°C for 45 min. Reactions were carried out in 20 μ l volumes containing 1 \times PCR Buffer (20 mM Tris-HCl pH 8.0, 50 mM KCl), 0.05 U μ l $^{-1}$ *Taq* polymerase (Invitrogen), 1.5 mM MgCl_2 , 0.2 mM each dNTP (Invitrogen), and 10 ng of DNA. After amplification, primers and unincorporated dNTPs were degraded using EXOSAP-IT (Dugan et al. 2002), and products were sequenced using the DYEnamic dye terminator kit (GE Healthcare). Products were size-separated and visualized on a MegaBACE 1000 (GE Healthcare). Sequences were edited using MEGA 4 (Kumar et al. 2008). Gender was determined for all individuals using the method described by Shaw et al. (2003).

Data analysis. To compare the data from southern feeding group whales to those of the larger population, we compared our mitochondrial sequence data to those reported by LeDuc et al. (2002). Their study reported mitochondrial sequences from 120 ind. representing eastern Pacific gray whales. The majority (>90%) of the samples were from stranded individuals found throughout their range, from southern California to the Chukotka Peninsula in Russia. The remaining samples were collected from subsistence takes, as biopsies of live whales, and from fisheries bycatch. Fifteen of the samples in LeDuc et al. (2002) were from southern feeding group whales. These were removed from the analyses, leaving 105 samples from the LeDuc et al. (2002) data set to compare with our data set of 40 ind. Because the vast majority of samples from the study by LeDuc et al. (2002) were from dead individuals (either stranded, as bycatch, or hunted), the chance of duplicate samples from the same individual being represented in their data is negligible. Given the num-

ber and geographic range of the sampled whales in the study by LeDuc et al. (2002), our rationale for choosing these for comparison was that these sequences would be a good representation of the larger population of eastern gray whales.

Sequences were aligned with CLUSTALX (Thompson et al. 1994). Alignments were conducted under a range of gap opening and extension penalties and compared by eye to establish the optimal alignment. The sequences were very similar, and all alignments were the same under the tested conditions. Haplotype and nucleotide diversity (π) (Nei 1987) were estimated using Arlequin ver. 3.5.1.2 (Excoffier et al. 2005). Variations between mtDNA sequences were recorded, and identical sequences were grouped into haplotypes. Final haplotype assignments were confirmed with FaBox ver. 1.35 (Villesen 2007). Population differentiation of the mtDNA sequences between the southern feeding group and the larger population was estimated using the analysis of molecular variance approach described by Excoffier et al. (1992) as implemented in the program Arlequin. The significance of the resulting estimates of F_{ST} and Φ_{ST} was tested using 1000 permutations. Relationships among haplotypes were visualized via a median-joining network using the program Network 4.5.1.6 (Fluxus Technology).

To gain insight into the nature of the observed population substructure, we estimated effective population sizes, migration rates, time since divergence, and growth rates for the 2 sample sets using the Isolation with Migration program (IM; Nielsen & Wakely 2001, Hey & Nielsen 2004, Hey et al. 2004). However, repeated trials with various parameter options suggested that there was not enough information in our data set to obtain accurate estimates for all of these values (data not shown). Instead, we focused on estimating just the effective population sizes and migration rates using the program MIGRATE (Beerli & Felsenstein 2001, Beerli 2006). The Bayesian inference approach was implemented, using a transition/transversion ratio of 11.22 and an α estimate of 0.09 for the gamma distribution of mutation rate heterogeneity among sites (both estimated using TREE-PUZZLE, Schmidt et al. 2002). We used the Metropolis-Hastings method of generating posterior distributions. The program was run with uniform prior distributions and 1 long chain. To ensure consistency between runs, MIGRATE was run 5 times with a burn-in of 100 000 steps, and a run length of 10 000 000 steps with data recorded every 500 steps. The likelihood ratio test option of MIGRATE was also used to test the hypothesis that the 2 sample sets have different effective population sizes. For the likelihood ratio test, 10 short chains and 1 long chain were run, with a burn-in of 50 000 steps. For the short and long chains, the run length was 10 000 000 steps with

data recorded every 500 steps. Specifically, the hypothesis tested was $\Theta_{\text{southern}} = \Theta_{\text{larger}}$. Theta (Θ) is a parameter that describes the genetic diversity within a population. The genetic variation existing within a single population is ultimately the result of mutations. The rate at which mutations are observed is a combination of the mutation rate (μ), which is how often mutations occur, and the effective population size (N_e), which represents how many 'opportunities' there are for mutations to occur in each generation. The product of these values represents the probability of a mutation occurring within the population in each generation, and this value is called Θ ($\Theta = N_e\mu$ for mitochondrial sequence data). With genetic data, we tend not to know the values of N_e and μ , but the data available are often the frequency of different DNA sequences and the number of mutations separating them. Thus, it is possible to estimate Θ from the data, and use that to make inferences of N_e and μ . Therefore, in this case we can assume that μ is the same for the southern feeding group and the larger population, and therefore comparisons of Θ estimates between the 2 groups directly correspond to comparisons of N_e .

RESULTS

DNA was extracted and mtDNA control regions sequenced from 40 gray whales representing the southern feeding group. Gender was determined for 37 of the 40 sampled whales, and resulted in 15 males and 22 females. This represents a slight female bias, which is contrary to previous studies, which obtained a slight male bias (Steeves et al. 2001). The sequencing protocol resulted in 336 bp of comparable sequence among individuals. Twenty-seven polymorphic sites were identified, which resulted in 18 haplotypes in the southern feeding group whales (Fig. 1). The sequences published in the study by LeDuc et al. (2002) (522 bp) were longer than those obtained here, and therefore all 336 bp from the southern feeding group sequences could be compared to those from the larger population. None of the variable sites or haplotypes identified in the southern feeding group were new; all were also represented by the sequences described by LeDuc et al. (2002) (Fig. 1). However, trimming the sequences of LeDuc et al. (2002) to the comparable 336 bp between the data sets did remove some variable sites that differentiated some of their haplotypes. Specifically, their haplotypes 'G' and 'O' were collapsed into 1 sequence (called 'G' in Fig. 1), haplotypes 'L', 'U', and 'AD' were collapsed into sequence 'L', and haplotypes 'AC' and 'AG' were collapsed into haplotype 'AC' (Fig. 1).

Although no haplotypes were found only in the southern feeding group samples, the distribution of

Fig. 1. *Eschrichtius robustus*. Variable sites characterizing haplotypes from both sample sets of gray whales. NFG, SFG, and TOT (top right) indicate the number of individuals from the northern feeding group (i.e. the larger population), the southern feeding group, and the total number of individuals with each haplotype, respectively

haplotypes was significantly different between the 2 groups, with values of 0.0125 for F_{ST} ($p = 0.0303$) and 0.0311 for Φ_{ST} ($p = 0.0254$). The median-joining network shows that although there is some differentiation between the haplotypes from the 2 feeding groups, for the most part the haplotypes from each are scattered throughout the network (Fig. 2). Haplotype diversity and π were estimated at 0.928 and 0.0199, respectively, for the southern feeding group. These values are very similar to estimates obtained for samples representative of the larger population, which were 0.95 and 0.016, respectively (LeDuc et al. 2002).

The results from the MIGRATE analyses are shown in Table 1. Estimates for each value are very similar across iterations, suggesting that the program was run long enough to reach convergence on the estimates. The estimates of Θ for the southern feeding group and the larger population are clearly different. This observation was confirmed by the likelihood ratio test, which rejected the hypothesis of $\Theta_{\text{southern}} = \Theta_{\text{larger}}$ ($p < 0.001$). The

95% confidence intervals for the migration rate estimates are extremely large, making them uninformative. This result is not surprising, however, because the approach implemented by MIGRATE is known to recover precise and accurate estimates of Θ even in situations where there is not enough information in the data to recover meaningful migration rate estimates (Beerli 2006).

Because the sample of haplotypes found in the southern feeding group represents a subset of the haplotypes found in the larger population (albeit at different frequencies), we conducted further analyses to ensure that our results were not simply due to the effect of sampling. For this assessment, we generated a new set of 40 sequences (representing a simulated southern feeding group data set) by randomly sampling the sequences of LeDuc et al. (2002), using R (R Development Core Team 2009). Thus, this process generated a simulated data set for the southern feeding group under the hypothesis that it represents a random subset of the larger population. This process

Fig. 2. *Eschrichtius robustus*. Median-joining network for the gray whale sequences. Transitional mutations are indicated with a line, with the number of lines showing the number of transitional mutations. Lengths of the lines connecting nodes are not proportional to the number of mutations. Sizes of the circles are proportional to the haplotype frequencies in the entire data set. Pie charts indicate the proportion of that haplotype found in the larger population (black) and southern feeding group (gray). 'mv' nodes represent inferred nodes that are missing from the data set

was repeated 10 times, generating 10 simulated data sets containing the data from LeDuc et al. (2002), as well as the simulated data for the southern feeding group. Analyses of F_{ST} and Φ_{ST} were conducted for

each simulated data set using Arlequin, as were likelihood ratio tests for testing the hypothesis of $\Theta_{southern} = \Theta_{larger}$ using MIGRATE, under the same conditions as were used for the original data.

Table 1. *Eschrichtius robustus*. Results from the MIGRATE analysis. Included is the estimated mean for each parameter, as well as the 95% credibility intervals in parentheses (both obtained using the Bayesian approach in MIGRATE). M is the immigration rate m divided by the mutation rate μ . For mitochondrial DNA data, the number of immigrants per generation can be calculated by multiplying M by Θ . Included are the estimates for each of the 5 iterations of the program, as well as the average across all 5 iterations. Southern and larger indicate the southern feeding group of the eastern North Pacific gray whale population, and larger population, respectively

Iteration	Θ_{larger}	$\Theta_{southern}$	$M_{southern-larger}$	$M_{northern-southern}$
1	0.0430 (0.0220–0.0690)	0.0206 (0.00550–0.0380)	522 (205–860)	572 (250–920)
2	0.0462 (0.0235–0.0735)	0.0199 (0.00550–0.0385)	516 (190–865)	565 (245–960)

4	0.0421 (0.0165–0.0715)	0.0212 (0.00650–0.0425)	515 (190–865)	572 (240–950)
5	0.0430 (0.0200–0.0710)	0.0220 (0.00650–0.0445)	480 (175–810)	526 (195–875)
Avg	0.0436 (0.0205–0.0716)	0.0209 (0.00610–0.0404)	511 (191–854)	559 (228–925)

None of the simulated data sets showed significant signs of structuring based on F_{ST} or Φ_{ST} , and none showed significant differences in estimates of Θ (Table 2). Thus, the significant differentiation found for the real data set, based on all 3 of these analyses, suggests that the observed differentiation is indeed real, and not just an artifact of sampling.

DISCUSSION

The conservation and/or management of wildlife populations requires knowledge of how individuals are subdivided into separate entities that have relatively independent demographic processes, which are often referred to as 'management units' (MU). Such information is required to identify how each unit, and the popu-

Table 2. *Eschrichtius robustus*. Results from simulation tests under the hypothesis that the southern feeding group represents a random sample of the data set from LeDuc et al. (2002). Included are the F_{ST} and Φ_{ST} estimates, and associated p-values (in parentheses), from Arlequin, as well as p-values from likelihood ratio tests conducted in MIGRATE testing the hypothesis of $\Theta_{\text{southern}} = \Theta_{\text{larger}}$, where southern is the southern feeding group of the eastern North Pacific gray whale population, and larger is the larger population (not including the southern feeding group)

lation as a whole, will respond to exploitation and/or unintentional impacts. Moritz (1994) was the first to provide a working definition of MUs in a population genetics context, and defined them as

...populations with significant divergence of allele frequencies at nuclear or mitochondrial loci, regardless of the phylogenetic distinctiveness of the alleles. (p. 374)

While this definition has been widely applied in population genetics studies, it has recently been argued that MUs should be defined based on criteria demonstrating demographic isolation rather than simply rejecting the hypothesis of panmixia (Waples & Gaggiotti 2006, Palsbøll et al. 2007, Waples et al. 2008). This idea makes intuitive sense, because the true question for management is whether the units will respond differently to the pressures of concern (e.g. exploitation and/or unintentional mortality). However, there is a disconnect between inferring demographic independence and genetic estimates of differentiation because populations can be demographically independent even when long-term migration rates are high enough to result in relative genetic homogeneity (Waples & Gaggiotti 2006, Waples et al. 2008).

The data presented here show that the southern feeding group of gray whales represents a distinct MU under both of these criteria. The analysis showing statistically significant differentiation of mitochondrial haplotypes demonstrates qualification as an MU under the criteria of Moritz (1994). Moreover, the analysis showing that the effective sizes of both groups are different ($\Theta_{\text{southern}} \neq \Theta_{\text{larger}}$) shows that the maternal lineages of the southern feeding group represent a distinct seasonal subpopulation. Indeed, if they were not

an independent unit but instead just represent different samples from the same mitochondrial 'population,' then estimates of Θ from the 2 data sets should converge on the same value. Thus, the southern feeding group qualifies as a separate MU under the criterion of Palsbøll et al. (2007). Combined, these data show that the southern feeding group requires separate management consideration with regards to resuming whaling.

Hastings (1993) showed that populations behave in a demographically independent manner when migration rates are less than ~10%. We have intentionally not converted Θ estimates to N_e estimates because this requires knowledge of the substitution rate (μ). Estimates of μ for the control region of baleen whale mtDNA vary by over an order of magnitude (e.g. Rooney et al. 2001). Moreover, μ , whatever its true value is, is undoubtedly the same for the southern feeding group and the larger population, and therefore comparing estimates of Θ is an appropriate and less controversial method for comparing N_e . Regardless, if we apply the μ estimate of 1.0×10^{-10} mutations site⁻¹ yr⁻¹, estimated by Alter & Palumbi (2009) for North Pacific gray whales, the resulting estimates of migration rates are << 1%. In this case, we are not dealing with migration rates between reproductive populations per se, but rather exchange rates between maternally based feeding groups. As with the haplotype frequency data, this result shows that the southern feeding group represents a distinct seasonal subpopulation.

Estimates of Θ represent long-term averages over the lifetime of the population; therefore, these genetic analyses provide information on an evolutionary time scale, whereas wildlife managers are generally more interested in the current state of a population (e.g. at the ecological time scale; Waples et al. 2008). To address this disconnect, we reiterate that photo-identification data of contemporary individuals also results in the same conclusion that the southern feeding group represents a distinct seasonal subpopulation based on maternally directed site fidelity. Photo-identification data show that the majority of whales sighted in the southern feeding areas are re-sighted there in subsequent years (Darling 1984, Calambokidis et al. 2002), and that the majority of calves first sighted in the southern feeding area with their mothers are re-sighted there as juveniles and adults (Calambokidis et al. 2010). Therefore, the combination of photo-identification and genetic data suggests distinct subdivision of the southern feeding group at both the evolutionary and contemporary (or ecological) time scales.

We reiterate that the southern feeding group likely mates with the rest of the population in the winter breeding grounds, and that the structuring we see is the result of maternally directed site fidelity to different feeding grounds. We used mtDNA (rather than

nuclear markers) to test this hypothesis specifically for this reason, because such a pattern would be reflected in mtDNA and not nuclear DNA. This type of population substructure is common in whales (e.g. Hoelzel 1998), and has proven important for management. The rationale is that, because of this site fidelity, knowledge of specific feeding areas is only present within certain matriline. Therefore, if whales are extirpated from a specific feeding ground, they will not be 'replaced' (or the area will not be re-populated) by others from the larger population because knowledge of that feeding area has been lost. Indeed, such localized extinctions and lack of subsequent re-population of areas (despite an increasing overall population size) is widely documented in whales (e.g. Northridge 2008). Thus, the combined genetic and photo-identification data showing that the southern feeding group represents a distinct maternally based seasonal subpopulation indicate that these whales require separate management consideration from the larger population.

Previous studies have suggested that the haplotype diversity in the southern feeding group is too high to have resulted from strict maternally directed site fidelity beginning with a few founders after the cessation of commercial whaling within the past century (Ramakrishnan et al. 2001). Under the hypothesis that this group was founded after the cessation of whaling, only a few closely related haplotypes should be represented within the southern feeding group, as opposed to the pattern seen in Fig. 2. In addition, the hypothesis of a founding event within the past century is not consistent with the known sighting information. Indeed, gray whales have been seen in the southern feeding grounds throughout their history, including in times of lowest abundance (Swartz et al. 2006, and references therein). Moreover, if a few individuals recently founded the southern feeding group, then the estimate of Θ_{southern} should be substantially smaller, as effective population size estimates are heavily influenced by bottlenecks.

Instead, what the sighting and genetic data suggest is that the southern feeding group of gray whales predates whaling. Under this hypothesis, the haplotype diversity is expected to be high, because those lineages that survived whaling would be a random sample from a much larger population. Substantial gaps would also be expected between existing haplotypes resulting from the removal of haplotypes by whaling. This pattern is exactly what is seen in Fig. 2. The similarity of haplotypes, and the degree of haplotype sharing between the southern feeding group and the larger population, both suggest some degree of migration between the 2 groups. However, although reliable estimates of migration rates could not be obtained here, the data clearly show that the rate of migration is low

enough for the 2 groups to represent independent demographic entities. The southern feeding group therefore qualifies as a separate MU, and requires separate management consideration.

A larger sample set, and the analysis of more molecular markers (particularly nuclear markers), is obviously desirable for addressing topics such as this one. Moreover, it is possible that further structuring within each of these identified groups exists, but is as yet undetected. However, given the clarity of the results obtained and the implications that they have for the management of these whales, it seemed important to publish these data as soon as possible so that they could be available for informing management decisions. We are currently collecting more samples and collaborating with other scientists to increase the number and geographical representation of our sample set. Protocols for analyzing nuclear loci are also being developed. Combined, these efforts will allow for larger-scale analyses of this issue in the near future.

Acknowledgements. Funding for this work came from the Natural Sciences and Engineering Research Council of Canada (NSERC), a Canadian Research Chair grant to B.N.W., and the Pacific Wildlife Foundation through donations from Remote Passages and Jamie's Whaling Station, and a grant from Clayoquot Biosphere Trust in Tofino, BC. We acknowledge the earlier work on this subject by T. Steeves and the transfer of her samples to this data set. We also thank A. Lang for help identifying which southern feeding group samples were duplicated in the LeDuc et al. (2002) data set. We thank the members of the Aboriginal Whaling Management Procedure (AWMP) scientific committee of the International Whaling Commission (IWC), N. Rose, and 3 anonymous reviewers for comments and discussions that improved this manuscript.

Steller's sea lion.

Abstract

Mitochondrial DNA sequence data were used to examine the phylogeographic history of Steller's sea lions (*Eumatopias jubatus*) in relation to the presence of Plio-Pleistocene insular refugia. Cytochrome *b* and control region sequences from 336 Steller's sea lions reveal phylogenetic lineages associated with continental refugia south of the ice sheets in North America and Eurasia. Phylogenetic analysis suggests the genetic structure of *E. jubatus* is the result of Pleistocene glacial geology, which caused the elimination and subsequent reappearance of suitable rookery habitat during glacial and interglacial periods. The cyclic nature of geological change produced a series of independent population expansions, contractions and isolations that had analogous results on Steller's sea lions and other marine and terrestrial species. Our data show evidence of four glacial refugia in which populations of Steller's sea lions diverged. These events occurred from approximately 60 000 to 180 000 years BP and thus preceded the last glacial maximum.

Introduction

Several empirical studies have documented the impact of glacial cycles on phylogeographic patterns of terrestrial species of plants and animals with a Beringian distribution (Holder *et al.*, 1999,2000; Abbot *et al.*, 2000; Clarke *et al.*, 2001; Barnes *et al.*, 2002; Flagstad & Roed, 2003). The chronology and geomorphology of glaciation in the North Pacific has been well-documented, and there is a growing body of evidence indicating large ice-free regions in Beringia (BER) and south of the ice sheets in Eurasia (EUR) and North America (NA) that served as refugia during the Wisconsin glaciation 65 000–18 000 years ago (Fig. 1) (Pielou, 1991; Hewitt, 2000). Several species of terrestrial plants and animals confined to these regions reflect patterns of phylogeographic structure that are temporally concordant with these geological events (Holder *et al.*, 1999; Abbot *et al.*, 2000; Barnes *et al.*, 2002; Fedorov & Stenseth, 2002; Fleming &

Cook, 2002; Zink *et al.*, 2002; Flagstad & Roed, 2003; Hundertmark *et al.*, 2003). Support for ice-free regions during the last glacial maximum (LGM) also comes from patterns of endemism seen in organisms from coastal islands of British Columbia, Southeastern Alaska and the Gulf of Alaska (Clague, 1989; Heusser, 1989; Cook *et al.*, 2001; Lacourse *et al.*, 2003). For instance, terrestrial species occupying the Alexander Archipelago, Kodiak Islands and the Queen Charlotte Islands (Fig. 1) are considered genetically divergent from mainland relatives as a consequence of insular isolation (Cowan, 1989; Heusser, 1989; Byun *et al.*, 1997; Holder *et al.*, 1999,2000; Clarke *et al.*, 2001; Barnes *et al.*, 2002; Fedorov & Stenseth, 2002; Fleming & Cook, 2002; Brunhoff *et al.*, 2003; Fedorov *et al.*, 2003). As with these terrestrial species, marine mammals and birds, including the sea otter *Enhydra lutris* (Cronin *et al.*, 1996), harbour seal *Phoca vitulina* (Stanley *et al.*, 1996; Gorbics & Bodkin, 2001; Westlake & O'Corry-Crowe, 2002), marbled murrelet *Brachyramphus marmoratus* (Congdon *et al.*, 2000) and rock ptarmigan *Lagopus mutus* (Holder *et al.*, 1999,2000) show similar patterns of divergence. Many of these taxa display female breeding site fidelity, and mitochondrial (mtDNA) gene sequences support genetic

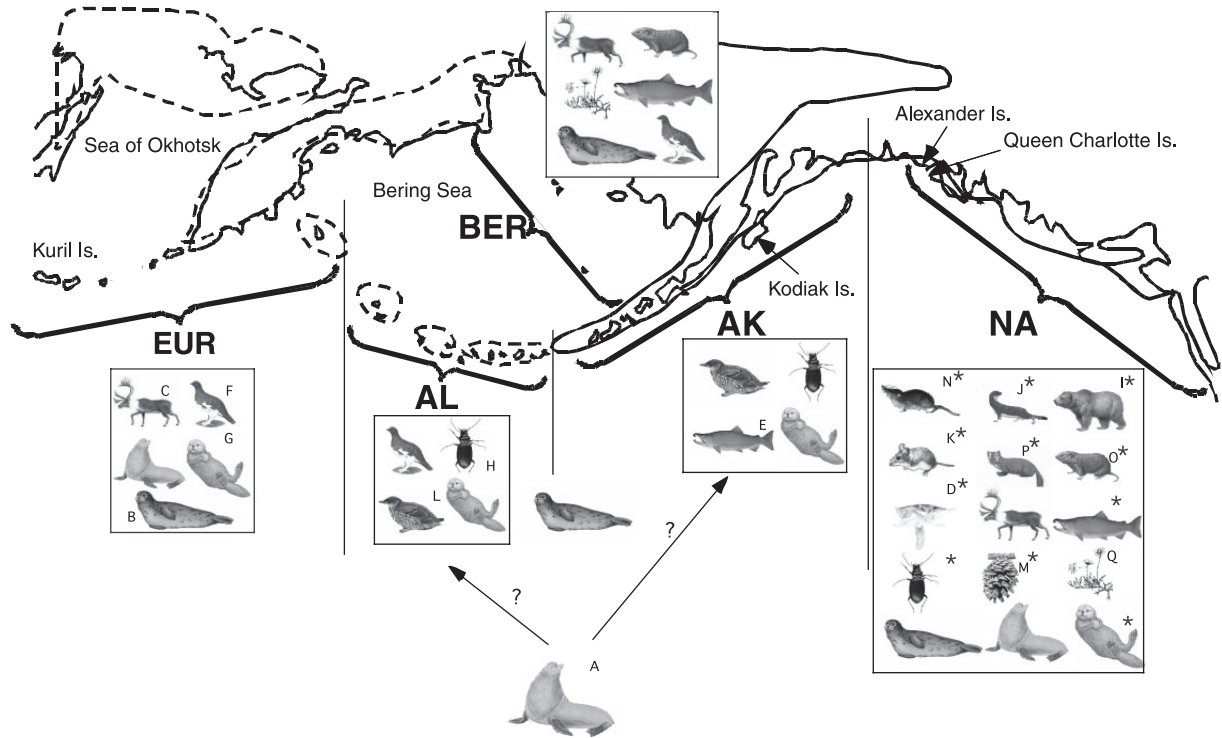

Fig. 1 Association of putative refugia and genetic structure of North Pacific biota. This figure summarizes previous studies of genetic structure of species occupying regions that were subjected to glaciation during the Plio-Pleistocene. Congruence in the distribution of genetic diversity for a wide variety of plants and animals suggests glacial vicariance shaped the history of these species in a similar fashion. Vertical lines roughly correspond to statistically significant breaks in genetic diversity, each associated with a glacial refugium: EUR, Eurasia; AL, Aleutian Islands; AK, Gulf of Alaska and mainland Alaska; NA, Continental North America; BER, Beringia. Asterisks indicate mainland North American taxa which have forms endemic to the Queen Charlotte and Alexander Islands. The solid curve outlines the general limits of the Cordilleran ice sheet during the last glacial maximum (LGM) 18 000–20 000 years ago (Mann & Peteet, 1994). Boundaries of the EUR ice, which remain disputed (Mann & Hamilton, 1995; Rutter, 1995; Grosswald & Hughes, 2002), are represented by hashed curves. Taxa identification: A, *Eumetopias jubatus* (Baker *et al.*, 2005; Bickham *et al.*, 1998); B, *Phoca vitulina* (Westlake & O’Corry-Crowe, 2002); C, *Rangifer tarandus* (Flagstad & Roed, 2003); D, *Glaucomys* sp. (Kavanaugh, 1989; Abbot *et al.*, 2000); E, *Oncorhynchus kisutch* (Smith *et al.*, 2001); F, *Lagopus mutus* (Holder *et al.*, 1999); G, *Enhydra lutris* (Cronin *et al.*, 1996; Gorbics & Bodkin, 2001); H, *Nebria* sp. (Kavanaugh, 1989; Clarke *et al.*, 2001); I, *Ursus americanus* (Byun *et al.*, 1997; Barnes *et al.*, 2002); J, *Mustela erminea* (Fleming & Cook, 2002); K, *Peromyscus* sp. (Cowan, 1989); L, *Brachyramphus marmoratus* (Congdon *et al.*, 2000); M, *Pinus contorta* (Lacourse *et al.*, 2003); N, *Sorex* sp. (Cook *et al.*, 2001); O, *Microtus* sp. (Cook *et al.*, 2001; Brunhoff *et al.*, 2003); P, *Martes* sp. (Cook *et al.*, 2001); Q, *Dryas integrifolia* (Tremblay & Schoen, 1999).

differentiation between rookeries within regions associated with putative insular isolates (Fig. 1). For example, there are genetic breaks in haplotype diversity that define one or more genetic lineages within the Aleutian Islands (AL), the Gulf of Alaska (AK) and coastal continental NA, which contain one or more of the putative insular refugia that remained ice-free at the LGM (Fig. 1).

Steller’s sea lion (*Eumetopias jubatus*) is a highly vagile marine mammal with rookeries distributed along rocky continental coasts and near-shore islands from Northern California, through the Gulf of AK, along the AL Archipelago, to the Kamchatka Peninsula, Kuril Islands and the Sea of Okhotsk in Asia (Fig. 2). The species has been studied intensively since the mid-1970s, and as a result, genetic material from more than 2000 individuals has been collected from every rookery within the species’ range, and the breeding biology and dispersal behaviour of this species

has been well-documented (Raum-Suryan *et al.*, 2002). Previous studies of mtDNA haplotype diversity (Bickham *et al.*, 1996, 1998; Baker *et al.*, 2005) defined three genetic stocks of Steller’s sea lion – ‘eastern’ (California to Southeast AK), ‘western’ (Prince William Sound to the Commander Islands) and ‘Asian’ (Kamchatka Peninsula, Kuril Islands and Sea of Okhotsk) – with a geographic distribution of genetic diversity generally similar to that of the harbour seal, sea otter, rock ptarmigan, and marbled murrelet (Fig. 1). Combined, the results from mitochondrial (Bickham *et al.*, 1996, 1998; Baker *et al.*, 2005) and nuclear loci (Trujillo *et al.*, 2004) support behavioural observations that female Steller’s sea lions return to within 500 km of their natal rookeries to reproduce throughout their lifetimes, and that gene flow among regions is predominately mitigated through the long-distance dispersal of males (Raum-Suryan *et al.*, 2002).

Fig. 2 Map of Steller's sea lion rookeries represented in this study. Sample sizes are in parentheses. 1, Iony Island (27); 2, Chernyya Brat'ya (13); 3, Srednego Island (15); 4, Raikoke Island (14); 5, Lovushki Island (19); 6, Antsiferova Island (13); 7, Zheleznaya Bay (9); 8, Kozlova Cape (11); 9, Medny Island (23); 10, Agatu Island (5); 11, Buldir (4); 12, Attu Island (4); 13, Kiska Island (13); 14, Amchitka Island (2); 15, Ulak Island (6); 16, Gramp Rocks (2); 17, Seguam Island (5); 18, Yunaska Island (3); 19, Adugak Island (4); 20, Bogosloff Island (2); 21, Ogchul Island (2); 22, Akun Island (2); 23, Akutan Island (24); 24, Ugamak Island (13); 25, Amak Island (1); 26, Clubbing Rocks (5); 27, Atkins Island (8); 28, Pinnacle Island (13); 29, Chowiet Island (2); 30, Chirikof Island (2); 31, Walrus Island (2); 32, Marmot Island (6); 33, Chiswell Island (2); 34, Sugarloaf Island (4); 35, Fish Island (9); 36, Seal Rocks (8); 37, White Sisters (6); 38, Hazy Islands (18); 39, Forester Island (5); 40, North Danger Rocks (3); 41, Triangle Island (5); 42, Rogue Reef (1); 43, St. George Reef (1).

The congruent distribution of genetic variation among terrestrial-breeding marine taxa supports the presence of insular refugia during the LGM. However, the extent to which these insular refugia shaped the phylogeographic history of terrestrial-breeding marine taxa remains inconclusive (Holder *et al.*, 1999). To investigate this, we present three testable predictions of the patterns of mtDNA population structure expected from species isolated among insular refugia during the Plio-Pleistocene. First, the effects of glacial vicariance should be detectable in the analyses of maternal lineages, especially in species with female philopatry. Second, geographic regions that demonstrate significant genetic structure are expected to be associated with putative glacial refugia. Third, the rate of coalescence events within maternal lineages is predicted to be synchronized with the chronology of geological events.

To test these hypotheses we studied the mitochondrial DNA control region and complete cytochrome *b* gene from 338 Steller's sea lions, distributed among 43 rookeries. Control region sequences were previously reported in a much larger study of population genetics designed to investigate stock structure of this species (Baker *et al.*, 2005). Based upon haplotype frequencies, they concluded that there are three stocks of Steller's sea lions: an eastern stock includes rookeries from California to southeastern AK, a western stock includes rookeries from Prince William Sound to the Commander Islands, and an Asian stock includes rookeries on the Kamchatka Peninsula, Kuril Islands and Sea of Okhotsk. Their study did not employ a phylogenetic analysis of the sequences or any specific tests to relate population subdivision to geological history. In this study we report new sequence data for the cytochrome *b* gene from a subset of the animals used by Baker *et al.* (2005), and we perform analyses to investigate the

relationships among geographic distributions of haplotypes, the phylogenetic history of the haplotypes, and the geological history of the North Pacific region. Our results provide support for the presence of glacial refugia proposed by the congruent distribution of multiple taxa with similar distributions, dispersal capabilities, and dependence on suitable terrestrial breeding habitat. Specifically, we present evidence that geographic variation of the Steller's sea lion is consistent with one or more insular refugia in the Pacific Northwest, Gulf of AK, AL Islands and Russia, and that following glacier recession, rookeries were re-colonized in a linear pattern, resulting in contemporary isolation-by-distance (IBD) between historical refugia. Collectively, this study provides one of the most thorough tests of insular refugia hypotheses, and it illustrates the response of a terrestrially breeding marine mammal to habitat perturbations resulting from glacial cycles.

Materials and methods

Sampling

Tissues were selected from an archive of flipper punches from pups taken at their natal rookeries (Fig. 2) collected from 1994 to 2003. Because Steller's sea lions are not known to twin, it is assumed that all samples are from unrelated individuals. Emphasis was placed on obtaining representation of previously recognized genetic stocks (Bickham *et al.*, 1996) and from regions containing putative insular refugia (Fig. 2), as well as representatives of all 80 control region haplotypes known from pups taken at rookeries at the time we conducted this work. All samples had previously been sequenced for a 238 bp segment of the control region (Bickham *et al.*, 1996, 1998; Trujillo *et al.*, 2004; Baker *et al.*, 2005).

Data collection

Total genomic DNA was isolated using either a standard phenol–chloroform protocol (Maniatis *et al.*, 1982) or a Qiagen DNeasy kit (Qiagen, Valencia, CA, USA). The complete cytochrome *b* (cyt *b*) gene and 238 bp of the 5' end of the mitochondrial control region (Bickham *et al.*, 1996) were amplified with the polymerase chain reaction (PCR). External primer sets included: (1) cyt *b* – LGL 765F, 5'-GAAAAACCAACGTTGTWATTCAACT-3' and LGL 766R, 5'-GTTTAATTACAATYTYAGCTTTGGG-3'; (2) control region – LGL 283F, 5'-TACACTGGTCTTGTAACC-3', LGL 1115R, 5'-ATGACCCTGAAGAA-RGAACCAG-3'. Methods for analysis of the control region were reported previously (Bickham *et al.*, 1996). For cytochrome *b*, approximately 1–2 µL of DNA template were included in 50 µL PCR reactions containing the following: 5 µL each 10X Amplitaq PCR buffer (Perkin Elmer, Boston, MA, USA), 25 mM MgCl₂ and 10 mM deoxynucleotidetriphosphates (dNTP's, 2.5 mM each), 1 µL each of 10 mg mL⁻¹ bovine serum albumin (BSA), 10 µM of each primer, and 5 units (U) of Amplitaq (Perkin Elmer) DNA polymerase. Reactions were performed in an ABI 2700 (Applied Biosystems, Foster City, CA, USA) thermocycler with an initial denaturation at 95 °C for 2 min, followed by 25 cycles of 95 °C (45 s), 50 °C (40 s), 70 °C (2 min 30 s), and a final extension at 72 °C for 10 min.

Amplicons were electrophoresed in 1.5% agarose-TBE (tris, boric acid, EDTA) and visualized under UV light. Prior to sequencing, excess oligonucleotides and dNTP's were removed with a QIAquick PCR purification kit (Qiagen, Valencia). Cleaned PCR products were sequenced with ABI (Applied Biosystems) BigDye sequencing chemistry and an ABI 377 automated sequencer. All amplicons were sequenced in both directions, and two internal primers (560, 5'-GCAACCCTAACACGATTCTTCG-3'; 610, 5'-CCAGTTTCGTGTAGGAATAATAGG-3') designed for Steller's sea lion were used to sequence cytochrome *b* to obtain complete overlap in both directions.

Sequences were aligned with default parameters in Clustal X (Thompson *et al.*, 1994), and published sequences of *E. jubatus* (GenBank accession X82311), *C. ursinus* (AF380888, AF384390 AF380890, AF384389), *P. vitulina* (L39204, AF522864 X82306, AF522865), and *Zalophus californianus* (X82310, L37031), the sister-taxon to Steller's sea lion (Wynen *et al.*, 2001), as guides. The alignment of cyt *b* was unambiguous and contained no insertions or deletions. Subsequent to the Clustal X alignment of the control region, visual alignment in MACCLADE VERSION 4.0 (Maddison & Maddison, 1992) was used to make minor adjustments. Because the mitochondrial genome is inherited as a single genetic locus without recombination, the cytochrome *b* and control region sequences were concatenated to produce a fragment of 1378 base

pairs. This alignment is available from authors upon request. All subsequent statistical analyses were performed on this combined data set. The sequences for 28 cytochrome *b* haplotypes were submitted to GenBank under accession numbers DQ144995–DQ145022. All control region sequences were previously submitted to GenBank by Baker *et al.* (2005).

Diversity indices, model of evolution, and rate of substitution

DNASP VERSION 3.99.5 (Rozas & Rozas, 1999) was used to estimate haplotype diversity (Nei, 1987), nucleotide diversity (π) (Nei, 1987), theta, and number of segregating sites. Standard error of these measurements was determined from a null distribution generated from 10 000 random permutations of the data keeping sample size constant. The average number of pair-wise differences was estimated with the program MEGA VERSION 2.1 (Kumar *et al.*, 1993,2001) with gamma-corrected Tamura–Nei (Tamura & Nei, 1993) distances. A 95% confidence interval for the pair-wise distances was calculated from 100 bootstrap replications.

MODELTEST VERSION 3.06 (Posada & Crandall, 1998) was used to test 54 nested hypotheses of nucleotide substitution. The Tamura–Nei model (Tamura & Nei, 1993) with a correction for rate variation among sites (Yang, 1996) and a proportion of invariant sites [$I = 0.9176$; (Waddell *et al.*, 1996)] was selected as the model that best fit the substitution pattern for both genes, and was used in all analyses that employed a model of evolution.

A maximum likelihood analysis of edited *E. jubatus* ($n = 2$, this study) sequences, aligned with GenBank sequences from *C. ursinus* ($n = 3$) and *Z. californianus* ($n = 2$), was performed in PAUP* VERSION 4.0B10 (Swofford, 1999) with model parameters selected via ModelTest Version 3.06 (Posada & Crandall, 1998) and rooted with *P. vitulina* as an outgroup. The resultant phylogeny (not shown) was congruent with a previous analysis (Wynen *et al.*, 2001), with *E. jubatus* and *Z. californianus* as sister taxa and *C. ursinus* at the base of the *E. jubatus* and *Z. californianus* clade. This phylogeny with maximum likelihood optimized branch-lengths was subsequently used in RHINO VERSION 1.2 (Rambaut, 2003) to estimate the divergence time and substitution rate of the *E. jubatus* lineage. Two calibration points, the divergence of *E. jubatus* and *Z. californianus* at 2.0 ybp and *C. ursinus* and the family Otariidae at 6.0 ybp (Repenning, 1976), were used to estimate substitution rates. The rate of evolution obtained with RHINO was compared to that derived with the formula $r = K/2T$ (Li & Graur, 1991), where K is the number of pair-wise differences between Steller's sea lion and *Z. californianus*, and T is the date of divergence in millions of years (ybp). The date of divergence of 2.0 ybp (Repenning, 1976) from the fossil record was used as a calibration point in this analysis.

Prediction 1: genetic structure of female lineages

Phylogenetic relationships among mtDNA haplotypes within the *E. jubatus* lineage were estimated following the statistical parsimony procedure of Templeton *et al.* (1992) with the program TCS VERSION 1.1.3 (Clement *et al.*, 2000). The haplotype network obtained from TCS was used as the framework for sequential nesting of haplotypes into clades (Templeton, 1998). Reticulations, or equally parsimonious connections within the network, were resolved with two procedures. First, alternative connections between haplotypes were broken following a series of rules based on coalescence theory (Crandall & Templeton, 1993). Second, synapomorphies in the form of nonsynonymous substitutions in the *cyt b* gene, a conservative class of substitution, was used to resolve all cases in which assignment to a nested series was ambiguous ('stranded clades') (Templeton *et al.*, 1987; Templeton & Sing, 1993). The program GEODIS VERSION 2 (Posada *et al.*, 2000) was used to test the null hypothesis of random geographic distribution of genetic variation. This program performs two analyses. The first is an $r \times c$ contingency test of geographic locality and frequency of haplotypes. The second is the estimation of haplotype dispersion within and among nested clades (Templeton, 1998). In both cases, the significance of results was derived from comparison to a null distribution generated from 10000 randomizations of the data matrices.

Templeton's nested clade procedure (Templeton *et al.*, 1987, 1992; Templeton, 1998) was used to define genetic boundaries of populations by simultaneously incorporating evolutionary history and contemporary geographic distribution and frequency of haplotypes. With this method, it is not required that the number or geographic boundaries of populations be defined *a priori*, but rather genetically distinct populations are defined via statistical tests for association of evolutionary lineages and their geographic distribution. Statistical significance is determined with a permutation procedure that increases the power to detect population structure in species whose genetic variation otherwise does not display a definitive geographic pattern (Templeton, 1998, 2004). Because the relative age of clades increases with nesting level, the most contemporary population boundaries were determined from the distribution of 1-step clades that had a significant geographic association in the NCA. The geographic distribution of haplotypes within clades at deeper nested levels (> 1-step) was used to characterize the temporal shift in the geographic distribution of population boundaries over time. A hierarchical AMOVA (Excoffier *et al.*, 1992) was performed with ARLEQUIN VERSION 2.00 (Schneider *et al.*, 1997) to measure the strength of the genetic structure among populations with boundaries defined with NCA, and to quantify the partitioning of variation within rookeries, within populations of rookeries, and among populations. Significance

values of ϕ statistics (Weir & Cockerham, 1984) were calculated by comparison to a null distribution derived from 10 000 random permutations of the data.

Prediction 2: association of glacial refugia and population boundaries

The program IBD VERSION 1.5 (Bohonak, 2002) was used to perform a Mantel test that assessed significance of the correlation between geographic and genetic distances. The slope of the regression plus 95% confidence intervals was estimated with reduced major axis regression (RMA), which is considered a more appropriate estimator of slope in IBD analyses than ordinary least squares regression (Hellberg, 1994).

A partial regression was performed with IBD to test for significant association of genetic divergence and putative insular refugia while controlling for the effect of geographic distance. A third variable matrix was created from pair-wise comparisons of rookeries that were or were not potentially separated by inhospitable (ice covered) rookeries at the LGM. For example, a '1' was assigned to individuals from rookeries that were not putatively separated by ice sheets at the LGM, and a '0' was given to comparisons among rookeries that were potentially isolated or extirpated via glacial vicariance. In this manner, we tested for an effect of ice sheets on genetic divergence among rookeries. Furthermore, population boundaries derived from NCA were compared to the geographic location of putative refugia (Fig. 1).

Prediction 3: dates of population divergence and glacier chronology

The stochastic nature of lineage sorting within species makes estimation of intraspecific divergence with a single locus problematic. In an attempt to circumvent this potential problem, times of divergence among populations of Steller's sea lion were calculated with two methods. First, the time to most recent common ancestor (TMRCA) of clades was estimated with the program BEAST VERSION 1.0.3 (Drummond *et al.*, 2002; Drummond & Rambaut, 2003a) that uses a Bayesian approach with a MCMC search strategy to calculate from an aligned sequence matrix, a model of evolution, and a rate of nucleotide substitution, the posterior probability density distribution of divergence dates of clades. One important feature of BEAST is the ability to analyze concatenated DNA sequences from multiple data partitions that have different models of evolution. Therefore, the concatenated cytochrome *b* and control region partitions were assigned independent models of evolution derived from MODELTEST. Three independent MCMC chains were run for 1 000 000 steps each to optimize the scale factors to an acceptance rate probability of 0.25 for each parameter (Drummond *et al.*, 2002). Each initial MCMC chain was run with scale factors adjusted as

suggested by the operator analysis (Drummond & Rambaut, 2003a) until the scale factors and the length of chains were adequate to produce an effective sample size (ESS) (Drummond *et al.*, 2002) greater than 100 for all estimated parameters. The final BEAST analysis consisted of two independent MCMC chains of 2 500 000 steps each with optimized search settings. TRACER VERSION 1.0.1 (Drummond & Rambaut, 2003b) was used to examine the burn-in period, the degree of mixing, the shape of the probability density distribution, and 95% confidence intervals for estimated divergence dates. A final examination of the two runs combined suggested that the two chains sampled from similar probability density distributions, and that mixing during the search was adequate. The quality of the MCMC search was also supported by high (> 100) ESS values. Second, the TMRCA of clades was estimated by calculating the average number of pair-wise differences between haplotypes within each clade, and multiplying this by the point estimate and 95% confidence intervals of the maximum-likelihood derived mutation rate of the concatenated data partitions (see previous section).

Results

Diversity indices, model of evolution, and rate of substitution

Comparisons of 336 individuals of *E. jubatus* yielded 64 variable sites and 107 haplotypes for the combined data. Haplotypes differed from each other by an average of 2.26 substitutions, and nucleotide diversity was relatively low at 0.18%. Of the 107 haplotypes, 93 were found only in a single individual, and haplotype diversity was 0.89 (± 0.01).

The maximum likelihood estimation of the rate of substitution for *E. jubatus* was 1.9% per myr with a 95% confidence interval of 1.5–2.8%. Similarly, the method based on the average number of pair-wise differences produced a substitution rate that ranged between 1.5 and 1.9% per myr with an average of 1.7%, well within the 95% confidence interval of the maximum likelihood estimate.

The maximum likelihood analysis of divergence times proposed a separation of the *E. jubatus* and *Z. californianus* lineages approximately 2.25 myr ago, with a 95% confidence interval of 1.57–3.06. This divergence estimate was cross-validated with independent calibrations, i.e. the 2 myr *E. jubatus*/*Z. californianus* and the 6 myr sea lion/*C. ursinus* fossil dates fell within the 95% confidence intervals of divergence dates derived from the ML analysis of molecular data.

Prediction 1: genetic structure of female lineages

The nested clade procedure produced a network with four nested levels (Fig. 3), each with clades that demon-

strated statistically significant geographic patterns (Table 1). For example, Clade 4-2 contained 100% of the haplotypes collected in NA rookeries (British Columbia to California, Fig. 1), and Clade 4-1 showed the opposite pattern containing the majority of haplotypes from EUR (west of the Commander Islands) (Fig. 4). Those rookeries in the central portion of the range, from the Gulf of AK (Fig. 1) through the AL Islands (Fig. 1), most often had haplotypes distributed equally between the two 4-step clades (Fig. 4). There is a similar pattern to the geographic distribution of haplotypes in 1-, 2-, and 3-step clades, but geographic resolution increases as the nested level decreases. For example, 2-step clades show association between EUR and NA, but also clearly demarcate a lineage (clade 2-6) geographically restricted to the AL and AK regions (Fig. 4). Clades at the first nested level defined four lineages, each associated with EUR, NA, AL and AK regions (Fig. 4). Boundaries of contemporary Steller's sea lion populations were defined from the geographic limits of these four regionally associated lineages. Measures of population structure provided additional statistical support for genetic subdivision of *E. jubatus* into these four populations (Table 2).

Prediction 2: association of glacial refugia and population boundaries

The four populations identified with the nested clade procedure roughly corresponded to the location of the NA, EUR, AL and AK refugia (Fig. 4). The partial regression revealed statistical support for the association of genetic distances between rookeries and putative glacial refugia ($r = 0.18$, $P < 0.05$). Additionally, the Mantel and RMA analyses supported a significant positive correlation between genetic and geographic distance between rookeries ($r = 0.36$, $P < 0.001$).

Prediction 3: dates of population divergence and glacier chronology

Estimates of TMRCA derived from Bayesian and maximum likelihood methods varied, so that no two estimates from different methods overlapped in their dates (Table 3). When the results of each method were examined independently, the confidence intervals tended to be large regardless of the method used, such that in most cases estimates of TMRCA among lineages were not significantly different from each other (Fig. 5). Dates derived by the Li & Graur (1991) method produced the smallest confidence intervals with the greatest degree of discrimination of inter-clade divergence (Table 3). These dates were generally 150 000–200 000 years younger than those of the Bayesian method, and the confidence intervals were more consistent (Table 3). Nevertheless, regardless of the method used to derive the dates, analyses supported a divergence of *E. jubatus* populations prior to the Wisconsin glaciation.

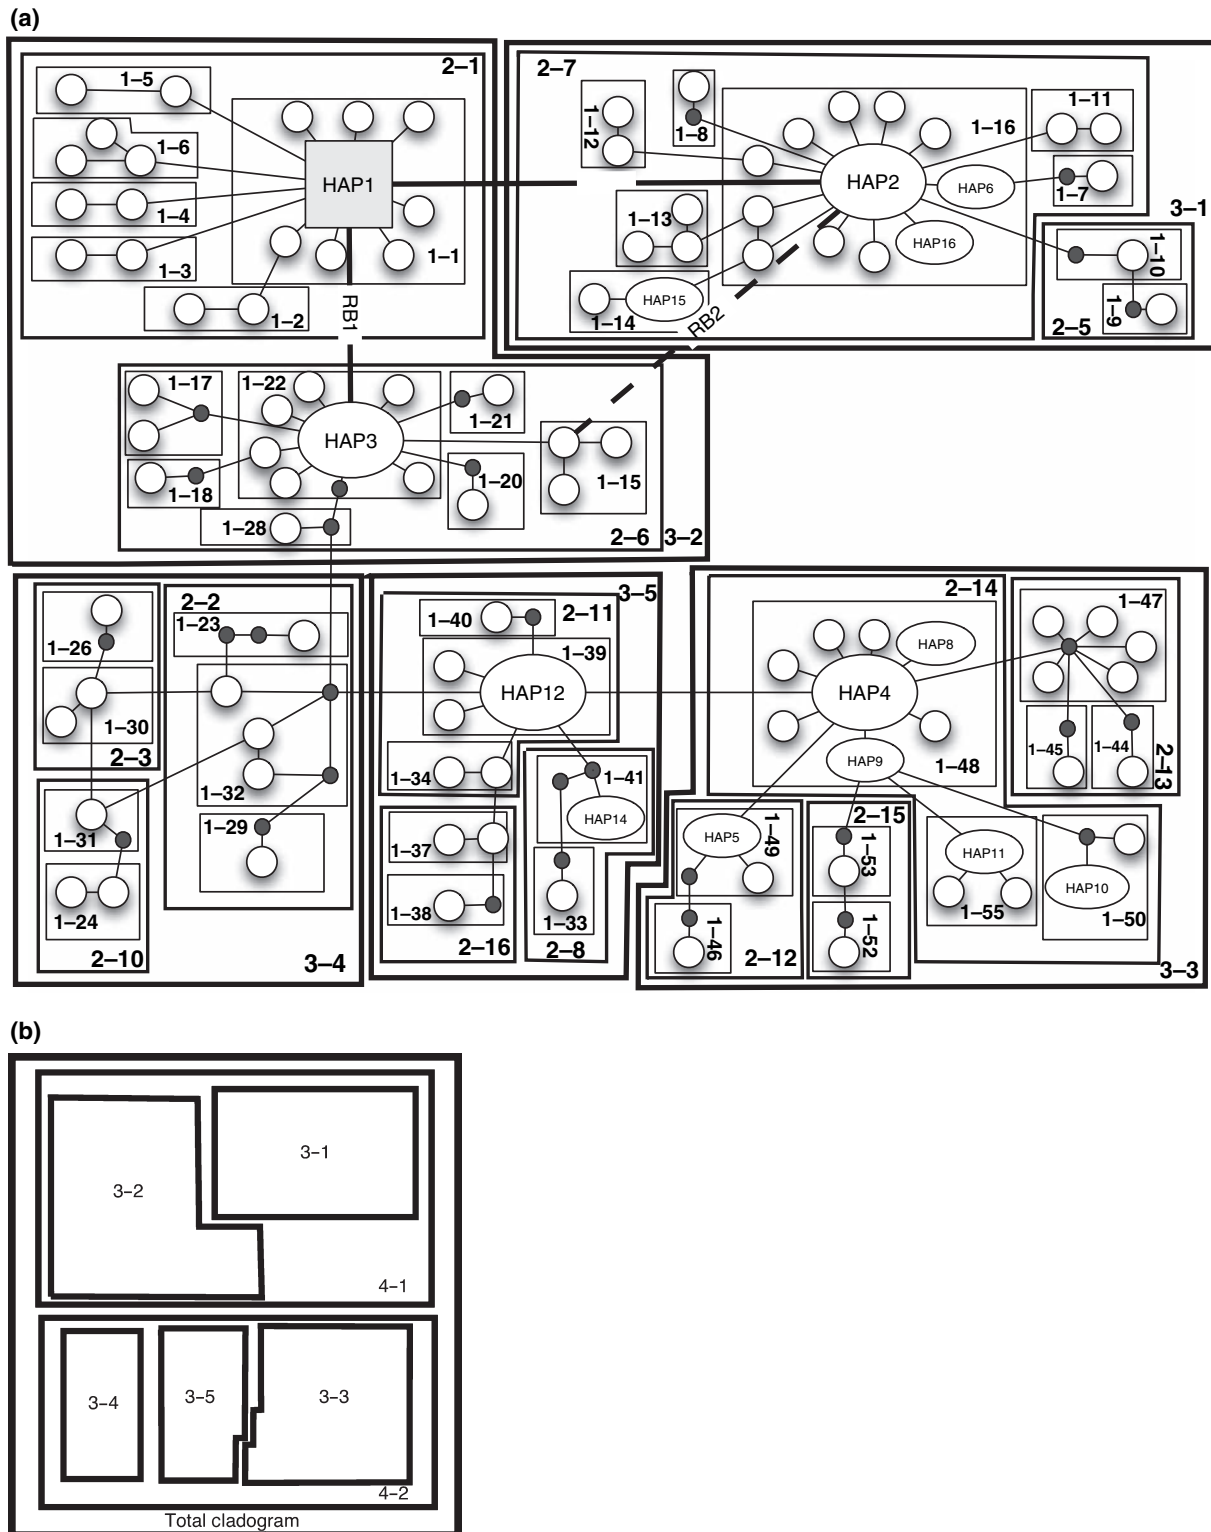

Fig. 3 Nested cladogram. (a) Nested levels 0–3. Haplotype codes are as in Table 1. Ovals designate haplotypes with a frequency > 1 and are roughly proportional to frequency. Solid circles represent inferred intermediate haplotypes. Alpha-numeric designations refer to individual sea lions possessing unique haplotypes. Each line indicates one mutational step. Reticulations are indicated with dashed or heavy solid lines. RB = Reticulation Break. (b) Nested levels 3 and 4.

Table 1 Summary of inferences regarding demographic events deduced from clades with significant nested clade values.

TIP, tip clade, INT, interior clade.
Clade numbers within parentheses represent those lower-level clades within the nested series with significant evidence for demographic events. A greater-than or less-than symbol indicates a D_c or D_n value that is significantly larger or smaller than expected if haplotypes were distributed randomly. P -values indicate probability that the D_c or D_n estimated from the data were observed by chance. Inferences were drawn from the nested clade analysis key of Templeton (1998). The steps in the chain of inference can be examined by comparison to this key.
*Results are not significant at $P < 0.10$.
†Results of chi-square were significant ($P < 0.05$), but lack of tip clades prevents nested clade inference.

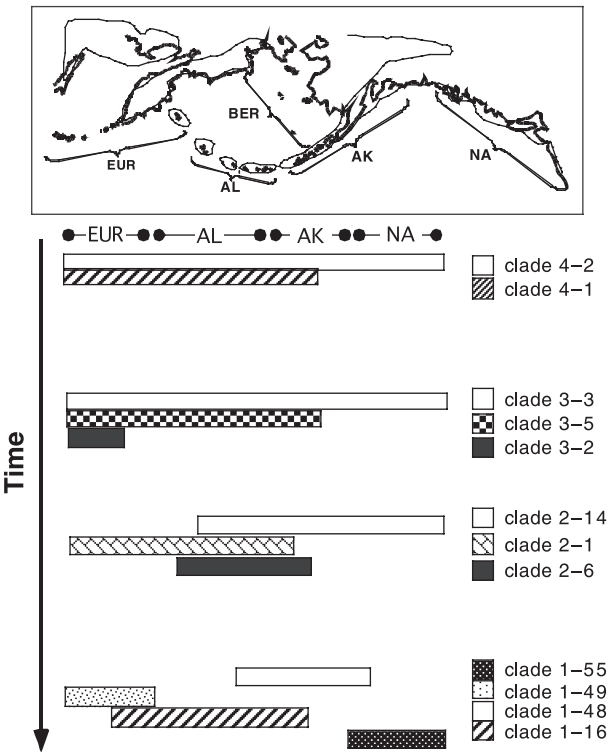

Fig. 4 A summary of *Eumetopias jubatus* phylogeographic history. Shifts in the geographic distribution of lineages over time are synthesized to present a relative chronology of *E. jubatus* phylogeographic history. The horizontal bars represent the geographic distribution of individual clades within the nested series, and therefore roughly correspond to coalescent events. Clades at the 1-step nested level represent the most recent demographic events, and roughly correspond to four glacial isolates.

Table 2 Results of analysis of molecular variance among five Steller's sea lion populations derived from the nested clade procedure.

Variation source	d.f.	SS	Components	Variation (%)
Among groups	4	70.8	0.28 Va	17.39 $\Phi_{ct} = 0.17^*$
Within groups	37	61.5	0.05 Vb	3.24 $\Phi_{sc} = 0.04^*$
Within rookeries	287	366.2	1.28 Vc	79.37 $\Phi_{st} = 0.21^*$
Total	328	498.5	1.6	

* $P \leq 0.001$.

Because the maximum likelihood divergence estimates had consistently narrower confidence intervals (Table 3), they were used to create a chronology of the history of Steller's sea lion lineages (Fig. 5). In general, the pattern of geographic distribution of maternal lineages suggested that three regional groups formed early in the history of the sea lion (Fig. 4), and that the formation of these groups was loosely associated temporally with glacial cycles (Fig. 5). The broad-scale geographic partitioning of lineages (i.e. 3- and 4-step clades) were coincident with two major ice ages, earlier than the LGM, where sea levels were as much as 140 m below current levels (Fig. 5).

Nested clade inference suggested multiple demographic events in the phylogeographic history of *E. jubatus* (Table 1, Fig. 4). In particular, these results indicated that the rookeries in EUR and NA, at the ends of the species' distribution, experienced multiple periods of geographic isolation and expansion. Nested clade (D_n) and clade (D_c) distances revealed at least three different periods of restricted gene flow between the EUR

(A) **BEAST** estimates of time to the most recent common ancestor (TMRCA) for clades identified by nested clade analysis as having experienced a significant demographic event (Fig. 4, Table 1). Results are from independent MCMC chains (G4 Runs 1, 2) and the average over runs (combined) plus 95% confidence intervals derived from the Bayesian probability distributions (BPD). ESS = Effective Sample Size. (B) TMRCA estimated with the method of Li and Graur (1991) based on the average number of pairwise differences among haplotypes. Dates of divergence were calculated for the 95% CI limits of the estimated rate of substitution of the mitochondrial DNA locus.

and other rookeries (Table 1). In other cases, rookeries in CA were isolated from rookeries from AK east to EUR (Fig. 4, Table 1). Therefore, the nested clade inference key supported the interpretation derived independently from observed patterns of lineage distribution, namely that three groups-Eurasian (EUR),

NA and a central Alaskan/Aleutian (AK + AL) appeared multiple times during the history of the species (4-, 3- and 2-step clades, Fig. 4), with a recent addition of a fourth group that formed from the division of the central group into AK and AL populations (1-step clades, Fig. 4).

Fig. 5 The chronology of coalescent events derived from the average pair-wise divergence among haplotypes in lineages and the 95% confidence interval of the maximum likelihood estimated rate of substitution. Fluctuations in sea level were derived from Rohling *et al.* (1998) and are presented relative to current sea levels in meters (m). Grey shaded regions represent major periods of glaciation, and lines above and below peaks demarcate the confidence intervals of sea level heights at periods of glacial maxima. LGM is last glacial maximum. TMRCA is time to most recent common ancestor.

Discussion

Predictions 1 and 2: Genetic structure of female lineages and glacial refugia

One attribute of the nested clade approach is its ability to infer historical processes from the phylogenetic association of lineages that otherwise do not display a definitive geographic pattern (Templeton, 1998, 2004). In the case of Steller's sea lion, inferences derived from the nested pattern of haplotypes revealed multiple vicariant events, corresponding to either the formation or degeneration of populations associated with glacial refugia (Table 1, Fig. 4). In particular, our results support the association of breaks in the distribution of genetic variation along the coast of NA, including the Gulf of AK and British Columbia, that are congruent with ice-free islands during the LGM, notably Kodiak Island, the

Alexander Archipelago and the Queen Charlotte Islands (Fig. 4). In addition, breaks in the distribution of genetic variation suggest that EUR and AL Island rookeries represent remnants of two independent glacial refugia. The exact locations of these refugia are unknown, but they were likely small, ice-free areas in these regions, similar to those off the coast of British Columbia and the Gulf of AK. There are several other lines of evidence supporting an effect of glacial refugia on the structuring of female lineages of Steller's sea lion. First, the derivation of population boundaries was performed with simultaneous incorporation of haplotype frequency and evolutionary history in the nesting procedure. We argue that this is a powerful, objective approach to defining populations without the need for *a priori* assumptions of either the number or geographic boundaries of populations. Furthermore, basic predictions of coalescence theory lead to similar conclusions regarding the genetic

structure of maternal lineages among geographic localities, i.e. the change in distribution of lineages over time can be interpreted without reference to the nested clade inference key as evidence for the formation of populations at different geographic scales throughout the history of the species (Fig. 4). Yet the most compelling evidence is found in the similar patterns of population structure of Steller's sea lion and other taxa (Fig. 1), including harbour seals and sea otters, that provide additional support for the presence of refugia somewhere within these two regions (Cronin *et al.*, 1993; Bickham *et al.*, 1996; Westlake & O'Corry-Crowe, 2002). In total, we suggest that the geographically extensive sampling of Steller's sea lion rookeries and the congruent patterns of population structure derived from studies of multiple taxa independently validate the presence of multiple insular refugia and their importance in shaping the phylogeographic history of taxa in the North Pacific and Bering Sea.

The divergence between Steller's sea lion populations generally followed a pattern of IBD, with the greatest amount of divergence between rookeries in EUR and NA. This is not unexpected given the relatively early separation of these clades at the 4-step nested level (Fig. 4). However, it is possible that patterns of IBD arise in response to limited dispersal between regions that resulted in the accumulation of genetic divergence over time, and it is not necessary to invoke glacial vicariance as the explanation for patterns of population structure. Nevertheless, the pattern of temporal progression from 4-step to 1-step clades (Fig. 4) suggests that the boundaries of EUR and NA isolates were somewhat ephemeral, and that AL and AK populations formed and persisted following the expansion and divergence of EUR and NA isolates. The pattern of IBD seems more consistent with a scenario of re-colonization of AL and AK regions from EUR and NA refugia following glacier recession, which is consistent with the presence of multiple insular refugia.

Prediction 3: dates of population divergence and glacier chronology

Estimates of coalescence times suggest a demographic history of *E. jubatus* that predates the Wisconsin glaciation (Fig. 4, Table 3). These results are consistent with several previous studies that attributed population structuring of Arctic species to demographic events older than the LGM. For example, patterns of genetic subdivision of the rock ptarmigan are presumably the result of events occurring prior to the LGM (Holder *et al.*, 2000; Brunhoff *et al.*, 2003). Klicka & Zink (1998) examined the evolution of NA songbirds and proposed that the 35 species of birds in their study underwent speciation prior to the late Pleistocene. Given that *E. jubatus* split from *Z. californianus* approximately 2 000 000 years ago, it is not unreasonable to expect *E. jubatus* populations to

currently bear a signature of the effects of glacial cycles that are much older than the Wisconsin glaciation.

The distribution of ice sheets and the duration of the glacial cycles occurring earlier in the Pleistocene are not as well understood as the Wisconsin glaciation. There is strong evidence, however, for changes in sea level associated with glacial cycles dating back to the early Pleistocene (Rohling *et al.*, 1998). Over the last 450 000 years, the sea levels have been as much as 150 m below current levels (Rohling *et al.*, 1998). Many areas of the coastline that are now submerged by seawater were exposed during glacial periods, and served either as corridors for the dispersal of plants and animals (e.g. BER) or as isolated refugia. The fragmentation and expansion of *E. jubatus* coincides with periods of ice sheet advance and retreat, namely the long glacial cycles between 150 000 and 300 000 years ago (Fig. 5, Table 2). This chronology of events is consistent with a scenario of multiple, independent fragmentations by advancing glaciers during interglacial stades, followed by isolation and divergence in several refugia until the ice receded. If it is assumed that contemporary patterns of genetic variation bear the signature of both historic and current processes, one could infer that the effects of insular refugia on population structure represent more recent, fine-scale events in the history of *E. jubatus*, compared to the formation of older and larger glacial refugia associated with the NA mainland. Concordance between the distributions of insular refugia proposed in this study and similar studies of other biota provide additional evidence for the existence of these smaller refugia, despite the inability of phylogenetic methods to detect their formation.

However, it is important to note that confidence intervals associated with estimates of intraspecific divergence times are large, and that there is lack of concordance among estimates derived from different methods. This is not unexpected given the intraspecific lineage sorting process that can be complicated by demographic factors such as population growth, expansion and substructure within regions due to reproductive and dispersal behaviours (Ball *et al.*, 1998; Hoelzer *et al.*, 1998). Nevertheless, results of this study are compelling given the degree of congruence among the structuring of multiple taxa with overlapping distributions, similar dispersal capabilities and ties to terrestrial breeding localities. Even if the dates of divergence of Steller's sea lion are loosely associated with glacier advance, the pattern of population structure supports a region-wide series of phenomena that have shaped the history of multiple taxa before the LGM.

In summary, the pattern of diversification of female lineages of Steller's sea lions appears to correlate with the glacial advances and retreats during the Pleistocene, from approximately 60 000 to 180 000 years BP (Fig. 5). Four populations, ostensibly derived from distinct glacial refugia, are recognized including NA, AK, AL and EUR.

In a previous study of the population genetics of this species, Baker *et al.* (2005) examined control region sequences from 1568 pups taken from 50 rookeries from throughout the range of the species. That study, which focused primarily on population genetic analyses using haplotype frequencies, resolved three genetically distinct stocks. An eastern stock ranges from northern California to southeastern AK and equates to NA in this study. An Asian stock includes rookeries in the Sea of Okhotsk, Kuril Islands and Kamchatka Peninsula and equates to EUR in this study. And, a western stock ranges from Prince William Sound to the Commander Islands and equates to AK and AL in this study. The addition of the cytochrome *b* dataset and the nested clade analysis performed in this study provide an evolutionary framework that increases our understanding of the dynamic nature of population structure of this endangered species.

Acknowledgments

The National Marine Fisheries Service provided funding for this study. We thank V. Burkanov and D. Calkins (coordinators for the collecting trips in Russia) and T. Gelatt and K. Pitcher of the Alaska Department of Fish and Game. All specimens were humanely treated and collected under Marine Mammal Protection Act permit 782-1532-02. We gratefully acknowledge A. Rambaut and A. Drummond for help with BEAST analysis and editing xml input files. Thanks to D. Honeycutt and C. Matson who provided detailed editorial comments and R. Trujillo who provided some of the DNA sequence data.

Introduction

Catching gray whales was not easy, but because it could be profitable catches in the nineteenth century greatly depleted the number of gray whales. Yankee whalers who dared the dangerous coastal and lagoon waters of Baja California in winter and the treacherous ice-filled seas of the North Pacific and Pacific Arctic in summer to chase the

wily and destructive devil fish, or gray whale, have much to tell us about their prey. Experiences of the chase, catch reports, and observations that would increase catches reveal much about the populations, behavior, migrations and their timing, the ranges and thus whaling grounds, food, predators, whale size, and other data related to the gray

ed to the gray

whales. The history and geography of nineteenth century gray whaling, which shed light on the preceding subjects, are important concerns of this chapter. First, however, we should follow whalers through history to the gray whaling waters which were confined to the North Pacific.

It was a long sail, historically, from the Atlantic shores from which high-seas whalers had set forth in their vessels since the thirteenth century (Sanderson, 1956, p. 136), to distant Pacific coasts along which Yankee and European whalers of the nineteenth century found an unfamiliar prey awaiting their harpoons and lances, the gray whale. These whalers found and pursued gray whales in coastal waters of Alta (Upper) California, Baja (Lower) California, Northwest Mexico, and in the Bering, Okhotsk, and Pacific Arctic seas. Once in the Pacific Ocean, whalers searched out that ocean's whaling grounds rapidly.

The first whaler to enter the Pacific was the ship *Amelia* (*Emelia*) of London which rounded Cape Horn in 1789 (Henderson, 1972, p. 16). Whalers then pushed their ships up the west coast of South America, and by 1793 the Englishman Colnett had conducted a survey for whales on the ship *Rattler* as far north as Cape San Lucas (Fig. 1), (Henderson, 1972, p. 15). By 1795, Captain John Locke on the English ship *Resolution* had carried out the first genuine whaling venture in the eastern North Pacific Ocean, during which he reached Baja California. Locke sailed around the Cape of Good Hope with supplies for Australia; he probably sailed next to India and/or China, and thence across the broad North Pacific without a landing until he reached Baja California in October–November 1795 (Cumpston, 1964, p. 29; Henderson, 1972, pp. 17–21). His landfall was near the mouth of the Guadalupe River, and he put ashore just south of there for badly needed "recruits" (supplies) at Ensenada de Todos Santos and later at the end of the peninsula at San José del Cabo. At these places, the Spaniards on the weak mission frontier met his needs and learned that he had 500 barrels of whale oil on board, undoubtedly the sperm whale oil which whalers of those years most desired.

Following Locke's visit, armed English whaleships came to Baja California and Alta California waters, at the end of the eighteenth century and in the early years of the nineteenth century, to prey on sperm whales and the small and isolated Spanish-governed communities alike (Henderson, 1972, p. 21). These whalers followed closely in the wake of English and Yankee vessels that had been guided to the sea otter and fur trade of the Northwest Coast of America by the discoveries of Captain James Cook in 1778 (Henderson, 1972, p. 16). Yankee whalers soon followed the English, and after 1815 American whaleships in the Pacific Ocean outnumbered those of other nations. It was from the coast of Baja California that the first two whaleships arrived in the Hawaiian Islands in 1819—the American ships *Balaena* (New Bedford, Captain Gardner) and *Equator* (Nantucket, Captain Folger) (Stackpole, 1964, pp. 267–268). From that island mecca of Pacific whalers, ships subsequently cruised northward in summer to Japanese seas, the northwest coast of America, and the northeast coast of Asia (both known as the Northwest Coast to whalers), to the Bering and Okhotsk seas, and finally in 1848 to the Pacific Arctic Ocean. The coasts of the Californias became important sperm whale grounds where American, English, and European whalers made abundant catches (Henderson, 1972, pp. 21–22).

or Spring: ▲. mud hole.

North Pacific Whaling

When whalers began to depart the Hawaiian or Sandwich Islands in spring to cruise for sperm, right, and bowhead whales, they also left ice and cold at summer's end to return to the Hawaiian Islands in autumn. Thence in winter the whalers could steer for a variety of warmer grounds: New Zealand or even Chilean waters, the line or equator, and the Marianas; most important for this history was the Coast of California ground which to the whalers meant the ground on the west coast of Baja California. Among the various winter cruises, the sail to California was considered a short and easy one during which southern westerlies blew ships to the coast and trade winds carried them back to the Islands. The crossing in each direction took only about 3 weeks.¹ Another recommendation for the cruise to California was that ships could lie at anchor all season in a bay or lagoon or make short runs up and down the coast instead of ranging where wind and wave could be damaging and costly.

A whaling pattern evolved in the North Pacific which involved visits to the Hawaiian Islands in spring and autumn and whaling in northern parts of the Pacific in summer and in warmer parts of that ocean in winter.²⁻⁴ Hundreds of vessels called each spring and fall at the Hawaiian Islands for recruits and to get rid of some whaling hands and sign on others, many of whom were Kanakas. To the Yankee, a Kanaka was any Pacific islander, but most were from Polynesian islands and of those most were from the Hawaiian Islands.¹ Because the northern season when right and bowhead whales were captured was the most productive season for most whalers, the number of "seasons out" from home meant the number of summer seasons spent in the Pacific. Winter whaling on the coast of California or elsewhere was known as "between the seasons" whaling (Henderson, 1972, pp. 85-86). In addition to the cruise patterns which sent most gray whalers from the Hawaiian Islands to Baja California and back to the Islands in the spring, some whalers from New England or San Francisco sailed out of that port directly down the coast to the gray whaling grounds. Some left San Francisco in the spring and summer in search of sperm whales or elephant seals before going after the grays. Other whalers out of New England ports and San Francisco remained in peninsular waters or went south from there to search for sperm whales after the winter gray whaling season had ended (Henderson, 1972, pp. 85, 91-94, 188, 268-270).¹

Gray Whaling Beginnings

During the several decades preceding gray whaling when whalers worked the sperm whale fishery of Baja California, they recognized gray whales as "scrag" whales

¹See also logbooks in Whaling Archives (see Appendix).

⁴See also reports in *Whalers' Shipping List and Merchant's Transcript*, New Bedford, Massachusetts.

and even chased them, but so far as the record shows they never caught any. Of course, native peoples of Baja California and the shores of the northern Pacific Ocean, Okhotsk Sea, and Arctic Ocean, as well as Spaniards, Mexicans, and Siberian Russians, also knew and recognized this whale (Henderson, 1972, pp. 35, 59, 71, 73; Mitchell, 1979, pp. 309–311).⁵ Eventually two Connecticut captains who came to the Coast of California decided to go after the grays. Magdalena Bay, known to the whalers as Marguerita Bay, an immense complex of bays and lagoons on the southwest coast of Baja California, was a well-known "between the season" protected haven which sperm whalers from the coast knew well, and it was also a calving and mating ground to which gray whales migrated each winter (Fig. 1).

Thus, whalers had long known that gray whales frequented the bay when Captain James Smith of the New London ship *Hibernia* and Captain Josiah Stevens of the Stonington bark *United States* decided to chance pursuit of grays there in the winter of 1845–1846. That winter in Magdalena Bay, in the first gray whaling by western man on record, the whalers of *Hibernia* captured 22 grays and those of *United States* took 10 (Henderson, 1972, p. 82). They found that the gray whales had no bone worth saving. More importantly, they learned, as did all whalers who chased grays, that they were in a dangerous business. The grays killed the second mate and badly injured the first mate of *United States*. Thus was initiated the nineteenth century gray whaling which would eventually disastrously deplete the population of gray whales in the eastern Pacific California herd and make a significant reduction in the Okhotsk Sea or Korean herd of the western Pacific.

Whalers' Names for Grays

Some of the characteristics of the gray whale are revealed by the various names that the nineteenth century gray whalers applied to this whale which was new to the chase. Even before gray whaling began on the Coast of California, whalers there hunted sperm whales and also recognized this different whale, which they called a scrag whale because they identified it with a whale of that name reportedly taken off New England coasts in the seventeenth and eighteenth centuries (Dudley, 1725, p. 258). However, early in the history of the fishery of this whale the whalers began to call it California gray, gray whale, gray back, and California whale. Devil fish and hard head were names plainly derived from the reaction of the whales to their hunters, who recognized the gray as a dangerous prey knowing that in the lagoons of Baja California the whales commonly crashed into and stove boats with their heads. The names mussel digger, mud digger, or digger referred to the whales' habit of bottom dredging, which had been observed by the whalers especially in the lagoons. Whalers used two names more on the northern summer grounds than on the Coast of California; one was ripsack, which apparently referred to the manner in which blubber came off the whale in cutting-

⁵See also logbooks in Whaling Archives recording cruises to the Okhotsk Sea (see Appendix).

in (flensing), and scamper down, also the name of another whale but unmistakably used to refer to grays, was the other. Curiously, some whalers referred to the whales by one name on the summer grounds and another on the winter grounds—for instance, ripsack in the Arctic or Okhotsk seas and devil fish or gray on the Coast of California (Henderson, 1972, pp. 26–27, 35).¹

Initial Period of Gray Whaling

The first years of gray whaling, including the winters of 1845–1846 through 1853–1854, have characteristics that distinguish them from later years. At that time, Magdalena Bay was the only significant gray whaling ground being visited and thus supplied nearly the entire catch (Table I). A few vessels did whale along shore on the coast in addition to entering the bay; the first was the ship *Dromo* of New London in 1851–1852.^{6a} Moreover, the captains of some vessels which whaled in the Bering Sea and Arctic Ocean made small incidental gray whale catches when their main quarries, bow-head and right whales, were not available to be chased. Thus, the catch per vessel was small as was the total catch in northern waters.^{1,2,4,6}

Connecticut vessels, perhaps from venturesomeness born of competition with the New Bedford and other southern Massachusetts ports, sought out the new fishery and dominated it. Perhaps commercial connections and information drew Connecticut ships together in winter at Magdalena Bay. At any rate, in the second winter of whaling at Magdalena Bay, 1846–1847, three New London, two Stonington, and two Mystic whalers met with one New Bedford ship on that ground.^{1,2,4} In the early period, half of the perhaps 50–60 cruises to Magdalena Bay were made by vessels from Connecticut ports. Southern Massachusetts ports, including New Bedford, sent their ships to the new ground only 10 or 11 times. Two vessels each came from Sag Harbor, Long Island, and Warren, Rhode Island, and one from Cold Spring Harbor, Long Island. In 1852–1853, one of the first whalers out of San Francisco, the ship *Aquetnet* (Captain Curry) fished at Magdalena Bay. Foreigners also were willing to try their luck in the new fishery, and from Le Havre came five French vessels and from Bremen and Amsterdam one each.^{1,2,4,6} Thus, the representation of hailing ports by vessels at the new ground was distinctive; it was not dominated by ships from southern Massachusetts ports, most of the captains and owners of which probably had not yet the need or desire to chance the pursuit of gray whales.

In this earliest period many of the vessels on the coast or that entered Magdalena Bay to escape weather or cooper oil were sperm whalers, while some captains pursued humpback whales in and outside the bay; however, on at least 50–60 cruises, the whalers concentrated on taking gray whales. The daring and crafty crews of a few vessels captured many; for example, the men of the New London ship *Brooklyn* (Captain Jeffrey) took 29

⁶See also "Dennis Wood Abstracts," manuscript records of whaling voyages 1831–1873. New Bedford Free Public Library, New Bedford, Massachusetts.

^{6a}Whalemen's Shipping List and Merchant's Transcript; March 30, 1852, p. 18.

whales in 1846–1847.^{1,2,4,6} Most, however, took far fewer. Captain Curry of the *Aquetnet* of San Francisco got only four grays in 1852–1853, although he was at Magdalena Bay from late December to mid-February.^{1,2,4,6,7} Some crews were “skunked,” that is, they left the bay without taking any oil and were undoubtedly glad to quit such a dangerous business. During the earliest gray whaling period, few captains brought their ships and men back for a second season of the new and hazardous whaling. One who did was Captain James Smith of the New London ship *Hibernia* who had originated gray whaling in 1845–1846 with an excellent catch of 22 whales; he returned the following winter to make another catch at least equal to his first.

A Mexican government report from the mid-nineteenth century archives at La Paz tells us that during the first 3 years of gray whaling at Magdalena Bay, 1845–1846 through 1847–1848, 38 whaleships captured 338 whales in Magdalena Bay (Espinosa, 1854, p. 125). If this report is added to other reports of whalers at the bay later, then the total number of cruises to Magdalena Bay in the early period may have been nearly 70, and the total capture may have been nearly 500 whales. However, if estimates are based on whalemens' records in logbooks and newspapers, the estimate for the early period is closer to 50–60 cruises and 400–450 captures. The capture discrepancy could then amount to as many as 100 whales. This is probably explained by the Mexican report having included some vessels whose crews were not gray whaling, and thus vessel and catch totals were increased by including sperm and humpback whalers. If there were 50–60 cruises for grays and 400–450 captures, then the average catch per vessel was 7–9 whales, figures that seem reasonable in a new fishery in which the men of some vessels caught many whales and those of others caught few or none.

Scammon's statement that in the winter of 1848 (1847–1848) 50 whaleships went to Magdalena Bay is an obvious exaggeration (Scammon, 1874, p. 268). Scammon did not arrive in California until 1850 and he did not whale at Magdalena Bay until the winter of 1855–1856, when he began his gray whaling career at the bay on the San Francisco ship *Leonore*; this was 2 years before he first whaled in Scammon's Lagoon on the brig *Boston* (Henderson, 1972, pp. 82, 267–271). In the winter of 1847–1848, records show that only 20 gray whaling vessels were at Magdalena Bay and that their crews captured at most some 140 gray whales, or an average of 7 each.^{1,2,4,6}

A pattern that would persist throughout the history of the fishery had been established; some crews, experts at gray whaling, made exceptional catches, many took few whales, and some who had no knowledge of or taste for chasing the tough grays came away from the Coast of California without a drop of oil.

Right in the middle of the earliest gray whaling period there were three seasons, 1848–1849, 1849–1850, and 1850–1851, during which pursuit of the gray backs stopped. Scammon attributed the abandonment of gray whaling to the disastrous destruction of boats, loss of life, and frequent injuries sustained by those who pursued the grays or devil fish and to the concentrated whaling and associated noise and try-pot fires, which drove the whales outside Magdalena Bay (Scammon, 1874, pp. 268–269). Moreover, the low price of the dark-colored gray whale oil and the fact that the whale's bone

⁷See also reports in *San Francisco Alta California*, San Francisco, California.

(baleen) was next to worthless contributed to the temporary abandonment of the fishery (Henderson, 1972, p. 84).^{1,2,4,6} However, the proximity of the California ground to the Hawaiian Islands and San Francisco and probably also overfishing of sperm whales on the Coast of California soon brought revival of the gray whale fishery at Magdalena Bay in the winter of 1851–1852. During that season and the two seasons following it, between 4 and 12 vessels visited Magdalena Bay each winter, and the catch of 1852–1853 was between 65 and 75 whales.^{1,2,4,6}

The number of whales which were mortally wounded but escaped the whalers in the early period was probably about 1 for every 10 captured. Although the bomb-lance was not much used in the early period and more whales therefore probably escaped after being attacked, fewer of those which escaped would have been mortally wounded than when the bomb-lance came into wide use in the fishery. Thus, unrecovered dead whales probably averaged about the same relative to those caught both before and after the use of the bomb-lance, which mortally wounded more whales but which also brought death before the wounded animal could swim beyond the inside waters in which its carcass could be recovered. Thus, in the early period of gray whaling at Magdalena Bay, whalers probably captured 400–450 grays and killed about 450 to 500.

The few cruises alongshore in the early period probably garnered whalers only about 25 grays, and the number of grays captured on the northern summer grounds probably amounted to only about 52 whales. By the late 1840s whalers in the northern Bering Sea and Arctic Ocean, as well as in the Okhotsk Sea, had observed and commented upon gray whales in their logbooks. They often referred to them as scrag whales, but they chased and captured few as these early whalers were still impressed with the abundance of right and bowhead whales in the northern waters. The loss of grays in the northern waters was high as the wounded whales could escape in fog and under ice to die unretrieved; thus the size of the kill was nearly one-half again that of the catch (see Table I, footnote g). As shore whaling had only just begun in this period (at Monterey in 1854), probably only some 10 gray whales were captured there in the initial year of whaling. Whalers made some 75–85 cruises for grays in the early period, and one shore station had been opened along their migration route. The total catch on all grounds in the early period was only some 487–537 grays, and the total kill was between 555 and 610 (Table I). These figures are lower than the estimates I made for this period in 1972 because I have since reviewed more and better records. Nevertheless, my estimate of the total catch and kill of gray whales in the nineteenth century remains about the same because of increases corresponding to other times and places.

Bonanza Period of Gray Whaling

By far the most important gray whaling period was that which lasted the 11 winters from 1854–1855 through 1864–1865. In that period whalers made about two-thirds of all the captures and kills of grays in the California herd that took place prior to the near

abandonment of gray whaling from ships in the mid-1870s. Whaling increased at the old ground of Magdalena Bay; in the winter of 1856–1857, whalers captured 250 grays there and for six seasons (1855–1856 through 1860–1861, gray whaling remained intensive at the bay (Henderson, 1972, p. 151).

At Magdalena Bay, whalers frequented the northern bay of the complex known as Main or Weather Bay as in past seasons, but they also learned of new highly productive parts of the complex. Many vessels anchored in Lee (Almejas) Bay, south of Weather Bay, where they chased the whales especially at the "Mud Hole" at the northeast corner of Lee Bay and along the eastern shore of this bay. More daring captains with large ships, but especially those with small brigs and schooners, had their boat crews tow and kedge their vessels northward into the tortuous, shallow channels of Estero Santo Domingo, north of Weather Bay and behind the long barrier bar, where at low tide vessels rested on their beam ends (Fig. 1). In the bonanza period, 1854–1855 through 1864–1865, whalers on some 125 cruises to Magdalena Bay captured about 1400 grays but killed about 1540 (Table I).

As important as the increase in whaling at Magdalena Bay were the discoveries of new grounds. At the Mexican *Laguna Ojo de Liebre* in 1857–1858, Captain Charles Melville Scammon with the San Francisco brig *Boston* and her schooner–tender *Marin* opened a short-lived bonanza of gray whaling at this calving and mating ground of the gray whale (Henderson, 1872, pp. 113–116, 261). The lagoon became known among whalers as Scammon's Lagoon. During the bonanza period at this lagoon, whalers on 36 cruises took some 553 devil fish and caused the death of about 608 (Table I). Just north of Scammon's Lagoon lie Black Warrior (*Guerrero Negro*) Lagoon and Manuela lagoons. They lie behind the same barrier bar as does Scammon's Lagoon, but are separated from it and one another by transverse bars. Both are mostly tidal flats and have little channel area for gray whale occupance. Few captains poked their vessels' bows into these lagoons, especially after the Honolulu bark *Black Warrior* had entered the lagoon that acquired her name and with her tender, the schooner *J. D. Carr*, had cruised in the lagoon for 2 weeks without success in December 1858 and then was lost just outside while being towed out by the boats of several vessels when swept against the shore by a current (Henderson, 1972, pp. 29–30, 119–121; Scammon, 1874, p. 123). Laguna Manuela, north of Black Warrior Lagoon, has other names, but probably acquired that name from the San Francisco whaling brig *Manuella* which was wrecked in 1871, apparently along its outer coast (Henderson, 1972, p. 48). Whaling vessels did not enter that lagoon. What few gray whales were caught in the two lagoons were taken by boats from whaleships lying outside along the coast.

The same sagacious whaler who first entered the lagoon now bearing his name, Captain Scammon, was also first into another calving and mating area, Ballenas or San Ignacio Lagoon. The husband of Scammon's wife's sister, Captain Jared F. Poole, had seen the lagoon in 1857 and in 1858 he tried to find a channel into it. In the winter of 1859–1860, Scammon took a small fleet of San Francisco vessels into the lagoon (Henderson, 1972, pp. 122–123). That year his schooner–tender *Kate* led his bark *Ocean Bird* and two other barks, Poole's *Sarah Warren* and Captain Easton's *Carib* with two other tenders, between pounding breakers and across the shallow bar into Ballenas Lagoon (Fig. 1). This

was a feat with which Scammon had become familiar at Scammon's Lagoon. Boats of two New Bedford ships joined whaling at the lagoon that winter, but only *Henry Kneeland* went in; *John Howland* remained outside. In subsequent winters many of the grays captured at Ballenas Lagoon were taken in shallow waters behind bars lying southeast of the lagoon mouth (Henderson, 1972, p. 154). Moreover, whalers who chased grays inside Ballenas Lagoon and its southeastern lagoons (*esteros*) also attacked the whales in Ballenas Bay outside the lagoon (Henderson, 1972, pp. 154–155). Thus, it is sometimes difficult to determine if a particular ship captured a whale inside or outside the lagoon itself; only if one has logbook records at hand, rather than newspaper accounts, can he determine how many whales were taken inside or outside the lagoon. The best estimate I can make is that during the bonanza period whalers on some 20 cruises captured about 350 whales, but killed some 385 at the main lagoon and in the smaller lagoons (*esteros*) to the southeast of Ballenas Lagoon (Table I).

Other new whaling grounds and practices were quickly discovered and exploited. At San Diego Bay, San Quintín Bay, and at Turtle Bay (Saint Bartholomew's Bay), ships anchored out of the weather and sent their boats into the kelp beds outside where they lay in wait for grays traveling their migration routes to and from northern waters (Henderson, 1972, pp. 28–29). At San Quintín and Turtle bays, whaleships sometimes waited outside the harbors; at San Quintín, in the lee of tiny San Martín Island (Henderson, 1972, p. 29). At María Bay, south of Cape San Lázaro on the sand bar coast outside northern Magdalena Bay, many whalers also awaited migrating whales. Alongshore whaling, in which vessels waited along the migration route, sometimes anchored and sending their boats off for whales, became a common practice especially when lagoon whale populations began to decline. Thus, whalers along the coast north of several lagoons had a chance to waylay whales en route to several calving grounds.

The stretch of coast where alongshore whaling was most concentrated was between the south shore of Vizcaíno Bay, around Natividad Island and Cape San Eugenio, and on south to San Roque and Asunción islands (Fig. 1). The lee sides of islands and headlands here afforded protection for the waiting ships. From the ships, boats set out down the migration route propelled by sails and steady northern winds to capture grays by the method that Scammon called "sailing them down" (Scammon, 1874, p. 27). Boats with captured whales could row (pull) the whales back to the ships or the ships could sail south after their boats. A practice employed by some captains was that of buoying their anchors so that they could slip anchor quickly to sail after boats fast to rapidly swimming wounded whales.¹ Off the San Benitos Islands and Cedros Island, off San Juanico, the last point between Ballenas and Magdalena bays, and off Cape San Lucas, whalers also practiced alongshore whaling (Fig. 1). In Ballenas Bay, whalers also took advantage of whaling along the migration route by pursuing whales entering and leaving Ballenas Lagoon. During the peak period of gray whaling, whalers on some 80 alongshore cruises captured some 900 whales, but killed about 990 (Table I).

Some masters took their vessels to places in the Gulf of California, but especially to grounds along the mainland coast of the southern Gulf and south from there (Henderson, 1972, pp. 30–31, 96–97, 165–166). Most important of these grounds was Banderas Bay, which was the southern limit of gray whaling at about 20°N latitude. Others

included inlets and alongshore waters at Yavaros and Tojahui in southern Sonora, and Navachiste, Santa María, and Altata on the coast of Sinaloa (Fig. 1). A few captains also chased grays at the Tres Marias Islands where the primary quarry was the humpback whale. Scammon once made a notation that grays also went to the head of the Gulf. He wrote "Around Consag Island and off Shoal Point near the head of the Gulf of California large numbers of California Gray whales have been seen in March (Henderson, 1972, pp. 31-32). In the bonanza period whalers in perhaps 15 cruises captured about 150 gray whales, but killed some 165 in the Gulf and along the Mexican mainland coast (Table I).

During this peak period of gray whaling, 1854-1855 through 1864-1865, shore whaling, using shore-based whaleboats and try-works on the beach, was initiated and expanded at a series of places on the Alta California shore and in Baja California. This low-cost kind of whaling without ships was never important in Mexican waters where the gray whalers on ships made almost all of their catch, and some of the shore stations there were not started until the final, declining period of gray whaling. However, in the peak period at Magdalena Bay, local Mexicans, as well as Americans and English whalers (probably deserters) who lived northeast of the bay at Comondú, came to the shores in winter to practice "carcassing." This operation involved the retrieval of "stink-ers" or dead whales and also carcasses which still had tongues and organs in them, to try-out the blubber and meat in order to sell oil to ships in the bay (Henderson, 1972, p. 127). These shore whalers also caught a few live whales. Moreover, in 1860-1861 at least there was a shore station on the southeast side of Ballenas Lagoon, at a place that was designated as Carcass Town on Scammon's map of the lagoon and is still called *La Freidera* (Try-pot or Tryworks) by local Mexicans (Henderson, 1972, p. 100). Those vessels anchored for the season at San Diego and San Quintin bays, which sent their boats outside to whale, became in essence floating shore stations. Shore whalers at all stations probably captured some 1190 grays, but caused the death of 1428 during the peak period of gray whaling (Table I). Not many of these whales were captured or killed in Baja California waters.

Beginning in the 1840s, as whalers in summer cruised farther and farther northward up the coast of Asia to enter the Arctic Ocean in 1848, gray whales on their northern summer grounds were attacked when right and bowhead whales were nowhere to be found; the whalers had really come north for those two whales. By the peak period of gray whaling, whalers in many vessels pursued grays in the north, but with rare exceptions they captured few on any one northern cruise. In 1858, when ice conditions were bad in the Bering Straits, whalers caught gray whales early in the season, as they often did, before they could sail on north in search of bowheads.⁸ In that summer Captain Fisher of the Edgartown bark *Rose Pool* reported on the catches of 30 vessels in the Bering and Arctic seas as of July 18. Of the 30, 5 had gray whale catches amounting to a total of 13; none had captured more than 4. However, that year another report tells us that the New Bedford bark *Emerald* (Captain Peirce) as of August 25 had a catch of 2 bowheads, but 9 devil fish.⁹ As mentioned earlier, many were killed but lost in fog and

⁸*Seaman's Friend and Temperance Advocate*, Honolulu; October, 1858, p. 80; November, 1858, p. 86; December, 1858, p. 94.

⁹*Seaman's Friend and Temperance Advocate*, Honolulu; November, 1858, p. 86.

under ice; so that more whales were lost, relative to those caught, than in any other sector of the gray whale fishery. Grounds of the California herd where grays were most pursued and captured included the Koryak Coast and Anadir Sea, waters in and off Plover and Saint Lawrence bays, the coast of Saint Lawrence and King islands, the Bering Straits (especially off East Cape), the Chukchi Sea, and all along the north coast of Alaska eastward nearly to Point Barrow. Even during the later period of steam whaling, none appears to have been sighted in the open northern Arctic Ocean on such bowhead grounds as those around Herald Island.¹⁻⁴ In the north, it appears that there was more of a mix of large and small whales, for many of the grays captured in the north yielded less oil than those taken on the Coast of California. In all, whalers on about 80 northern cruises probably captured 175 grays, but killed some 232 during the bonanza period (Table I).

As the waters in which gray whales could be caught became widely known and as techniques and equipment improved, the number of vessels that came to the Coast of California each winter increased. The years of maximum cruises and catches were between 1857-1858 and 1861-1862. After rapid depletion, the grounds sustained significant whaling until the mid-1860s. Some captains sought not only grays but also sperm whales or humpbacks or elephant seals. Some cruises by small vessels out of San Francisco were called "pick-up" cruises, and on such a cruise in 1856-1857 the schooner *Henry* (Captain Reynolds) was out 10 months, excluding only summer, and returned with gray and sperm oil, green turtles, and the dried meat and shells of abalone (Henderson, 1972, pp. 94-95).

Catches were low for crews that knew not the ways of the gray whales and gray whaling but large for the experts. In 1856-1857, the few men on the schooner *Henry* filled their casks in just 4 weeks in Estero Santo Domingo where they obtained 500 barrels of oil from 19 whales. Scammon, on the bark *Ocean Bird* in 1858-1859 at Scammon's Lagoon, captured 47 whales in 3 months of whaling and returned to San Francisco with 1700 barrels of oil. On 9 different days from December 9 through February 27, his boat crews took 2 whales per day, and between January 13 and 17, 1859, they captured 6 whales (Henderson, 1970, pp. 39, 45-48, 52, 58; 1972, p. 91). In a catch which may have been made partially at Scammon's Lagoon but probably mostly in Ballenas Bay and Lagoon, Captain Whelden of the New Bedford ship *John Howland* took 1700 barrels of gray whale oil in the winter of 1860-1861.¹⁰

There are a number of reasons why gray whaling revived after its initiation and decline at Magdalena Bay in the late 1840s. Some reasons included the discovery of new grounds, and others were the new practices, techniques, and equipment that aided gray whaling. Among the most significant contributions to the improvement of gray whaling was the use of the bomb-lance. This device was a large shoulder-held gun which fired a pointed bomb so that a tough gray could be wounded or killed while a whale boat and crew were already attached to it by harpoon and line (a "fast" boat) although out of the range of danger (Henderson, 1972, p. 98). However, sometimes the bombs were fired while a fast (attached) boat was right next to a whale, in order to take the fight out of the whale before hand-lancing began, and sometimes bombs were fired

¹⁰Whaleman's Shipping List and Merchants Transcript; records of her catches, January-June, 1861.

into whales even before the harpoons had been thrown (darted).¹ Nevertheless, because the bombs were expensive, many gray whales were killed without the use of bomb guns even after the instrument became common.¹ Scammon said that the first winter's whaling at Scammon's Lagoon would have been a failure had it not been for the bomb-lances he had on board (Scammon, 1874, pp. 263–264). To shore whalers who had to catch grays swimming rapidly past the station along the migration routes, bomb-lances were especially useful in waylaying whales that were some distance from the boats.

Greener's guns, which were swivel-mounted in the bows of whaleboats, fired harpoons greater distances than they could be thrown, and these contrivances became especially useful in shore whaling or whaling outside lagoons in the breakers, where the migrating whales or rough water precluded close approach and use of the hand-thrown harpoon (Henderson, 1972, p. 98). Scammon termed this practice "whaling in the breakers" (Scammon, 1874, p. 28). Those whalers who employed the Greener's gun also used bomb lances and other kinds of guns which attached boats to whales or killed whales.

During the bonanza period of gray whaling on the Coast of California, vessels from a wide range of home ports entered the fishery. The Connecticut whalers continued to come, but so now did many from the ports of southern Massachusetts such as New Bedford, Fairhaven, and Nantucket. Others came from the Long Island ports. Moreover, vessels from San Francisco and Honolulu increasingly joined in the gray whaling. Some of these vessels were small brigs and schooners, especially well suited for reaching shallow grounds such as the long lagoon, Estero Santo Domingo, which leads northward from Magdalena Bay. German whalers, some of Hawaiian registry, and French whalers continued in the fishery; one Russian vessel, the brig *Constantine*, came to Scammon's Lagoon in 1859–1860 (Henderson, 1972, p. 261).^{1–4} Her master Captain Lindholm, a Swede from Russian Finland, whaled in the Okhotsk Sea with the Russian whalers, and undoubtedly had been induced to come to the Coast of California by gray whalers who sought bowheads and rights in the Okhotsk Sea in summer (Beane, 1905, pp. 208–209).

The total catch and kill of gray whales in the California herd in the bonanza period were probably about 4718 and 5348 respectively (Table I). For whaling vessels, Magdalena Bay remained the most important ground; the alongshore ground was second in importance, followed by Scammon's Lagoon and Ballenas Lagoon. Grounds of lesser significance for the whaleships in the winter season were those in the Gulf of California and along the mainland shore of Mexico. However, whalers were catching a fair number of grays now on their summer grounds in the Bering Sea, Arctic Ocean, and Okhotsk Sea. Very significantly, shore whalers on the coasts of both Alta and Baja California, but especially in Alta California, probably had caught and killed more grays than whalers in any other single sector of the fishery except at Magdalena Bay.

Because the number of whales in the California herd was not large, gray whaling grounds were rapidly depleted during the 11 seasons in the bonanza period. Whalers essentially abandoned Scammon's Lagoon by the mid-1860s, and by that time Ballenas Lagoon was little more productive than was Scammon's. Magdalena Bay still had more whales left than did its northern counterparts but had declined rapidly as a gray whaling

ground. The Coast of California was entering its final period as a gray whaling ground for sailing ships.

Period of Declining Gray Whaling

The last period of significant whaling from ships on the Coast of California was from the mid-1860s into the early 1870s. It was a period of such declining rewards that at its end masters of whaleships had abandoned most of the gray whaling grounds. During this last period, the formerly important grounds at Magdalena Bay, Scammon's Lagoon, and Ballenas Lagoon were reduced to minor whale grounds. For example, only 5 vessels entered Scammon's Lagoon. However, because so little whaling had occurred there since 1861–1862, Captain James McKenzie made fair catches of 14 whales each season in the winters of 1868–1869 and 1869–1870. He and his crew visited the lagoon alone on the New Bedford barks *Eagle* and *Hercules*, successively (Henderson, 1972, pp. 263, 266). At Magdalena Bay in late January of 1867, J. Ross Browne visited the shores during his explorations for the Lower California Company, and at that time he found only 2 whaleships in the bay. Although the whalers had "scoured" the waters of the bay for 2 months, they had captured only 2 whales, and the whalers told Browne that it was then an achievement to capture 2 or 3 whales per month (Henderson, 1972, p. 172). Actually some 16 vessels did visit Magdalena Bay in 1866–1867, but most were whaling alongshore outside and had come in for wood and water and to look for grays.¹ The New Bedford ship *Milo* (Captain Hawes) spent only 2 weeks in the bay and saw a few whales, but captured none.¹¹

Whalers on vessels engaged in alongshore whaling and shore whalers, however, continued to do relatively well (Henderson, 1972, pp. 174, 178). Both exploited the grays along their migration route and so had the advantage of waylaying whales headed to or from the several calving and mating grounds. At San Quintín, masters of vessels anchored inside the bay made moderate catches as late as the winter of 1866–1867 by whaling outside the bay (Henderson, 1972, p. 39, n. 24). Moreover, shore whalers, with their low investment, could make a living from small annual catches. This opportunity thereby attracted enough men into shore whaling to bring about the establishment of numerous shore stations and the largest catch of any sector of the gray whale fishery. As whaling declined on the west coast of Baja California, a few whalers still sought out grays in the Gulf of California and along the mainland coast of Mexico where they made small catches (Henderson, 1972, pp. 175–176). However, the northern grounds remained important because although few vessels now cruised the Coast of California, a good many went north into the Arctic Ocean and Okhotsk Sea in search of bowhead whales. In the northern Bering Sea and the Arctic Ocean, the California herd probably suffered as great a catch and kill as it did during the peak period of gray whaling (Table I). More whaleships caught grays than they did earlier, but usually only a few grays were taken by

¹¹Ship *Milo* 1863–1868; New Bedford Free Public Library.

any one vessel. In 1871, however, Captain Valentine Lewis of the New Bedford bark *Thomas Dickason* captured 1 at Plover Bay and 10 off King Island, which lies in the northeastern Bering Sea.¹²

In the final period of significant gray whaling from sailing ships, whalers on some 25 cruises probably took about 150 whales at Magdalena Bay, but killed 165. At Scammon's Lagoon, some 38 whales were captured and about 42 killed on 5 cruises, whereas at Ballenas Lagoon and in adjacent waters whalers on about 7 cruises probably killed some 55 whales and retrieved perhaps 50. Alongshore whaling from about 45 cruises accounted for the death of approximately 440 grays and the capture of 400 of them. In the Gulf of California and on the coast of mainland Mexico, whalers probably made only 10 cruises and captured 50 grays from a kill of 55. On the northern summer grounds, whalers took more grays per cruise as bowhead and right whales became more scarce. On some 40 cruises, 175 grays were probably captured out of 232 killed. The most important part of the gray whale fishery had become shore whaling, because of the low costs involved and the opportunity to prey on all of the much reduced California herd as it passed along the coast. Shore whalers, almost all of whom were from stations in Upper California, probably captured 960 grays from among the 1152 they killed (Table I). During the period of declining gray whaling from ships, considerably fewer than one-half as many gray whales were captured or killed as during the preceding bonanza period. Two-thirds of the whales caught and killed fell victim to shore and alongshore whalers. Whaling at the formerly productive lagoons and Magdalena Bay was essentially abandoned by the end of the period.

Throughout the entire period of significant gray whaling from whaleships on the Coast of California (1845–1846 through 1873–1874), whalers had made a total of about 563–573 cruises to California and northern waters on which they captured and killed gray whales. Moreover, shore stations, easily established and moved, had become involved in the gray whale fishery on the California coasts (Chapter 6, this volume). In all, the gray whalers captured approximately 7028–7078 whales of a total kill of about 8044–8090 (Table I).

Whaling and Whale Population

From its inception, nineteenth century gray whaling had a devastating effect on the population of the California herd. The kill was, to a large extent, concentrated on the cows and calves that were easily killed in the crowded lagoons and bays. Calves, however, were not counted in the recorded catch or kill. Because most of the cows carried fetuses, or would have been impregnated had they not died, or had calves which either were killed or died of starvation, the reproductive capacity of the population was greatly reduced through this excessive slaughter of cows and calves relative to the kill within the total population (Henderson, 1972, pp. 132, 149).

¹²Nicholson Whaling Collection, C798, 1866; Providence Public Library.

The number of grays killed during the initial period of 9 winters of concentrated whaling and the summers following those winters averaged only 62–68 whales per year. This was undoubtedly a sustainable kill for the existing population. During the peak period of gray whaling (1854–1855 through 1864–1865), in 11 winters and succeeding summers the number killed averaged 486, which must have far exceeded a sustainable kill. And in the 10-year period of whaling decline (1865–1866 through 1873–1874), although the kills declined each year, the average kill of 214 per year was still well in excess of that sustainable by a rapidly declining population.

The population decrease is clearly demonstrated by the precipitous decline in the ability of the major calving grounds to sustain whaling. At Scammon's Lagoon, after only 4 years of intensive whaling (1858–1859 through 1861–1862), so few whales remained that few whaling vessels continued to visit the lagoon. With a total kill at Scammon's Lagoon of 650 whales, the lagoon was essentially emptied of whales. Captain Nye of the New Bedford bark *Louisa* reported on February 20, 1873 that whales were scarce and that he had taken only 2 whales at the lagoon during the entire season (Henderson, 1972, p. 170).

At Ballenas Lagoon, a total catch of some 400 whales eliminated most of the population on that whaling ground. Scammon and a few other masters had initiated whaling there in 1859–1860. That winter and the next were seasons of big catches. However, only seven seasons later, in 1866–1867, whalers apparently had essentially abandoned Ballenas Lagoon as an exploitable ground.

The huge complex of waters at Magdalena (Marguerita) Bay sustained more whaling and for a longer time than did the two lagoons to the north. However, after a total kill there of a maximum of 2200 whales over a period of some 25 to 30 years, Magdalena Bay was ignored as a gray whaling ground.

Of course, many whales headed for the calving and mating grounds at the lagoons and bays were killed by alongshore whalers on ships and by other whalers from shore stations. These same whalers killed many of the grays as they made their way back to the northern summer grounds. Whether the grays were killed at the lagoons and bays, en route to or from those waters, or on their northern grounds, a total kill of only about 8100 eliminated pursuit of California gray whales as a truly profitable sector of the nineteenth century whaling business.

So few gray whales remained after 1874 that only whalers at a few shore stations or those on ships seeking right or bowhead whales in northern seas continued to kill a small number of graybacks. Nevertheless, those which survived may have numbered as many as 4000–5000 (Storro-Patterson, 1980, p. 9; Ohsumi, 1976), although they were no longer pursued intensively because of the inefficiencies of nineteenth century whalemen in small boats compared to those in modern powered catcher boats. Many nineteenth century whaling grounds appear to have been left behind for other places as soon as whales ceased to be easily found and captured.

Whalers captured or killed most of the whales at the known and originally crowded grounds within a period of two decades. At some individual grounds, such as Scammon's Lagoon, they eliminated most of the whales in only a few years. Thus, the whale kill must have represented most of the population of California gray whales alive at the

time gray whaling began. However, some gray whales survived at the well-known grounds, and a fair number must have spent winters sparsely distributed at various places along their migration route. Considering the kill of some 8100, unreplaced natural mortality, and those perhaps 4000 that may have survived in 1874, the population of the California herd of gray whales probably was not over 15,000 when gray whaling began at Magdalena Bay in 1845–1846 (Henderson, 1972, p. 185; Rice and Wolman, 1971, pp. 118, 130; Storro-Patterson, 1977, p. 46).

Scammon, estimating the number of gray whales killed by 1874 as 10,800, and the number of the California herd between 1853 and 1856 as 30,000–40,000, was undoubtedly high on both estimates (Henderson, 1972, p. 179). His estimate of 8,000–10,000 whales that may have survived in 1874 is also too high (Henderson, 1972, p. 183). Captain Packard (of a San Diego shore station) was probably low in his estimate that the population was only about 1,900 in 1874 (Henderson, 1972, p. 183). The size of catches and kills in the twentieth century, on the other hand, make the extremely low appraisals of population size in the late nineteenth century and early twentieth century obviously wrong (Henderson, 1972, pp. 183, 229).

Gray whales of the California herd did survive the onslaught of the nineteenth century Yankee and other whalers on ships and at shore stations in considerable numbers, as is illustrated by both sightings and catches in the late nineteenth and early twentieth centuries. Whalers on vessels from San Francisco and some other ports continued to exploit the Arctic bowhead fishery in those times, and they also continued to catch a few grays and sight many more (Henderson, 1972, p. 232).¹ As late as 1922, the San Francisco motor ship *Herman* arrived at Nome on July 10 with a catch of four devil fish which had an average yield of 28 barrels, only slightly lower than the average yield of grays on the coast of California during the boom years of gray whaling.¹³ Moreover, in the twentieth century, on floating factories, at shore stations where grays have been taken commercially and for scientific study, and from or for aboriginal communities in northeast Siberia and Alaska whalers have probably killed at least 4000 California gray whales (Rice and Wolman, 1971, p. 123; Storro-Patterson, 1977, p. 47; 1980, p. 8).

Nineteenth Century Whaling for Gray Whales in the Okhotsk Sea

Perhaps this is the place to insert that nineteenth century whalers when in northern waters in summer captured many gray whales in the Sea of Okhotsk, that is, grays of the so-called Korean herd.¹⁴ They did not capture grays until the late 1840s. By that time

¹³An "account book of P. James Laffin, shipping agent, San Francisco," in "San Francisco Crew Lists 1906–1928." Original at San Francisco Maritime Museum. Transcript read at Old Dartmouth Historical Society, New Bedford, Massachusetts.

¹⁴The information upon which the following observations are based is now being utilized by the author in a study of whaling in the Okhotsk Sea, and has been derived from newspaper accounts, books on the Okhotsk Sea, and manuscript whaling records and logbooks.

whalers had pushed their vessels far enough into the Sea to be on the northern and southwestern bowhead grounds of the Upper Sea, that part of the Sea north of 53°N where they found gray whales in abundance. By the early 1850s some captains chased and captured grays and soon some good-sized catches had been made, that is, catches of six or seven grays per vessel.¹⁵ The primary quarry of the whalers in the Okhotsk Sea was the bowhead; so whalers, as in the Bering Sea and Arctic Ocean, took grays only when no bowheads were around. Sometimes this meant a concentrated chase of grays for several weeks. As on other northern grounds, many of the grays captured were smaller than those taken on the Coast of California. Whales of only 10–15 barrels yield, less than half the average yield on the coast of California, were not uncommon in the Okhotsk catches, an indication that many young whales born the previous winter must have been captured. As in the Bering Sea and Arctic Ocean, whalers continued to pursue gray whales in the Okhotsk Sea into the late nineteenth century, that is, at least into the mid-1880s. The total number of grays taken and killed in the Okhotsk Sea by nineteenth century whalers probably approached that of those captured and killed in the Bering Sea and Arctic Ocean; and as the Okhotsk (Korean) herd must have been smaller than the California herd, greater inroads into that population must have been made in summers than were made in the California herd in that season.

Gray Whaling: Problems and Dangers, Practices, Equipment, Resources of the Shores and Bays, Trade, Catches and Yields

Shipwrecks on the Coast of California were surprisingly few considering the currents which swept the coast and the difficulties of working whaleships into, out of, and within the shallow lagoons with only very shallow water over bars across their mouths. Only about 10 vessels were lost during the nineteenth century whaling (Henderson, 1972, pp. 110, 117, 144–145, 170).^{1–4,6} Probably the most remembered of the wrecks is that of the Honolulu bark *Black Warrior* (Captain Brown) which, as previously described, was swept against the coast in December 1858 while being towed out of the lagoon that bears her name (*Guerrero Negro* in Spanish) (Henderson, 1972, pp. 109–110, 119–121).

The absence of hard bottoms throughout much of the lagoon area and on the bars saved a good many vessels from disaster, although damage from grounding hulls of heavily laden whalers was not uncommon. Once inside the lagoons and bays, whalers usually anchored their ships for long periods of time and sent their boats on what often turned out to be long chases. To facilitate cutting-in whales far from the ships and save a long boat tow of the whale or his rafted blubber back to the ship, schooner tenders accompanied some larger vessels into the lagoons (Henderson, 1970, p. 14). These schooners could work into the very shallow calving grounds, like those at the Mud Hole in Lee (Almejas) Bay, at Magdalena Bay, and the Nursery in Main Lagoon at the inner reaches of Scammon's Lagoon. It was in such places that cows and calves were concen-

¹⁵Seaman's Friend and Temperance Advocate, Honolulu; December, 1858, p. 84.

trated, whereas bulls when taken were in the outer lagoons, outside in the breakers, and along the migration routes. In the winter of 1861–1862 at Ballenas Lagoon, the 299-ton bark *Delaware* served as a tender to the larger ship (377 tons) *John Howland* so that the ship could remain completely outside the lagoon in Ballenas Bay (Henderson, 1972, p. 158; Starbuck, 1878, pp. 556, 560). Whalers staked out the channels of the lagoons to guide whaleships, tenders, and boats away from grounding and to prevent a 3- or 4-ft falling tide from leaving them high and dry (Henderson, 1970, p. 27). In Estero Santo Domingo, low tide at some places exposed a mile of sandy bottom on either side of the channel (Henderson, 1970, p. 27).

Dangers other than those of managing the ship awaited the gray whalers when they set out in their boats after gray whales in lagoons, bays, or alongshore.¹⁶ Whalers with long experience gave precedence to the grays as the most dangerous of whales. Many men were killed or badly injured in the business of gray whaling. In the bays and lagoons, equipment (whalecraft) and practices were geared to dangers as well as other peculiarities of "lagoon whaling." Of prime importance in all kinds of gray whaling was the use of the bomb lance, which has already been described. To make sure that the wily grays did not escape, often men in four or more boats would attack one whale which meant that if some got fast with their harpoons the whale would have less chance to escape. However, it meant also that lines could become fouled and boats overturned, so special rules of attack were normally observed. One of these was that the men in the first boat to locate and pull toward a whale would set a waif, which was supposed to give that boat and boats cooperating with it by ownership or agreement first chance at the whale.

In order to bring as many boats as possible to bear down upon a whale or several whales, captains often mated their vessels, that is, worked together and shared the catch. Sometimes as many as three vessels in a lagoon were mated. Lagoon whaling could be a crowded affair in which one whale could stave several boats and endanger many men. Unfortunately, so many boats often entered the small areas of calving waters where boats and whales were packed together that great confusion during the chase, disputes over claims to whales, and many accidents occurred. Such waters included the Mud Hole in Almejas Bay and the inner Main Lagoon at Scammon's Lagoon. Also in lagoon calving waters, whalers often had problems with calves fouling their lines and with confusing a rising calf with its mother so that they attacked the calf while the cow escaped. Whalers handled attacks on calves in two ways: some preferred to harpoon the calf first so that the cow would stay close by; others left calves alone out of fear that wounded and dying calves provoked the cows into more destructive behavior.

In the lagoons, boat crews sometimes bombed whales repeatedly so that if they escaped they would die and eventually rise to the surface to be captured. Whalers sometimes marked dead whales with a waif (flag) so that they could be located later, while boat crews went in search of more whales (Henderson, 1970, p. 72). Bombing and harpooning could sometimes be done while the boat was stationed where the whale could not reach it, as in shallow water on a tidal flat next to a channel. Moreover, in the

¹⁶The following observations about gray whaling have been abstracted from Whaling Archives (see Appendix).

channels currents could be swift and sweep a boat onto its quarry, to the dismay of the crew.

Some other kinds of equipment, in addition to the advantageous bomb lances and Greener's guns, were very useful to gray whalers. Because whalers often had to cut lines to keep their boats from being pulled a long way from their ships and even outside the lagoons or to keep from becoming foul of other boats' lines, a large supply of line was necessary. If ships were anchored in channels where currents were swift, a supply of extra anchors helped hold them in place. Kedges were needed in ships and boats alike to keep from running with the tide, to pull into shallow water, and to warp ships off the mud when grounded (Henderson, 1970, p. 32).¹ Gray whalers carried grapnels to haul sunken whales up from the shallow bottom. Some whalers carried cutting spades in their boats in order to stab into the "small" of the backs of the tough grays just ahead of the flukes, to slow the escape of a whale towing a boat about the lagoon.

Whalers at the lagoons spent much time ashore. They often beached their boats when away from the ships on long searches for whales, at times overnight (Henderson, 1970, p. 14).¹ Sometimes a dead whale beached itself and was then cut-in ashore and the blubber rafted back to the ship (Henderson, 1970, p. 27).¹ To make more room aboard the ships during the busy whaling season, carpenters and coopers sometimes worked ashore; sails, rigging, and casks also were sometimes stored ashore (Henderson, 1970, pp. 21-22, 59).¹ Moreover, whalers often went ashore to cut wood, obtain water, and shoot birds, rabbits, and deer; they also traded with Mexicans who traveled to the shores with cattle, cheese, fruit, game, and other trade items from near or distant ranches and towns (Henderson, 1972, pp. 125; 1975, pp. 51-52). Even some "ladies of the evening" trekked across the desert from La Paz to Magdalena Bay to come aboard ships waiting to whale (Henderson, 1975, p. 53). Some whalers with time on their hands, when whales were scarce both before and after the whaling season, walked inland to visit Mexican and American ranchers who lived near the shores of Magdalena Bay (Henderson, 1975, p. 53).¹ Deserters, who did not find berths on other vessels and thus remain undiscovered, were usually unsuccessful except for those few who found refuge on ranches and in towns near Magdalena Bay. However, most deserters were caught by Mexicans who returned them for a reward, or the desperate men themselves returned from the desolate desert. Some died in their attempted escapes (Henderson, 1970, p. 26; 1972, p. 128; 1975, p. 53).¹

The waters of the bays and lagoons or those just outside were especially attractive to the whalers in the food supply they afforded. During their stays the whalemen were well provided with green turtles, spiny lobsters, abalone, oysters, and clams. Whalers salted fish and caught live turtles in quantity at the end of the season to provide free food on board after they left the Coast of California (Henderson, 1970, p. 71).¹

The many inducements to whalers on the Coast of California included the possibility of doing little if any sailing for the season; the provision of cheap food from the shore, especially the favorites of New Englanders (i.e., beef, cheese, and fresh milk); the abundance of free food in the sea; the availability of cheap Mexican laborers aboard ships and ashore as collectors and processors of "stinkers;" the low number of successful desertions; the ready supply of wood and water ashore; and the mild weather.

Even if many catches were low, the cruise to the Coast of California was a cheap and a pleasant way to spend the "between the seasons" winter in anticipation of a good northern summer catch in "the season."

Because the bays and lagoons were quiet places where whalers could repair ships and sails and paint their vessels, rather than remain in such places as Honolulu and San Francisco where expenditures were necessary and desertions easy, many whaleships arrived at the Coast of California grounds early in the winter. But then, so did the whales. Although January and February were the months in which most whales were caught, whalers captured and killed many before and after those months. In the winter of 1858–1859 at Scammon's Lagoon, Captain Scammon on the San Francisco bark *Ocean Bird* was 20 miles into the lagoon in The Narrows when he saw the first whales on November 24.¹⁷ By November 26, he had anchored for the season off Cooper's Lagoon (Nursery Inlet), and from December 11 on he and his crew saw whales regularly from The Narrows to the inner lagoon. His men chased their first whale on December 18 and captured their first on December 22. Nevertheless, on December 20 Scammon and Captain Poole, on the San Francisco bark *Sarah Warren*, had made the kind of agreement that became common among bay and lagoon whalers on the Coast of California; they agreed to let a good number of whales come into the lagoon before beginning to whale. Scammon's men killed their last whale on March 13; of 47 grays captured that season, they took 7 in late December and 6 in early March. As did whalers at other lagoons and bays, Scammon's crew spent the last days or weeks on the ground at such tasks as catching turtles and fish and cutting wood. That season *Ocean Bird* went over the bar and out of Scammon's Lagoon on March 27.

Unfortunately, whalers made essentially no reports on the measurements of grays but were interested only in the oil yield of their catches, either per whale or for the season. However, oil yields reveal relative sizes of whales from one time or place to another. Most gray whales yielded 35 barrels (31.5 gal per barrel). In fact, newspaper reports from whale grounds almost always equated 1 gray whale to 35 barrels of oil. If a ship was reported to have taken 10 grays, her catch would be reported as 350 barrels.^{2–4,7} During the entire period of gray whaling up to the early 1870s, Scammon also equated 1 gray to 35 barrels of oil (Henderson, 1972, p. 138). In some reports he reported that the yield averaged between 20 and 40 barrels (Henderson, 1972, p. 138). In the early years of gray whaling whalers caught some whales that were much larger. In 1858–1859 at Scammon's Lagoon on *Ocean Bird*, Scammon caught a whale on December 25 that yielded 55 barrels (Henderson, 1970, p. 37), and he said that very large grays might yield 60–70 barrels (Henderson, 1972, p. 137). The records of huge gray whales, which could have yielded the 101 barrels reported by a New London whaler and the 90 barrels reported taken from 1 whale caught by San Diego shore whalers, appear to be mistakes in catch size or species taken (Henderson, 1972, p. 137). Both could have been right whales. Perhaps there was some decline in the size of whales captured; various reports of the oil taken in 1846–1847 at Magdalena Bay by the New London ship *Hibernia* and the Stonington bark *United States*

¹⁷This and the following information about Scammon's whaling in 1858–1859 is from Henderson, 1970, pp. 17, 19–20, 21, 28, 31, 33, 35, 67, 68, 71; and from logbooks in Whaling Archives (see Appendix).

in the first year of gray whaling indicate an average yield of 45 to 55 barrels per whale.^{2,4,6} Nevertheless, except for that indication, average yields on the Coast of California do not seem to have declined with total catch declines, perhaps because some large bulls were taken outside the bays and lagoon in the late years of gray whaling (Henderson, 1972, pp. 140, 148–149). Catches on the northern grounds in the Bering Sea and Arctic Ocean as well as in the Okhotsk Sea did seem to produce lower yields per whale, however, probably because whalers on those grounds caught more young whales born the previous winter (Henderson, 1972, pp. 137–138).¹

Revisions of Gray Whaling History and Geography

The historical record supports a number of revisions in conceptions about gray whales and gray whaling which I should like to emphasize before ending this chapter. First, the idea that before gray whaling began there was a large population of grays in the California herd numbering 30, 40, or even 50 thousand is not borne out by the historical record of catches and the number of whales that survived in the twentieth century. The population of the California herd when nineteenth century whaling began was probably around 15,000 and certainly not more than 20,000 (Henderson, 1972, pp. 132, 154, 169–191).

Another misconception is that Scammon's Lagoon contained more gray whales than any other lagoon or bay on the Coast of California. Records of vessels on the grounds and reported catches demonstrate that in Magdalena Bay whalers caught and killed over three times as many whales as they did in Scammon's Lagoon (Table I). Moreover, in 4 years of intensive whaling at Scammon's Lagoon, it was effectively ruined as an important whaling ground, although Magdalena Bay endured at least 12 years of intensive whaling. Of course, the Magdalena Bay complex is much larger than Scammon's Lagoon and contains three distinct parts; these are, from south to north, Lee (Almejas) Bay; Weather, Main, or Magdalena Bay; and Estero Santo Domingo, the long lagoon behind the barrier bar north of Weather Bay. Nevertheless, in comparing the total size of Scammon's Lagoon to that of the Magdalena Bay complex, it would appear that whales were just as concentrated in Magdalena Bay as in Scammon's Lagoon.

Among the persistent errors concerning gray whale migration and range is that which places the most northern bays of winter habitation at San Diego and San Quintín bays. The report that Captain W. W. Clark killed two whales of some kind in the bay in 1842 may be true; on the other hand, it may simply have meant that he had his ship in the bay and captured the whales outside the bay as he did some 15 years later (Henderson, 1972, p. 28). This may be a good place to point out that Captain W. W. Clark was a Yankee who conducted shore whaling outside the bay in boats of the ship *Ocean* which was anchored in the bay (Henderson, 1972, p. 28). This Clark has been confused with another Captain Clark who was a shore whaler in California but who came from the Azores and changed his name from Machado to Clark (Henderson, 1972, p. 210, footnote 357). A few grays may have visited San Diego Bay; but if the account, in a 1908

history of San Diego County (Smythe, 1908, p. 110), of many calving whales passing in and out of the bay in the early 1840s were correct, it would seem that such a well-known and well-stocked potential whaling ground would have attracted many whalers to those waters after gray whaling was initiated at Magdalena Bay in the winter of 1845–1846. Such was not the case, and it appears unlikely that the harbor traffic, which is credited with driving the grays from the bay, increased that much in the early years of this quiet port between 1840 and 1846 (Henderson, 1972, pp. 28, 82–83, 133–134).

The maritime traffic, both at Scammon's Lagoon, since salt works were re-established there in 1857, and at Magdalena Bay, where fishing, agricultural export, and other marine traffic has been increasing since World War II, has not driven gray whale populations from those places. Thus, how could the few merchant ships visiting San Diego Bay in the early 1840s ruin the bay as a whaling ground for whalers who knew it well and had been taking large numbers of grays at Magdalena Bay between 1845–1846 and 1847–1848? Certainly by the time shore whaling from stations just inside San Diego Bay began in the late 1850s, the whalers were sailing their boats outside the bay to attack whales along the migration route (Henderson, 1972, p. 28); whaling vessels reported sighting shore boats whaling outside the bay.¹

Like San Diego Bay, the much smaller and shallower San Quintín Bay approximately 190 miles south of San Diego in Baja California was a protected place from which masters of whaleships could send out their boats. Some vessels reported at San Quintín were actually anchored outside, south of the small island of San Martín off Point San Quintín. From vessels anchored inside or outside the bay, whalers in their boats chased the grays along the migration route outside the bay (Henderson, 1972, pp. 28–29).

An historical myth about the discovery of Scammon's Lagoon has Captain Scammon following grays through the surf to find himself inside a lagoon full of whales (Henderson, 1972, p. 114). In fact, Indians and Spaniards had passed knowledge of the lagoon and its whales down to nineteenth century Mexicans (Henderson, 1972, pp. 53–54; 60–77). Sea otter hunters knew the lagoon prior to Scammon's entry (Henderson, 1972, pp. 102–103), and early sperm whalers on the coast of California, including those of the English ship *Toward Castle* (misidentified by Scammon as *Tower Castle*) which was wrecked in 1836 on the west side of the mouth of the lagoon, surely knew that the lagoon was there.¹⁸ Early hunters of Guadalupe fur seals and elephant seals at Cedros Island and the small island rookeries in Vizcaino Bay also must have known the lagoon (Henderson, 1972, pp. 102–104). At Elide Island almost on the coast and just north of Scammon's Lagoon, guano collectors had contacts with Mexican traders who must have told them about Scammon's Lagoon at least a year before Scammon went into it (Henderson, 1972, pp. 104–105). A most believable account of whaling on the Coast of California says that Scammon learned of the lagoon from a Mexican at Magdalena Bay, where Scammon whaled in 1855–1856 on the San Francisco ship *Leonore* and in 1856–1857 on the San Francisco brig *Boston* (Henderson, 1972, pp. 113, 115, 268). And in fact,

¹⁸Scammon's misidentification is in Scammon, 1869, p. 124 (see Henderson, 1972, pp. 109, 202, footnote 153). The correct identity of the vessel as *Toward Castle* is found in *Lloyd's Register*, July 1, 1838–June 30, 1839, T301; *Sandwich Island Gazette*, October 21, 1837, p. 3.

after a disappointing cruise on *Boston* whaling, sealing, and sea elephant hunting off the coasts of the Californias in the summer and autumn of 1857, Scammon decided to attempt to find a way into the gray whale lagoon of which he had heard at Magdalena Bay (Henderson, 1972, p. 115). Scammon had taken his brig from Cedros Island to the peninsular coast north of Vizcaíno Bay and had worked his way southward to Lagoon Head, just north of the three lagoons on Vizcaíno Bay (Henderson, 1972, pp. 115, 268). From the protected anchorage on the lee side of this headland, which other whalers must have visited by 1857, Scammon could easily have seen the mouths of the two northern lagoons (later named Manuela and Black Warrior lagoons). Later on the voyage, Scammon had arranged to have the small schooner-tender *Marin* sent south from San Francisco, and the two vessels met at Catalina Island to sail southward. After they arrived at Lagoon Head, Scammon sent his tender and three whale boats to explore southward along the coast. This expedition partially explored the two lagoons north of *Ojo de Liebre* (Scammon's) Lagoon. Then, after 2 days, news was sent back to Scammon that the tender had entered the large southernmost lagoon. Scammon then followed *Marin* and took his brig *Boston* into the lagoon which was to acquire his name (Henderson, 1972, pp. 115–116, 268).

A clarification of the translation of the Spanish name for Scammon's Lagoon, *Laguna Ojo de Liebre*, is needed at this point. Many authors have translated the name as Eye of the Jack Rabbit Lagoon or Jack Rabbit Eye Lagoon, rather meaningless names. The correct translation is Jack Rabbit Spring Lagoon. At the eastern end of the Lagoon is a freshwater hole or spring called *Ojo de Liebre* which takes its name from the *Llanos de Liebre* (Jack Rabbit Plains) on whose western edge the spring is located. These are old Spanish names, which probably go back to the mission period prior to the nineteenth century. *Ojo*, however, has other meanings than eye, one of the most common of which is spring, its obvious meaning at Scammon's Lagoon. The lagoon was named after the spring because it undoubtedly had more significance to Spaniards on the trail, which passed the spring, than did the lagoon. Thus, they named the Lagoon after the spring which in turn got its name from the plains to the east.

Another myth which has been perpetuated about Captain Scammon and the lagoon is that he kept his "discovery" concealed for several seasons, and that only by smelling the odors emanating from Scammon's trypots did other whalers later discover his secret (Henderson, 1972, p. 118). In fact, Scammon himself made arrangements in his second winter at the lagoon, 1858–1859 on the San Francisco bark *Ocean Bird*, to join his tender *A. M. Simpson* and the San Francisco bark *Sarah Warren*, commanded by the husband of Scammon's wife's sister, Jared F. Poole, at Lagoon Head from which the vessels entered the lagoon together on November 20, 1858 (Henderson, 1970, p. 17). Although Scammon's journal makes it clear that *Sarah Warren* awaited Scammon at Lagoon Head and sailed into the lagoon with him, in his book "The Marine Mammals" Scammon does not acknowledge Poole's company but indicates that Poole was among the captains who "succeeded in finding their way in" after Scammon had entered the lagoon (Henderson, 1970, pp. 17–18; 1972, p. 204, footnote 197; Scammon, 1874, pp. 265–266). Furthermore, captains on whaleships recruiting in the Hawaiian Islands had learned of the lagoon by the second year of whaling there,

pp. 109, 202, footnote 1, 1838–June 30, 1839.

through reports from Scammon's mate on *Boston* during the first year's whaling at the lagoon. Thus, by the second year of whaling at the lagoon a fleet of 18 vessels came from the Islands to attempt whaling at Scammon's Lagoon and those lagoons adjacent to it. Most of the masters found entry difficult, and after the loss of *Black Warrior* at Middle Lagoon (now Black Warrior or *Guerrero Negro* Lagoon) they went elsewhere on the coast. In the second winter of whaling at Scammon's Lagoon, however, seven vessels excluding tenders whaled at the lagoon, including the barks *Ocean Bird* and *Sarah Warren* of San Francisco; four from the Islands, and one, flying a New Granada flag of convenience, which was a merchant vessel-become-whaler and probably came south from San Francisco, the bark *Cleopatra* (Henderson, 1970, pp. 44-45, footnote 62; 1972, pp. 119, 161).

Summary

After whalers had worked the sperm whale fishery of the Coast of California and had largely turned their attention northward in the Pacific Ocean, they returned to the Coast of California in many vessels to attack gray whales in winter when they had fled the cold and icy northern grounds. The new ground was easy to reach from the whalers' recruiting ports in the Hawaiian Islands and San Francisco, and it afforded mild weather, little sailing, food supplies, and good catches for those who understood the ways of gray whales and gray whaling. Some whalers avoided this peculiar and dangerous kind of whaling. The gray whale fishery lasted only some three decades, but other nineteenth century whale fisheries were also short lived because whalers attacked whales without thought of conservation, moving on when whales were hard to find but often far from extinct on the grounds. Nevertheless, nineteenth century gray whaling from ships and shore stations on the coasts of the Californias caused a devastating decline in the gray whale population, and probably only the early whalers' inability to pursue a species to its end saved the California grays from near extinction or complete extirpation.

ception, quite rightly, to the association of the *Apternodus* lower jaw with the upper dentition indicated by the *Xenotherium* skull, although unacquainted with my subsequent description of the skull of *Apternodus*. He might also have strengthened his argument as to the adaptive nature of the skull proportions by reference to *Necrolestes* of the Patagonian Miocene, regarded by Scott as a distant relative of *Chrysochloris* with a marked resemblance to *Notoryctes* in many respects; also to *Proscalops secundus* of the Lower Miocene of South Dakota, a supposed talpid with several points of adaptive resemblance to *Chrysochloris*, etc. Moreover, the a priori probability of *Xenotherium* being an edentate (Zdansky specifies that he uses the term in its larger sense to include *Pholidota* and *Tubulidentata* as well as *Xenarthra*) is much strengthened by the discovery of *Metacheiromys* in the Middle Eocene and *Palaeonodon* in the Lower Eocene of North America, both of them representing a primitive and partly aberrant group of edentates, which I have called *Palaeonodonta*.⁷ It is quite likely that a small surviving relative of these Eocene palaeonodonts might be found in the Lower Oligocene of North America.

After looking over the matter somewhat cursorily, and in consideration of the trend of later evidence cited above, it appears to me that Zdansky and Simpson are almost certainly right in referring *Xenotherium* to the Edentata. I believe that it may be provisionally placed among the *Palaeonodonta*.

As to the supposed chrysochlorid humerus from the Lower Miocene of South Dakota, which I named *Arctoryctes terrenus*, it continues problematic. It shows the degree of fossorial specialization of the moles, but the fundamental plan of the humerus appears to be distinct, and offers some resemblance to that of *Chrysochloridae* although decidedly more specialized fossorially. On the basis of this alone one might suppose it to be the humerus of *Apternodus*, but neither this genus nor any allied form is known to occur after the Lower Oligocene. True moles of the peculiar and primitive genus *Proscalops* do occur in the same formation as *Arctoryctes*, and it is possible that this is the humerus of *P. secundus*, which has some curiously chrysochlorid features in the skull. If this be so, *Proscalops*, *P. secundus* at least, can hardly belong to the *Talpidae*, but must represent a distinct family,—a view for which considerable evidence might be adduced from its skull and teeth, but not enough in my opinion to be at all convincing. *Arctoryctes* is best left for the present as of problematic affinities.—W. D. MATTHEW, *University of California, Berkeley, California*.

NOTES ON THE CALIFORNIA GRAY WHALE

The California gray whale (*Rhachianectes glaucus*) has for some time been reported as on the verge of extinction. The writer was therefore pleased, while in the company of A. Brazier Howell of the United States National Museum during August, 1926, to have an opportunity of photographing and examining a whale of this species, as it was being cut up at the plant of the California Sea Products Company at Trinidad, Humboldt County, California. This animal was captured near shore at Crescent City, California, and was the only whale of this species taken by the company's whaling fleet at this point during six years of operation.

⁷ Matthew, 1918, Bull. Amer. Mus. Nat. Hist., vol. 38, art. 16, pp. 620-657, figs. 39-68.

With these data in mind, it was with no little surprise and pleasure that, on the afternoon of April 17, 1927, the writer saw three California gray whales in San Ignacio Lagoon, on the west coast of central Lower California. At the time he was on board the fishing boat "Nuchum," as a guest of Capt. O. M. Seely, on one of his fishing trips from San Diego down the Mexican coast. Early on the morning of the following day, April 18, the school was found to have been increased to five whales.

At this time the animals were occasionally almost touching the boat; in fact, the huge beasts twice ran into the anchor chain with such violence that we thought the chain had parted. There were two large adult cows, each with a calf, and a large adult bull. It was impossible to estimate the size of the animals with accuracy, but when one of the cows and her calf came up alongside the boat, the writer roughly figured her length to be between 40 and 45 feet, while the calf was between 18 and 22 feet.

During the hour and a half that the writer had the pleasure of watching these whales at close range, some habits were observed that have apparently never before been recorded. The actions of the young whales were extremely interesting. They seemed always to swim at the sides of their mothers, but they would blow just twice to the mother's once, although the mother would rise to the surface at each blow of the young. The actions of the young when sounding were exactly like those of the parent. In the writer's previous experience with whales in deep water, he had observed two types of submersion: one with an easy bend of the body when the animal was descending but a short distance below the surface, and the other with a sharp bend, as though the position of the animal would be vertical as soon as enough distance below the surface had been reached to cover the tail. This position is always assumed when whales leave the surface for a deep sound.

Both of these attitudes were assumed by the whales under observation on April 18, though to the writer's knowledge, from actual measurement, there were but $2\frac{1}{4}$ to 3 fathoms (13 feet 6 inches to 18 feet) of water in the area where the whales were sporting. Unfortunately, the water of the lagoon and along this part of the coast of Lower California at this season was so clouded with minute marine growth that a white object of good dimensions could not be seen three feet below the surface. The whales were therefore not visible beneath the water, although numerous "slicks" indicated the sweeps of their mighty flukes and told the direction in which they were traveling. The writer timed several of the submersions and found the young ones to blow at an interval of 50 seconds as a minimum and $2\frac{1}{2}$ minutes as a maximum. The mother's blowing occurred with every other rise of the young. This short period between breathings would not seem to hold with the adults when they are in deep water, for it is the writer's experience with finback whales that they stay down for periods exceeding twenty minutes.

The attentions of the bull were about equally divided between the two cows and he was three times observed in the act of copulation. The position of the two animals at this time was on their sides, with their bellies together and the flippers on the upper sides exposed; but at no time were the tails or parts of the tails above water. The length of time of cohesion was about 30 seconds. There was no visible struggle by either animal, nor was there any attempt to pursue or escape. The act, so far as it could be observed, consisted in the quiet appearance

above water of the parts of the bodies of the two animals in a parallel position, close together, and then the simultaneous appearance of the side flipper on each, in corresponding position, rolled upward to a vertical position from where the animals were touching. The flippers, when elevated above water, were seen to vibrate as though flipped by the wind. The two animals engaged were within 200 feet of the boat and it was easy to determine that one flipper was left and the other right by their positions.

The presence of small young of equal size with the two cows at the time of mating would suggest that the gray whales have a definite breeding season. With this knowledge, further observations may lead to some conclusion regarding the period of gestation.—LAURENCE M. HUEY, *Natural History Museum, San Diego, California*.

RELATIONSHIP OF PREDATORY MAMMALS AND BIRDS OF PREY TO RODENT LIFE

Much has been written concerning the effect that predatory mammals have on the rise and fall in abundance of various rodent species. Many contend that the persistent warfare on coyotes, bobcats, wolves, weasels, badgers, and other predatory fur-bearing animals is responsible for the excessive abundance, at times, of jack rabbits, field mice, ground squirrels, marmots, and pocket gophers.

While there is no doubt that predatory mammals are a factor in controlling rodents, yet they play but a small part in maintaining the natural balance. Larger factors are involved, and these include seasonal conditions, fecundity of the species, the acts of man in providing abundant food, and the presence of natural and other shelter. On the other hand, rodents the size of ground squirrels, or smaller, are more effectively decreased in numbers by raptorial birds than by predatory mammals. The quantity of rodent remains found in the stomachs and disgorges of individual owls is almost unbelievable.

Over a series of years, the writer has made observations in various sections where certain rodent species were extremely abundant. For several years Grant County, Washington, had been let alone by government hunters, as the residents and landowners believed that coyotes were necessary to keep down jack rabbits; but when rabies appeared there among coyotes and domestic dogs during August, 1921, it was necessary to clean out the coyotes. Hunters were concentrated in this and five adjacent counties, and approximately 1,800 coyotes were taken in the area during the year ending June 30, 1922. At the same time, jack rabbits had increased along with the coyotes in such numbers that organized campaigns were necessary to stop their depredations. During this same period, 61,000 jack rabbits were killed in Grant County and 94,000 in adjacent counties. During the fiscal year following, 2,062 coyotes were taken in the same district. Jack rabbits were practically at an "ebb." Since that time jack rabbits and coyotes have not been troublesome except in a few local spots.

During 1922 and 1923, serious field mouse (*Microtus*) outbreaks occurred in Washington in the Yakima, Wenatchee, and Okanogan valleys. The mice were very numerous in orchards and alfalfa fields. During previous years the growers had introduced house cats in great numbers—it was not unusual to see ten or twelve cats on three or four acres—but in spite of this the mice started damaging trees, so that organized poisoning was necessary. Orchardists distributed 75,986

Gray Whale re-inhabits former species area

Historic range of gray whale - *Eschrichtius robustus* Lillijeborg, 1861, is located in the Northern hemisphere. Gilmore (1955) proposed that in the interglacial period, there was a channel of swapping between stocks of gray whales in the North Atlantic and North Pacific. The gray whale is described on subfossil remnants from Sweden. These whales were feeding in the North Atlantic during summertime in the Baltic Sea and off Iceland and wintered off the coast of South-Western Europe or North-West Africa and south of 50° NE off the Atlantic coast of North America. The gray whale disappeared in Atlantic as a result of whaling at the beginning of the XVIII century (Mead & Mitchell, 1984; Sokolov, Arseniev, 1994). Gray whales are also distributed in North Pacific coastal waters. During the glacial period when the feeding areas moved South, the whales from West and East coasts could have mixed (Swartz *et al.*, 2006). The gray whale stocks were undermined by whaling in the North Pacific in XIX century.

There are two populations of gray whales in the Pacific Ocean which are considered by some researchers as divided into two substocks in each of them.

Some gray whales were reportedly occurring year round at the border of the USA and Canada (Pike, 1954; Wilke, Fiscus, 1961). In the summer here there are about two hundred such individuals known as the Pacific Coast Feeding Aggregation. These whales are not significantly different genetically or demographically from the rest of the Eastern population. It is suggested that panmixia between the main Eastern stock and Southern substock is not presented. Most of the whales of the Southern substock are observed in the feeding on a regular basis, while the other whales do not come every year and only in some areas (Calambokidis *et al.*, 2010).

The whales of main Eastern (or Chukotka-California) population feed along the mainland coast of the Eastern Siberian, Chukchi and Bering Seas, and winter mainly along the Baja California, Mexico coast. By examining whaling records Henderson (1984) made a qualitative conclusion that the population did not exceed 15.0 – 20.0 thousand whales before the initiation of commercial exploitation in the middle of the 19-th century. By 1900, the eastern population abundance had declined to 2.8 thousand individuals as a result of large-scale whaling. The population was restored after the ban of whaling in 1938 by the end of 1950-s were 6.0-8.0,

by 1968 had reached 13.5, in 1975 - 17.4, 1980 - 19.8, 1985 - 23.5 1988 - 26.9 thousand individuals. Thereafter, it declined by 1993 to 15.8 and by 1998 again reached the peak of 21.1 thousand individuals. In 2000 the number fell to 16.4 in 2002 - 16.0, and by 2007 had increased again to 19.1 thousand individuals (Laake *et al.*, 2009). This indicates that Eastern population abundance reached or even exceeded the initial pre-whaling abundance in 1980-88, 1998 and in 2007. Seemingly, the decennial abundance fluctuations were balanced by carrying capacity around 15.0-22.0 thousand whales. The above is believed to be caused by whale's prey species abundance, temperature regime and other factors (Rugh *et al.*, 2005).

Western population contains Okhotsk-Korean and Japanese substocks, which before 1910 jointly numbered about 1.0 -1.5 thousand individuals (Berzin & Vladimirov, 1981). Area of wintering and breeding of the small Japanese substock (knocked by the end of the XIX) were situated in the straits between the islands of Honshu, Kyushu and Shikoku, and summer feeding areas were situated at the North waters of Hokkaido (Andrews, 1914; Mizue, 1951).

The whales of the Okhotsk-Korean substock are fattening primarily in the coastal waters of the Okhotsk Sea, and they were sighted off the coast of Korea and China in winter time. The last whales were hunted at the southern coast of Sakhalin in 1926, at the northern Kuril Islands in 1942 (Mizue, 1951), off the coast of Korea sporadically and not annually the gray whales were hunted until 1966 (Brownell and Chun, 1977). Since that time, most researchers suggested that the western population had gone extinct. Nonetheless until early 1980-s some singles, couples sometimes and three whales once were sighting off the coast of South China Sea, Japanese Sea (near to Vladivostok) and Okhotsk Sea (Kuril Islands, South of Kamchatka) only in 1965, 1968, 1977, 1978 and 1979. In 1970 population estimated as 100-200 individuals (Berzin and Yablokov, 1978). Since the early 1980s the whales has began more common in groups: 1982 - 4 whales, 1983 - 8 (in the South of Kamchatka) and 3 (near Shantar Islands), 1982 - 14 whales and 1985 - group (in the south of Sakhalin Island), 1983 - 20 whales (in the northeast of Sakhalin Island), 1987 - 18 whales (the mainland coast opposite the South of Sakhalin), 1988 - 3 whales (Middle Kuril Islands) (Maminov, Blokhin, 2004; Nambu *et al.*, 2010). In the area of the Piltun lagoon (south-west of Sakhalin Island) were observed 34 whales in September and in the sea near to Cape of Kril'on the five whales in January, 1989 (Berzin *et al.*, 1990). It was believed that the spatial separation of Bering and Okhotsk Seas and lack of gray whales sightings in the northern part of the Okhotsk Sea and off Western Kamchatka provide enough evidence to consider the Western North Pacific population of gray whales completely independent (Vladimirov, 1994).

In late 1990-s early 2000-s based on systematic data collected by Russia-US Program off NE Sakhalin (Piltun lagoon) population's abundance was re-assessed around 100 whales (Weller *et*

al., 1999). The population was listed as Critically Endangered by the IUCN in 2000. In 2001 additional feeding location located south-east from Piltun nearshore feeding area was discovered and population was estimated to number at least 120 whales (Vladimirov, 2002). After applying the method of photo identification, including the 2002 Russian programs in other areas off Sakhalin and Kamchatka in 2004, the number was evaluated from 130 (Cooke *et al.*, 2008) to 140-150 individuals (Yakovlev and Tyurneva, 2004). From 1995 to 2009 were identified about 180 whales, about 80 of which about were first sighted as calves (Bradford *et al.*, 2010; Tyurneva *et al.*, 2009). Other researchers suggested that animals sighted at feeding grounds do not represent the whole population (Zemsky, Smelova, 2004), it's survival rates overestimated while abundance - underestimated (Vladimirov, 2004; Kanda *et al.*, 2010).

In 2005 IWC Scientific Committee noted, that about half of the year Western gray whales spend in waters of East Asia: Japan, Republic of Korea, Korean Democratic People's Republic and Peoples Republic of China and that additional removal of one reproductive female per year is likely to drive population extinct by 2050 (IWC, 2006, pp.10, 67). In 2009 it was noted that from 2005 population slowly increases and numbers about 130 (IWC, 2010, p.1, 17).

The contemporary **migration routes and wintering places** are unknown. Researchers suggest that they may pass from the Okhotsk Sea to the shores of Korea and China, through the Laperouse Strait (Czapski, 1963) and the Tatar Strait (Yablokov and Bogoslovskaya, 1984). Whales found off the coast of Eastern Kamchatka and the Commander Islands, and they can come here from the East coast of Japan along the Kuril Islands and are owned to "Japanese" substock of Western population (Maminov, Blokhin, 2004). It was also supposed that some of the whales may remain in the Sea of Okhotsk for winter in polinyas (Blokhin, 2004; Reeves *et al.*, 2008).

Some single gray whales have been noted at the **South-Eastern coast of Kamchatka** in the summer since the early 1980-s. (Blokhin *et al.*, 1985). In following years the number of the gray whale sightings and their numbers have been continually increasing off the central part of Kamchatka. The regular observations were not allowed to suppose whether these are due to the expansion of the Eastern population or as the result of special attention of scientists. It was believed that whales of Eastern population inhabit in the Northern waters off Kamchatka and the Commander Islands, and Western population is in the Southern Kamchatka. Some supposed that the northward extension of the Western North Pacific gray whales population range could have been caused by impacts of oil and gas development at Sakhalin shelf (Vertyanin *et al.*, 2004). **The lacks of isolation between Western and Eastern gray whales** are discussed many times.

Some authors discussed a possibility of western gray whales reaching feeding grounds of Eastern population (Omura, 1974; Vertyanin *et al.*, 2004). On the other hand, some authors

suggested considering whales migrating along eastern Japan as transients from Eastern population (Nishiwaki and Kasuya, 1970; Bowen, 1974).

Some authors believed that eastern gray whales migrate northward; leaving Alaska Gulf along south side of Aleutian chain and only around Commander Islands they turn to the North and enter into the Bering Sea (Gilmore, 1955). But this is not confirmed by the direct observations (Berzin, Rovnin, 1966). The researchers are not leave out the scattered migration of Eastern whales in North-West across the Bering Sea and turn around on St. Lawrence Island in the South-West direction along the Koryak coast. A stranded whale was found at the Commander Islands (Medny Island) in 1978, and in 1983 were met 55 gray whales in the northern border of Kamchatka Peninsula (Votrogov, Bogoslovskaya, 1986). They are occurred almost every year at the Bering Island since 1995. Nonetheless, in 2000 a whale, first sighted as a calf off Sakhalin in 1997, was photographed offshore Bering Island. The same whale was later identified off Sakhalin in 2002 (Weller *et al.*, 2003). The Institute of Marine Biology of the Far East Branch of Russian Academy of Sciences photocatalog of gray whaled identified off Kamchatka in 2004-2008 holds 78 whales [the catalog is a subject to annual updates]. Roughly half of the animals in this catalog, including females with calves, were at least once sighted off Sakhalin (Tyurneva *et al.*, 2009).

It is believed that the gray whales copulate in the winter areas and for them are characterized with polygamous relationships (Hubbs, 1962). The other researchers believe that the gray whales are likely to gravitate toward a monogamy (Calambokidis *et al.*, 2010). However, there are some records of mating being observed in April and September in Bering and Chukchi Seas (Tomilin, 1957; Clarke *et al.*, 1989). Some behavior with obvious mating features have been recorded in fall off Sakhalin (Vladimirov, 2004) and in the area of two population ranges overlap off Kamchatka (Vertyanin, pers. comm.).

There are some data that the distance from the tip of the rostrum to the base of the pectoral flippers, from the tip of the rostrum to the eye, the maximum width of the pectoral flipper, and the length of the baleen plates were statistically greater in the western gray whales, and that western gray whales had fewer baleen plates and fewer throat grooves (Zimushko, Ivashin, 1980). It was concluded analyzing data of size for more than 30 whales caught in 1925 off the North-East coast of Kamchatka that the young whales have come from the waters of Korea (Risting, 1928). The study the size of whales caught in 1980 in the Bering and Chukchi Seas has led to the same conclusion (Blokhin, 1982). Contrary, D.W. Rice (1998) summarized several studies that found no clear differences in skeletons of gray whales from the Atlantic Ocean and from the western and eastern pacific populations.

Populations of gray whales with respect to markers of mitochondrial and nuclear DNA have revealed that the western and eastern populations have been isolated, and, presumably, over a long time (LeDuc *et al.*, 2002; Brownell *et al.*, 2009; Burdin *et al.*, 2009; Lang *et al.*, 2010). Migration of whales of two populations towards to each other or unilateral migration of whales of one population - both hypotheses may be suggested, but none can be ruled out for gray whales migrating and feeding in the Russian seas based on mtDNA haplotypes distribution (Meschersky *et al.*, 2011). The study 6 of whales ran aground in Japan showed that there may be gene flow between the two populations, because of the long life and historically large abundance, the western population may still retains considerable amount of genetic diversity after sever, but recent, population reduction (Kanda *et al.*, 2010). While previous studies have supported genetic differentiation between eastern and western populations of gray whales, the relatively low level of genetic differences observed at nuclear markers suggests that some dispersal between the two populations could be occurring. The finding of two whales apparently sampled on both sides of the North Pacific, although subject to numerous caveats, provides support for that possibility (Lang, 2010).

The scenario of gray whale recovering its own natural history area has also been proposed (Ilyashenko, 2009), but without sufficient arguments and has been criticized (Brownell *et al.*, 2009). In favor of this scenario have been analyses the following information.

As marked above, there is no consensus that the Eastern and Western populations infallibly distinguished on any remarks.

Since the mid XX century individual whales of Western population were observed only in 1965, 1966, 1968, 1977, 1978 and 1979. The groups of whales were seen from the beginning of 1980, when the number of Eastern population exceeded the initial pre-whaling abundance.

It could be assumed that there had been the simultaneous growth of both populations. However, it should be noted that the period of completion of the next growth of the Eastern population in the late 1990-s there was the period of biggest mortality due to the stranded of 274 whales in 1999 and 368 in 2000 at the shores from California to Alaska (Brownell, 2010). The number of the Western population in these years was estimated at about 100 individuals, while in 1999 on Sakhalin were 19 skinny whales in 2000 - 30, 2001 - 21, further decreased the number of observing of whales. This phenomenon is recorded for the Eastern population (Burdin *et al.*, 2004). It means that the negative processes were synchronous in the Eastern and Western populations with different phases of population dynamics.

Exactly during the years previous to the peaks of the Eastern population in 1998 and 2007 were recorded, stranded or accidentally bycaught in nets the individual whales in 1996 near to

Hainan Island in Southern China (Zhu, 1998), 1995, 1996, 2005 and 2007. Hokkaido and Honsu. And only one of them were found on the West coast of Japan (Kanda *et al.*, 2010).

It is noted that the whales arrive to the coast of Sakhalin Island in late of May, usually from the North, and in November again shift to the North (Blokhin, Burdin, 2001). The similar migration patterns are observed for the Eastern Kamchatka (Vertyanin, pers. Comm.).

It is suggested that the daily consumption of food by the adult gray whale is about 1.0 - 1.2 thousand kilos (Zimusko, Lenskaya, 1970). The whales are spotty distributed in areas of summer feeding, and the changing of the feeding areas takes place not only for the years but also during the season (Bogoslovskaya *et al.*, 1981). Photo identification confirmed that a significant number of whales move from one station to another. For example, there were identified 77 of Sakhalin whales in 2009, and taking into account the photo identification data from Kamchatka the total amount are 117 individuals (Vladimirov *et al.*, 2010). In recent years, each year photocatalogues replenished with new adult whales, and some of whales do not meet the 5 - 7 years (Tyurneva *et al.*, 2009).

There is reason to believe that even the gray whale is considered as homing animal to the places of feeding and breeding, however, at the same the gray whale is a nomadic animal. In the 1980-s the gray whales of Eastern population have rarely came into the East Siberian Sea, and in 1990 they have becoming more common in Wrangel Island, where in some areas were met up to 7 individuals per 10 km (Kochnev, 2001). At the same time the whales have been met in the Eastern parts of the Beaufort Sea. The unique example of long-distance migrations was recorded meetings of a gray whale off the coast of Israel and Spain in May 2010 within the area of extinct Atlantic population (<http://www.epochtimes.ru/content/view/37236/5/>). The thirteen years old male was tagged in October 2010 with satellite transmitter near to Sakhalin have reached off Oregon US state coast in February 2011.

It is clear that in hundred years after the destructive whaling and as a result the measures of protection, the gray whale began to restore its habitat. The satellite telemetry is a priority and will promote measures for its recovery at the national level in the range states and international cooperation.

Protection measures. The above evidence suggests that the western part of the species range in the Pacific is being re-inhabited not by (or *not only by*) potentially survived whales of the relict Western population, but by Eastern animals re-inhabiting historic parts of the species range. At the same time, some individuals have continued or just started to use the historical winter areas to the South of the Sea of Okhotsk. Taking into account intensive exploitation of the continental shelf: fisheries and mariculture in Japan, Korea and China, oil and gas development in the Okhotsk Sea, it is critical to identify key habitats of the Western North Pacific population

of gray whales. Implementation of the Western Gray Whale Rangewide Conservation Plan recommended by IUCN (Western Gray Range Wide Workshop, September 2008, Tokyo) is needed, including consideration of Canada, USA and Mexico as range states.

Report of the Scientific Committee

The meeting was held at the Lotte Hotel, Ulsan, Korea, from 30 May-10 June 2005 and was chaired by Doug DeMaster. A list of participants is given as Annex A.

1. INTRODUCTORY ITEMS

1.1 Chair's welcome and opening remarks

DeMaster welcomed the participants to the meeting. He thanked the Government of Korea, the City of Ulsan and the local organising Committee for hosting the meeting and for providing the excellent facilities. He also extended his gratitude to the Korean organisers for all their help and for making all participants very welcome in Ulsan.

1.2 Appointment of rapporteurs

Donovan was appointed rapporteur with assistance from various members of the Committee as appropriate. Chairs of sub-committees and Working Groups appointed rapporteurs for their individual meetings.

1.3 Meeting procedures and time schedule

Grandy summarised the meeting arrangements and information for participants. The Committee agreed to follow the work schedule prepared by the Chair.

1.4 Establishment of sub-committees and Working Groups

Three meetings preceded the start of the Scientific Committee. The AWMP Standing Working Group (SWG) met 28-29 May, in which agenda items covered were incorporated into the AWMP main agenda and report (Annex E). Two-day Workshops on the Use of Market Sampling to Estimate Bycatch of Large Whales (27-28 May) and High Latitude Sea Ice Environments (28-29 May) were also held and the reports of these Workshops are given as SC/57/Rep4 and SC/57/Rep5 respectively.

A number of sub-committees and Working Groups were established. Their reports were either made annexes (see below) or subsumed into this report.

Annex D – Sub-Committee on the Revised Management Procedure (RMP);

Annex E – Standing Working Group on an Aboriginal Whaling Management Procedure (AWMP);

Annex F – Sub-Committee on Bowhead, Right and Gray Whales (BRG);

Annex G – Sub-Committee on In-Depth Assessments (IA);

Annex H – Sub-Committee on Other Southern Hemisphere Whale Stocks (SH);

Annex I – Working Group on Stock Definition (SD);

Annex J – Working Group on Estimation of Bycatch and other Human-induced Mortality (BC);

Annex K – Standing Working Group on Environmental Concerns (E);

Annex L – Standing Sub-Committee on Small Cetaceans (SM);

Annex M – Sub-Committee on Whalewatching (WW);

Annex N – Working Group on DNA (DNA); and
Annex O – Working Group on Scientific Permits (SP).

1.5 Computing arrangements

Allison outlined the computing and printing facilities available for delegate use. Requests for Secretariat computing would be addressed according to priorities set by the Convenors.

2. ADOPTION OF AGENDA

The adopted Agenda is given as Annex B1. Statements on the Agenda are given as Annex S. The Agenda took into account the priority items agreed last year and approved by the Commission (IWC, 2005c, pp.52-4). Annex B2 links the Committee's Agenda with that of the Commission.

3. REVIEW OF AVAILABLE DATA, DOCUMENTS AND REPORTS

3.1 Documents submitted

Donovan reported that the new pre-registration procedure had again been successful. With such a large number of documents, pre-specifying papers had reduced the amount of photocopying and unnecessary paper dramatically.

The list of documents is given as Annex C.

3.2 National progress reports on research

Progress reports presented at the 2001-05 meetings are accessible on the IWC website. Reports from previous years will also become available in this format in future.

The Committee reaffirmed its view of the importance of national progress reports and **recommends** that the Commission continues to urge member nations to submit them following the approved guidelines (IWC, 1998b). Non-member nations wishing to submit progress reports are welcome to do so.

A summary of the information included in the reports presented this year is given as Annex Q; the modified report template, taking account of the updates made in 2004, is available on the IWC website (www.iwcoffice.org/commission/sci_com/scprogress). The Committee **agrees** that the bycatch reporting tables for small cetaceans should be brought into line with those for large whales with respect to reporting fishing gear types (see Item 13.4).

3.3 Data collection, storage and manipulation

3.3.1 Catch data and other statistical material

Table 1 lists data received by the Secretariat since the 2004 meeting.

3.3.2 Progress of data coding projects and computing tasks

Allison reported that the first phase of work to encode the revised Soviet individual catch data from the Southern Hemisphere had been completed and the data are in the process of being validated. The validation stage is particularly important for these data, as the source records

Table 1
List of data and programs received by the IWC Secretariat since the 2004 meeting.

Date	From	IWC ref.	Details
Catch data			
5/4/05	Norway: N. Øien	E56	Individual common minke catch records from the Norwegian 2004 commercial catch. Access restricted (specified 14/11/00).
30/5/05	Japan: J. Morishita	D175	Individual catch records from the 2004 Japanese Whale Research Programme under special permit in the North Pacific (JARPN II) and the 2004/05 Japanese whale research programme under special permit in the Antarctic (JARPA).
30/5/05	Russia: R.G. Borodin	D176	Individual catch records from Russian gray and bowhead whale hunt 2004.
6/6/05	St. Vincent and the Grenadines: S. Punnett		Details of the humpback whale taken by St. Vincent and the Grenadines, 2005.
28/9/04	T. Kasuya	CD46	Data in support of Kondo and Kasuya (2002) on revised Japanese coastal catch statistics.
1/2/05	Korea: H. Sohn	E51	Korean data for the North Pacific common minke IA: (i) data for common minke bycatch or stranded 1996-2004; (ii) revised individual catch data 1980-86.
16/3/05	Greenland: L. Witting	E54	Greenland individual common minke and fin catch data, 1988-2004 (2000-04, incomplete) including skin sample data.
30/5/05	J. Brandon	E58	Individual Russian aboriginal gray whale catch records coded from the whale passports 1980-91 (supplied to Brandon by R. Brownell).
Sightings data			
18/3/05	P. Ensor	CD48(E)	2004/05 Southern Ocean Whale and Ecosystem Research Programme (SOWER) cruise data including blue whale data (sightings, effort, weather, ice edge, inter-stratum and way-pt.).
5/4/05	L. Burt	CD50	Database and Estimation of Software System (DESS) version 3.5.
4/1/05	Japan: T. Miyashita	E49	Japanese North Pacific common minke whale sighting data 1994, 1999-2003 for use in the forthcoming North Pacific common minke IA.
1/2/05	Korea: H. Sohn	E51	Korean sightings data 1999-2004 for North Pacific common minke IA.
Other data			
7/1/05	Japan: Y. Fujise	E57	Revised age data for JARPA Antarctic minke earplug samples 1987/88-2000/01, to replaces data sent 11/5/04.
21/1/05, 10/2/05	C.S. Baker	E50, E53	Genetic data for the North Pacific common minke IA. Revised data received 10/2/05.
7/2/05	Iceland: A. Danielsdóttir	E52	Overview of North Atlantic fin whale genetic samples examined at the Marine Research Institute, Iceland.
30/5/05	D. Palka	CD51-52	Simulation data sets 2004 (SC01-SC16) and 2005 (SC17-SC32).

are handwritten and many are of poor quality. The detailed biological data are not being coded in this first phase of the coding work.

The small technical workshop on the revised Soviet Southern Hemisphere catch data (consisting of Allison, Brownell, Donovan, Mikhalev and Tormosov plus an interpreter, see IWC, 2004b, p.2 and p.55) to consider how best to fill the gaps in the data, is expected to take place in September or October 2005. The Steering Group (Annex P(1)) appointed to assist with this work was retained and augmented with Findlay and Clapham with respect to Southern Hemisphere humpback whales (*Megaptera novaeangliae*) (see Item 10.3.1.2).

Data received from the 2003 season has been entered into the individual catch database and work has begun to enter the Faroese data from 1902 onwards supplied by Dorete Bloch.

Allison reported good progress on the summary catch database (begun last year), which aims to be a complete listing of all 20th century whaling catch data and to supplement the data held in the individual catch database. The summary database is now substantially complete and has been used to extract the revised catch series for use in the in-depth assessment of Southern Hemisphere humpback whales (see Item 10.3.1.2). Review of the database by members of the Scientific Committee would be appreciated; specifically, assistance would be welcomed in identifying any errors or additional sources of catch data.

Allison has worked with Bloch on catch data in the Northeast Atlantic with a view to obtaining a common agreed catch series with the North Atlantic Marine Mammal Commission (NAMMCO) (see also Item 6.2.2).

Information on catches of western North Pacific Bryde's whales (*Balaenoptera edeni*) has been collated using

information supplied by Ohsumi since the North Pacific Bryde's whale workshop in March (see Annex D, item 6). In addition the information was being used to identify Bryde's whales in the individual database which were not distinguished from sei whales (*B. borealis*).

Data from the 2003/04 SOWER sightings cruises have been validated and incorporated into the DESS database.

4. CO-OPERATION WITH OTHER ORGANISATIONS

4.1 Convention on the Conservation of Migratory Species (CMS)

4.1.1 Scientific Council

The 2005 meeting of the Scientific Council had not occurred during the IWC intersessional period. Perrin will attend as the IWC observer at the series of meetings in November 2005.

4.1.2 Agreement on Small Cetaceans of the Baltic and North Sea (ASCOBANS)

The report of the IWC observer at the 12th Meeting of the ASCOBANS Advisory Committee (AC) held in Brest, France is given as IWC/57/5F. Preparation for SCANS II was discussed and surveys will be conducted from 27 June-29 July 2005. This will cover the entire North Sea, Celtic Shelf and Gulf of Biscay and is intended to extend to offshore European waters during 2007. New data on population sizes, distribution and structures were reviewed and this included results of sighting schemes, genetic studies and photo-identification.

The IWC POLLUTION 2000+ programme was reviewed, and the AC looks forward to the final report of Phase I in 2006. The AC noted the value of such co-operation between the IWC and ASCOBANS and plans to

contact the IWC to re-establish the IWC-ASCOBANS Working Group on Harbour Porpoises (*Phocoena phocoena*). The AC intends to review its earlier management advice that a bycatch rate of 1.7% is not sustainable, and that 1% should be an alert to consider management measures (and see Item 13.2.3). Drafting of a Recovery Plan for harbour porpoises in the North Sea was continued, focusing on recommending specific management measures in specific areas where high bycatch rates are known to occur.

Implementation of the ASCOBANS Baltic Harbour Porpoise Recovery Plan, The Jastarnia Plan, is progressing and a related Working Group consisting of both environmental and fisheries stakeholders met in Bonn, Germany during March. Two recovery recommendations were extensively discussed; analyses of stock affinities in the transition zone and the development and application of acoustic monitoring techniques. Other relevant items discussed were bycatch reduction, marine protected areas (MPAs) and public awareness. The full report of this meeting is available on the ASCOBANS website (www.ascobans.org/index0504.html).

In light of the EU-Council Regulations, it was agreed that managing observer schemes on vessels under 12m should be investigated.

Further topics of interest to the IWC Scientific Committee included:

- (1) disturbance to small cetaceans due to seismic surveys;
- (2) approaches and progress in reducing/eliminating the adverse effects of military activity; and
- (3) comprehensive assessment of bottlenose dolphins (*Tursiops truncatus*) in European waters, including abundance estimates, distribution, ranging patterns, population social structure and gene flow and design of an integrated monitoring protocol to assess conservation status.

The full report of the meeting is available on the ASCOBANS website at www.ascobans.org/index0502.html.

The Committee thanked Reijnders for attending the meeting on its behalf and **agrees** that he or Donovan should attend the next AC.

4.1.3 Agreement on the Conservation of Cetaceans of the Black Sea, Mediterranean Sea and Contiguous Atlantic Area (ACCOBAMS)

The report of the IWC observer at ACCOBAMS meetings is given in IWC/57/51. At the 2nd meeting of the parties to ACCOBAMS held in Majorca, Spain from 9-12 December, a number of resolutions were adopted concerning:

- (1) a major abundance survey in the region;
- (2) improved compliance with rules concerning pelagic gillnets;
- (3) interaction between cetaceans and fisheries;
- (4) guidelines for the use of acoustic deterrent devices;
- (5) exchange of tissue samples;
- (6) guidelines on tissue banks;
- (7) photo-identification studies;
- (8) guidelines on research and disturbance;
- (9) a Conservation Plan for common dolphins (*Delphinus delphis*);
- (10) the impact of anthropogenic noise;
- (11) facilitation of research (e.g. by providing permits);
- (12) the value of protected areas;

- (13) effects of prey depletion; and
- (14) release of cetaceans into the wild.

The full report of the meeting is available on the ACCOBAMS website (www.accobams.org). The Committee thanked Donovan for attending on its behalf.

A Workshop on obtaining baseline cetacean abundance information for the ACCOBAMS area was held in Valsain, Spain from 17-19 December 2004. Cañadas, Fortuna and Donovan acted as the Steering Group. Previously, the ACCOBAMS Scientific Committee agreed that obtaining such data was the highest priority for research in the area and without it, it will be impossible to *inter alia* determine whether ACCOBAMS is meeting its conservation objectives. The first stage of the proposed project is obtaining baseline population estimates (stock structure and abundance) and distributional information in the ACCOBAMS area. The second stage will be to develop a long-term monitoring framework, both basin-wide and in identified local key areas. The workshop, chaired by Donovan, identified areas, species, potential methods and logistical requirements for a major acoustic and visual survey of the region and outlined a process for taking the project to completion. The full workshop report is available from ACCOBAMS and Donovan.

The 3rd meeting of the Scientific Committee of ACCOBAMS was held in Cairo, Egypt from 15-17 May. Donovan had been unable to attend and thanked Reeves for acting as an informal observer. Topics of interest to the IWC Scientific Committee included:

- (1) a major abundance survey in the area;
- (2) incidental catches in driftnets;
- (3) interactions between dolphins and fisheries;
- (4) anthropogenic noise;
- (5) fin whales (*B. physalus*) (Workshop proposed for November 2005);
- (6) vessel collisions (Workshop proposed for November 2005);
- (7) conservation plans, particularly for common dolphins, bottlenose dolphins and harbour porpoises in the Mediterranean Sea and all Black Sea cetaceans;
- (8) protected areas;
- (9) web-based whalewatching database;
- (10) live strandings;
- (11) prey depletion;
- (12) IUCN Red List status of cetaceans in the Agreement Area; and
- (13) proposed amendments to CMS appendices.

The Committee thanked Donovan for his work with ACCOBAMS and **agrees** that he should represent the IWC at the next ACCOBAMS meeting.

4.2 International Council for the Exploration of the Sea (ICES)

The report of the IWC observer documenting the 2004 activities of ICES is given as IWC/57/5A. During the year, the ICES Working Group on Marine Mammal Ecology (WGMME) met and discussed various issues, however these were not relevant to discussions of the IWC Scientific Committee.

During the Annual Science Conference held in Vigo, Spain (September 2004) several theme sessions incorporated discussions on marine mammals:

- (1) life history, dynamics and exploitation of living marine resources;

- (2) recent advances in the oceanography and biology of the Iberian waters and adjacent shelf seas; and
- (3) modelling marine ecosystems and their exploitation.

Further details under these topics are given in the observer's report. The Committee thanked Haug for the report and **agrees** that he should represent the IWC at the next ICES meeting.

4.3 Inter-American Tropical Tuna Commission (IATTC)

The 2005 meeting of the Scientific Council had not occurred during the IWC intersessional period. The Secretariat will ask Reilly if he will attend as the IWC observer at their next meeting.

4.4 International Commission for the Conservation of Atlantic Tunas (ICCAT)

The report of the IWC observer at the 14th extraordinary meeting of ICCAT held in New Orleans, USA is given as IWC/57/5E. Many topics were discussed and numerous recommendations made, although none directly relevant to cetaceans. The Committee thanked Centenera for attending on its behalf and **agrees** that Kell should represent the IWC at the next ICCAT meeting.

4.5 Convention for the Conservation of Antarctic Marine Living Resources (CCAMLR)

The report of the IWC observer at the 23rd meeting of the CCAMLR Scientific Committee held in Hobart, Australia, October 2004 is given as IWC/57/5B. Results from the 2004 IWC meeting relevant to CCAMLR were presented by Kock, including a request from the IWC Scientific Committee for CCAMLR to participate in the IWC Workshop on Sea Ice, which was held in Ulsan, 28-29 May and discussion of whale catches within the CCAMLR Convention area. The main items considered at the CCAMLR meeting of relevance to the IWC included status and trends of Antarctic fish stocks and krill, incidental mortality of marine mammals, ecosystem monitoring and management, and management under conditions of uncertainty.

CCAMLR will be participating in the International Polar Year (IPY) 2007/08 and this will include contributions to the Census of Marine Life (CoML). Countries conducting activities during the IPY, either as part of their national activities or specifically for the IPY include Australia, Argentina, Brazil, Chile, France, Germany, India, Italy, Japan, Republic of Korea, Russia, New Zealand, Norway, South Africa, Sweden, UK and USA. The CCAMLR Scientific Committee agreed that a synoptic survey in the South Atlantic region would be the most appropriate activity for CCAMLR in the IPY. Although focusing on krill, the survey would collect ancillary and biological data, including observations of marine mammals. The Scientific Committee of CCAMLR encouraged the participation of the IWC in both the planning and implementation of the cruise.

An intersessional Steering Group was established under Seigel (Germany) to progress the proposed IPY synoptic survey. The Antarctic CoML is likely to consist of a series of meridional transects around the Antarctic using vessels from a number of CCAMLR members. The Working Group on Ecosystem Monitoring and Management (WG-EMM) will provide standard protocols for measurements, which

will include scientific acoustics and ship-based surveys for mammals.

The Working Group on Fish Stock Assessment (WG-FSA) highlighted the records in CCAMLR of encounters of killer whales (*Orcinus orca*) and sperm whales (*Physeter macrocephalus*) with the Patagonian and Antarctic toothfish long-line fisheries. One incidental whale mortality was observed in the 2003/04 season. Its identity is yet to be confirmed, but it is tentatively thought to have been an Antarctic minke whale (*B. bonaerensis*). It was found entangled in the mainline of the longliner *Piscis* in CCAMLR sub-area 88.1.

Discussion of the IWC-CCAMLR collaboration appears under Item 12.3.2 and in Annex K, item 8.2. Reports of the CCAMLR Scientific Committee and its Working Groups are available through the CCAMLR secretariat and on its website. Edith Fanta (Brazil) was elected as Chair of the CCAMLR Scientific Committee for the next two years. The Committee thanked Kock for attending on its behalf and **agrees** that he should represent the IWC at the next meeting of the CCAMLR Scientific Committee.

Reilly or Thiele will attend WG-EMM meetings on behalf of the Committee.

4.6 Southern Ocean Global Ecosystem Dynamics (SO-GLOBEC)

Details of SO-GLOBEC activities and collaboration with the IWC are given under Item 12.3.2 and in Annex K, item 8.2. The Committee thanked Thiele for promoting and coordinating the collaboration and **agrees** that she should continue in this work, in conjunction with the Southern Ocean Collaboration (SOC) Steering Group (Annex P(21)).

4.7 North Atlantic Marine Mammal Commission (NAMMCO)

The report of the IWC observer at the 12th meeting of the NAMMCO Scientific Committee held in Vidareid, Faroe Islands, October 2004 is given as IWC/57/5G. The full report of the meeting will shortly be published in the NAMMCO annual report and is presently available on the NAMMCO website (www.nammco.no).

Preliminary results from the Icelandic research programme on common minke whale diet, and a new multi-species model incorporating common minke whales, harp seals and three fish species in the Barents Sea were reviewed. The Committee noted the lower than expected activity in the area of multi-species modelling and emphasised that progress will not be made unless significant additional resources are dedicated to it.

Advice for several cetacean species in West Greenlandic waters was requested from the Committee. Without a new abundance estimate for the area, the Committee was unable to comment on the sustainable yield levels for humpback whales. The Committee also could not review abundance, stock structure, migration and feeding ecology of killer whales in this area without additional information. The Committee welcomed the introduction of quotas for narwhals (*Monodon monoceros*) and white whales (*Delphinapterus leucas*) in West Greenlandic waters, but noted that the quotas still exceed the total removals recommended. The Committee reiterated its view that delaying the implementation of catch reductions will delay stock recovery and will lower available catches in the medium term.

The Committee evaluated the data collection and estimation procedures used in the Icelandic bycatch monitoring programme, and made several recommendations to improve the accuracy of bycatch estimation by Icelandic fisheries. The Committee outlined its priorities for 2005/06 and those relevant to IWC discussions can be summarised as:

- (1) assessment of North Atlantic fin whales, with refinement of assessments for the EGI area, and development of assessment models for Norwegian stocks;
- (2) assessment of narwhal and white whale stocks, particularly for West Greenland, in co-operation with the Scientific Working Group of the Canada/Greenland Joint Commission; and
- (3) planning for the North Atlantic Sightings Survey in 2007.

The Committee thanked Walløe for attending on its behalf and **agrees** that he should represent the IWC at the next NAMMCO Scientific Committee meeting.

4.8 International Union for the Conservation of Nature (IUCN)

The IUCN Independent Scientific Review Panel on Impacts of Sakhalin II Phase 2 on Western North Pacific Gray Whales and Related Biodiversity delivered its report in February 2005, which is available online¹. In accordance with IWC Resolution 2004-1 on the western gray whale (*Eschrichtius robustus*), Donovan participated on the panel. Recommendations from the panel are discussed under Item 10.4.5. A follow-up workshop was held in May 2005 to provide an opportunity for the Sakhalin Energy Investment Company, the potential lending banks and other stakeholders to discuss issues arising from the panel report. The workshop report is available at the IUCN website².

The IUCN Cetacean Specialist Group collaborated with the *baiji.org* Foundation, the Institute of Hydrobiology (Wuhan) and the Chinese Ministry of Agriculture to hold a Workshop on Conservation of the Baiji and Yangtze Finless Porpoise in late 2004. The full report is not yet ready, but a summary report is available online³.

The IUCN Red List of Threatened Species (www.redlist.org) continues to be updated in the light of new information and changes in status and several cetacean entries are currently under review.

The Committee thanked Cooke for his report. No meetings of IUCN are expected in the intersessional period.

4.9 Food and Agriculture Organisation (FAO)

The 26th Session of the Commission on Fisheries (COFI) held in Rome, Italy, March 2005 marked a decade of implementation of the FAO Code of Conduct for Responsible Fisheries. The report of the IWC observer at this meeting is given as IWC/57/5C.

COFI expressed its condolences to the countries and families of the victims of the Tsunami. Many participants reconfirmed their support for previous requests to investigate the interaction between marine mammals and fisheries. However, others were concerned that the foremost

aim of the IWC is the conservation and management of whales, and they expressed their concern that discussions of whaling in COFI might detract from other more important fisheries-related issues.

The Committee thanked Mae for attending on its behalf. No meetings are expected in the intersessional period.

The report of the IWC observer at the 21st session of the Co-ordinating Working Party on Fishery Statistics (CWP) in Copenhagen is given as IWC/57/5M. Issues of relevance to the Scientific Committee included agreement by the CWP on revised vessel classifications which are included in the 2005 International Standard Statistical Classification of Fishing Vessels (ISSCFV). The CWP received the report of the 2nd session of the FIRMS (Fisheries Resources Monitoring System) Steering Committee which preceded the CWP meeting, and included an invitation to the IWC to join FIRMS. FIRMS is a global information system on fisheries aimed at providing timely, reliable strategic information on fishery status and trends on a global scale. The FIRMS system includes the species, fishing technology, resources, fisheries, vessels, and management systems domains of information, which will be of use to the Scientific Committee in its work in estimating levels of bycatch. This matter is discussed further under Item 19.2 and in SC/57/Rep4.

4.10 North Pacific Marine Science Organisation (PICES)

The report of the IWC observer at the 13th annual meeting of PICES held in Hawaii, USA, October 2004 is given as IWC/57/5H. A one-day workshop held by the Marine Birds and Mammals Advisory Panel (MBM-AP) reviewed the region-specific trend of diet and feeding habits of marine birds and mammals, including cetaceans in the North Pacific and the following points were noted:

- (1) diet composition of top predators varies between west and east regions of the North Pacific;
- (2) diet composition of top predators has switched dramatically at decadal levels, probably related to regime shifts, El Niño and other climate factors; and
- (3) marine birds and mammals may be useful as ecosystem indicators.

A workshop entitled 'Factors Affecting Distribution and Foraging Ecology of Top Predators in the Okhotsk Sea' will be held at the next PICES annual meeting. Following a review of MBM-AP activities over its five-year existence, it was agreed that they should in future focus on new activities such as:

- (1) updating estimates of prey consumption for top predators;
- (2) development of climate and ecosystem indicators;
- (3) development of an understanding of the biogeography of top predators in the North Pacific; and
- (4) improving technology for oceanography using top predators as sampling devices.

The Committee thanked Kato for attending the meeting on its behalf and **agrees** that he should represent the IWC at the next PICES meeting.

4.11 Eastern Caribbean Cetacean Commission (ECCO)

The work programme of ECCO for the year 2004/05 was intended to focus on Grenada and Carriacou. The annual meeting to elaborate on these plans/programmes was

¹ <http://iucn.org/themes/business/isrp/index.htm>.

² http://www.iucn.org/themes/business/ISRP_Followup/ISRP_Followup_Workshop%20Report_Final_6June05.pdf.

³ http://www.baiji.org/workshop_2004/report.html.

scheduled for October of 2004. Due to the passage of hurricane Ivan and its devastating onslaught on Grenada, all planned activities and meetings had to be put on hold. A report on further developments will be ready for presentation to the next Scientific Committee meeting in 2006. The Committee thanked Lawrence for this information and **agrees** that he should represent the IWC at the next ECCO meeting.

5. REVISED MANAGEMENT PROCEDURE (RMP) – GENERAL ISSUES (SEE ANNEX D)

5.1 Finalise the guidelines and requirements for implementing the RMP

5.1.1 Develop the thresholds for defining ‘acceptable’ and ‘borderline’ performance for classifying the performance of RMP variants for Implementation Simulation Trials

Last year, the Committee recommended and the Commission endorsed the ‘Requirements and Guidelines’, for *Implementations*, noting that further work was needed to determine the thresholds that define ‘acceptable’, ‘borderline’ and ‘unacceptable’ conservation performance for *Implementation Simulation Trials (ISTs)*. SC/57/RMP1 presented calculations for these thresholds based on suggestions made last year. However, the author pointed out that applying them would lead to the 0.6 tuning of the *Catch Limit Algorithm (CLA)* performing ‘unacceptably’ when the initial depletion is 0.6.

The Committee concurred and **agrees** that the new approach described in Annex D (item 5.1.1) should provide the necessary threshold values when evaluating the conservation performance of each RMP variant for each *IST*. It also **agrees** that the approach should be evaluated intersessionally before final adoption by the Committee. The analyses required are detailed in Annex D (item 5.1.1) and the criteria evaluation will be conducted by Allison and Punt, under the guidance of an intersessional email group (see Annex P(31)).

5.1.2 Develop a list of agreed stock structure archetypes

The Committee **agrees** that the list of agreed stock structure archetypes should be developed as a number of case studies (e.g. for North Pacific Bryde’s whales, North Atlantic fin whales) have been completed, thereby benefiting from the experience gained during the process.

5.2 Further develop the ‘simple model filter’

The Committee had welcomed the development of the ‘simple model filter’ (Punt, 2003) as a computationally economical approximation of the RMP as an aid to developing *ISTs*.

The ‘simple model filter’ had been extended by Punt to be able to incorporate tagging data in parameter estimation. The result of applying it to western North Pacific Bryde’s whales is discussed under Item 6.1.2.1. The Committee thanked Punt for this work which will prove extremely valuable in its future work.

5.3 Finalise the issue of spatio-temporal considerations

At previous meetings, options have been discussed for handling cases where whaling on migrating populations (e.g. North Pacific common minke whales) can cause difficulties in defining *Small Areas*. The Committee **agrees** a modification to Annotation 2 to the RMP (Annex D, Appendix 2) which provides for the possibility of some

temporal and/or spatial restriction on whaling within a *Small Area* as part of an RMP *Implementation*. This is to make allowance for the possibility that *Small Areas* are specified in which whaling could take animals from stocks in proportions different to those present in such *Small Areas*. In such cases, simulations to test for the conservation performance of such an approach must be conducted so that whaling within a *Small Area* is assumed to occur in such a way as to maximise the risk with respect to depletion, while at the same time remaining consistent with operating procedures for the whaling activities proposed by the nation or nations concerned.

5.4 Finalise the issue of the CATCHLIMIT program for running it in trials situation

Given improvements in computing speed, the Committee **agrees** it is no longer necessary to adjust the convergence criteria for the CATCHLIMIT program to make it feasible for use in simulation trials; that would only be required if it turns out to be necessary when the program is actually used in specific trials. Hence, this issue does not need to be included on next year’s agenda.

5.5 Proposal for revision of the RMP

Last year, the Committee was formally notified (IWC, 2005j, p.10) that for common minke whales in the North Atlantic, Norway intends to propose a change to the *CLA* of the current RMP. SC/57/RMP3 presented a progress report on their work to complete the development process. The Committee noted the new information. Comments by Committee members are reported in Annex D, item 5.5.

5.6 Other

SC/57/O21 (see Annex G, item 3.3.3) presented an example of an analysis showing that the dynamics of populations for multi-species models could, under certain scenarios, differ appreciably from those under conventional single species models. The authors suggested that this might have implications for the RMP, and that it might at some stage be informative to investigate the performance of the RMP using such models as operating models.

The Committee noted that the RMP trial structure had included scenarios such as changing carrying capacity that *inter alia* can be considered to reflect multi-species behaviour. It therefore **agrees** that there is no need to conduct additional trials to confirm that the conservation performance of the RMP was satisfactory. The current difficulties of being able to develop multi-species models with adequate predictive capabilities are well known (e.g. IWC, 2005b, pp.413-26). Only if such capabilities are realised, should attempts to refine the RMP to take explicit account of multi-species effects be considered. Naturally any such refinements would need to demonstrate performance superior to that of the existing RMP under an appropriate set of trials.

5.7 Work plan

As noted under Item 5.1.1, the Committee **agrees** that the intersessional evaluation of criteria developed to determine whether the conservation performance of an RMP variant is ‘acceptable’, ‘borderline’ or ‘unacceptable’ will be a priority item for next year.

6. RMP – PREPARATIONS FOR IMPLEMENTATION (SEE ANNEX D)

6.1 Western North Pacific Bryde's whales

6.1.1 Report from the intersessional Workshop on the pre-Implementation assessment for western North Pacific Bryde's whales

The Committee considered the report of the intersessional Workshop (SC/57/Rep3), chaired by Donovan. The Workshop's objective was to work towards completion of the *pre-Implementation assessment* for western North Pacific Bryde's whales. It had considered the aspects required under the 'Requirements and Guidelines' for *Implementations* (IWC, 2005k, p.80) to complete a *pre-Implementation assessment*, specifically:

- (1) abundance estimates;
- (2) catches;
- (3) stock structure hypotheses;
- (4) dispersal rates; and
- (5) data for conditioning.

The Workshop had examined existing catch data and developed preliminary catch series for Japan (coastal and Bonin Islands), the USSR, the Philippines and China, Taiwan. It had identified several data sources as the basis for alternative catch series for simulation trials, and additional work needed to finalise the catch series for use in trials. Based on the stock hypotheses developed by the IWC (1999, p.116); together with additional genetic and non-genetic information, it identified five alternative stock hypotheses. Those were considered to be sufficiently inclusive that collection of new data during the *Implementation* process is unlikely to suggest a new stock hypothesis. The Workshop had agreed that the various stock hypotheses were not equally plausible, but did not assign plausibility weights to these hypotheses as this is scheduled for the 'First Annual Meeting' after it has been agreed that the *Implementation* process should begin. It identified several tasks to assist in assigning plausibility weights to trials.

Abundance data were reviewed and it had been agreed that the set of blocks surveyed in August-September would serve as the basis for using the early, as well as the most recent, survey data when estimating abundance and additional variance. Specifications were developed for calculations for computing the abundance estimates to be used for conditioning (and their variance-covariance matrix). Areas to be excluded when calculating abundance estimates for the offshore form of Bryde's whales to avoid including the small coastal form (or forms) were also identified.

The Workshop had identified information needed to estimate the rates of dispersal (defined as permanent transfer of individuals between breeding stocks) and mixing (temporary movement of animals spatially) and had established a small group to estimate mixing rates in sub-area 1. It had reviewed the specifications for the biological and technological parameters selected by the Scientific Committee in 1999 (IWC, 2000b, pp.10-11) and endorsed their use in future *ISTs*. It had also reviewed information pertinent to the *Maximum Sustainable Yield Rate (MSYR)* and identified work that might restrict the range of plausible values.

After reviewing the criteria for deciding whether the *pre-Implementation* process was complete and an

Implementation could begin (IWC, 2005e, pp.85-6), the Workshop had agreed that provided its recommendations were followed, the *pre-Implementation* process could be considered as completed.

The Committee accepted the Workshop report, and thanked the participants for substantially advancing the *pre-Implementation assessment* for western North Pacific Bryde's whales.

6.1.2 Preparation for Implementation

6.1.2.1 PROGRESS ON PRE-IMPLEMENTATION

The catch series for use in *ISTs* was progressed based on the recommendations of the intersessional Workshop (SC/57/Rep3). The catches reported as sei/Bryde's whales were split to species, and several alternative catch series were identified. A few remaining minor issues will be resolved before the 'First Intersessional Workshop'. The Committee **agrees** that the catch series to be finalised by SC/58 should form the basis for the North Pacific Bryde's whale *ISTs*.

SC/57/PFI1 reviewed the abundance estimates from the 1998-2002 surveys to complete the *pre-Implementation assessment*. Additional variance was estimated. The abundance estimate for sub-areas 1 and 2 based on the 1998-2002 surveys is 26,172 under the assumption of different mean school sizes, and 25,852 when the mean school size is assumed to be independent of block; their CVs are about 40%. A possible explanation for the high additional variance was provided.

Annex D, Appendix 3 takes account of the possible systematic change in whale distribution between the two survey periods. All the interaction terms are significant, and support a systematic change in distribution between survey periods. A drop in the estimate of the CV for the total abundance from about 40% to about 35% suggests that the additional variance reported in SC/57/PFI1 includes variation due to non-random effects.

The Committee **agrees** that the estimates of additional variance in SC/57/PFI1 and Annex D, Appendix 3 are adequate for the purposes of developing *ISTs*. It also identified three refinements to the approach in SC/57/PFI1 that could form an improved basis for analyses presented to the 'First Intersessional Workshop'. They are detailed in Annex D, item 6.1.2.1.

The Committee noted that, although not required for the *pre-Implementation assessment*, it will be necessary for it to review and agree the abundance estimates (and their variance/covariances) to be used when applying the RMP. However, that step can only be finalised once specifications for *Small Areas* are completed.

SC/57/PFI2 described an approach using mark-recapture data to estimate distribution proportions for putative stocks/sub-stocks in sub-area 1. It was based on Japanese marking data, the 'simple model filter' approach of Punt (2003), and the specifications developed by the Committee to include mark-recapture data when conditioning *ISTs* for western North Pacific Bryde's whales.

The Committee thanked the authors of SC/57/PFI1 and SC/57/PFI2 for their work and looked forward to the results of additional analyses. It noted that if they are to be used, analyses related to SC/57/PFI2 need to be completed by the 'First Annual Meeting', while those related to SC/57/PFI1 need to be completed by the 'First Intersessional Workshop'.

The Committee noted that the intersessional Workshop had not specified the lower bound for $g(0)$ for use in trials

(the upper bound was agreed to be 1), but had agreed that the decision regarding this lower bound would be made this year taking account of evaluations reported in papers to the present meeting. No papers regarding the lower bound for $g(0)$ were received. The Committee therefore **agrees** that the lower bound for $g(0)$ for the purposes of *ISTs* will be 1.

The Committee also **agrees** that the *ISTs* will need to account for possible systematic changes in distribution in the future if the estimates of additional variation are to be based on the approach outlined in Annex D, Appendix 3.

6.1.2.2 RECOMMENDED ACTION

The Committee noted that all the recommendations of the intersessional Workshop relevant to completion of the *pre-Implementation assessment* had been met. It therefore **agrees** that the *pre-Implementation assessment* for western North Pacific Bryde's whales is complete and **recommends** that *Implementation* can commence.

The Committee noted that an *Implementation* will normally be completed in two years (IWC, 2005d, p.78) during two intersessional meetings and two Annual Meetings, subject to sufficient resources being available. The necessary steps, and the resources required to complete the *Implementation*, are detailed in Annex D, item 6.1.2.2. In particular, a 'First Intersessional Workshop' (after which no new data may be introduced) needs to be held to develop an appropriate *ISTs* structure and to specify the associated conditioning. The Workshop is planned to take place during 25-29 October 2005 in Tokyo. Financial implications are discussed under Item 21. A Steering Group was appointed (see Annex P(17)).

6.2 Review of information on the North Atlantic fin whale

Last year, the Committee agreed that there were sufficient data to warrant initiation of the *pre-Implementation assessment* for North Atlantic fin whales and recommended to the Commission that the Committee initiate the *pre-Implementation assessment*. The requirements for completion of a *pre-Implementation assessment* are outlined in IWC (2005e, p.86).

6.2.1 Review progress on the development of stock structure hypotheses as part of the pre-Implementation assessment for North Atlantic fin whales

SC/57/PF13 summarised evidence from non-genetic data for stock structure of fin whales in the North Atlantic, based on: mark returns; morphometrics; pollutant levels; biological parameters; acoustic studies; and telemetry.

The Committee **agrees** with the conclusion of SC/57/PF13 that the non-genetic data indicate a separation between the western, central and eastern North Atlantic. A separate stock hypothesised to occur in the Mediterranean has been confirmed using genetic information (Bérubé *et al.*, 1998).

SC/57/PF14 presented the results from a genetic analysis of fin whales from the feeding grounds in the North Atlantic based on microsatellite variation. On a macrogeographical scale, the analysis confirmed that the North Atlantic fin whale is genetically structured on the feeding grounds. The genetic divergence of fin whales from different feeding grounds indicates separate breeding units and the low level of genetic divergence observed suggests a recent origin for the stocks.

Annex D, Appendix 4 outlined a set of stock structure hypotheses for North Atlantic fin whales based on

inferences from genetic and non-genetic data. The Committee **agrees** that the data support consideration of additional stock structure hypotheses in which the East-Greenland-Iceland area is divided into East-Greenland-West Iceland and East Iceland areas. Further work related to identification and refinement of stock structure hypotheses was identified, *viz*:

- (1) the data for each feeding ground should be used to test for departures from random mixing; and
- (2) additional genetic data for fin whales found in waters off Canada and the Faroe Islands should be included in the analyses on which stock structure hypotheses are based.

6.2.2 Planning for completion of the pre-Implementation assessment

Issues to be addressed in completing the *pre-Implementation assessment* for North Atlantic fin whales at the Committee's 2006 meeting are detailed in Annex D, item 6.2.2. The Committee established an intersessional Working Group (see Annex P(16)) to progress this work.

The Committee **recommends** that IWC scientists attend the Workshop proposed by the NAMMCO Scientific Committee, given its focus on general scientific issues related to stock structure of fin whales and other non-management related issues such as the development of a final catch series. Financial aspects are discussed under Item 21. The Committee **agrees** that relevant scientists from the NAMMCO Scientific Committee be invited to the 'First Annual Meeting' at which stock structure hypotheses will be discussed further and used as the basis for *ISTs*.

It was noted that a timetable similar to that outlined in Annex D, item 6.1.2.2 for western North Pacific Bryde's whales would be required if the *pre-Implementation assessment* for North Atlantic fin whales is to be completed at the Committee's 2006 meeting, and if the Commission agrees to initiate the *Implementation*. In this regard, other tasks required of the Secretariat computing department may necessitate delaying the start of the *Implementation* until after the Committee's 2007 meeting.

6.3 Work plan

The Committee **agrees** on the following, in priority order:

- (1) conduct the 'First Intersessional Workshop' for western North Pacific Bryde's whales; and
- (2) finalise the issues related to completing the *pre-Implementation assessment* for North Atlantic fin whales.

7. ESTIMATION OF BYCATCH AND OTHER HUMAN-INDUCED MORTALITY (SEE ANNEX J)

7.1 Estimation of bycatch based on fisheries data and observer programmes

7.1.1 Review data from FAO

Last year, the Committee recommended that continued collaboration with FAO, particularly on the Inventory of Fisheries database, would be helpful to investigate fishery data that may allow better estimates of large whale bycatch. Northridge reported on intersessional collaboration with FAO. The Inventory of Fisheries is being compiled on a

regional basis and at its present stage will be most relevant for fisheries likely to have a large whale bycatch in the Northeast Atlantic and the Northwest Pacific. However, further work is required to produce the level of detail that would be most useful to the Committee. The Committee welcomed this work and **recommends** that it is continued. Specifically, it **agrees** that Northridge should continue work in collaboration with FAO, with the aim of integrating bycatch records into the Inventory of Fisheries.

It was noted that the information flow should be a two way process, with bycatch records held by the IWC being provided to FAO, and FAO able to assist the Committee by providing detailed information on the nature and scale of fisheries in areas where large whale bycatch might be an issue of concern.

In order to facilitate this, the Committee **agrees** that the IWC should join the FIRMS agreement, and it **recommends** that the Secretary implements this.

7.1.2 Review progress on standardised reporting in progress reports

The Committee reviewed a summary of the national progress reports to assess how well the revised reporting requirements had been adopted. The Committee **agrees** that the revised table provided data in a more useful format than previously. The Committee **encourages** countries who had not been able to submit data in the requested format this year to try to do so in future.

It was agreed that a fuller explanation of the codes that are used to describe the fate of entangled whales and how they were observed would be helpful, and gear codes should be updated periodically, as they are revised by FAO. To this end, a web link to the appropriate codes will be included in the national progress report guidelines for next year, provided a website with such information exists.

The Committee **agrees** that the distinction should be made in national progress reports between those countries that have monitoring schemes, where no records imply a low or zero bycatch rate, and others for which no such schemes exist and thus where the absence of records cannot be taken to imply a low or zero bycatch rate.

7.1.3 Determination of appropriate coverage rates for estimating cetacean bycatch

There had been no new papers presented on this topic this year, but it was noted that this issue was on the agenda of member states of the European Union, as recent legislation required them to make estimates of cetacean bycatch in selected gillnet and pelagic trawl fisheries. This will require some consideration of this topic by those countries and members of the Committee involved in such schemes are requested to report any progress to next year's meeting.

The Committee was reminded that in some areas certain types of fisheries are difficult to monitor using observers and further consideration of this topic is needed.

A preliminary worldwide overview of records of cetacean interactions with longlines was presented to the Committee (SC/57/BC3). Longline fisheries for large pelagic fish are widespread and have expanded in recent years. Documented mortalities of whales include sperm and humpback whales, notably in the South Atlantic and Gulf of Alaska. The Committee looks forward to seeing an updated version of the paper at next year's meeting. It was also suggested that where possible, records of encounters between longlines and whales should include information

on whether the whales left with any lines attached, as this has implications for their future survival.

7.2 Estimation of bycatch based on genetic data

7.2.1 Review results from intersessional workshop on the market survey approach

At last year's meeting, the Committee had strongly recommended that the methodological workshop (on the use of market sampling to estimate bycatch) should take place as described in the proposal (IWC, 2005c, p.13). A Steering Group (Berggren, Donovan, Hammond and Zeh) was appointed, who contacted potential invitees to participate in a planning meeting that was to take place during autumn 2004. At that meeting, the intention was that information needs for the Workshop would be reviewed, papers needed to provide background for the workshop would be identified, a list of participants would be finalised and meeting logistics would be arranged. However, it was not possible to find dates when most of the invited participants to the planning meeting were available. The Steering Group therefore decided that the planning meeting and Workshop should be replaced by a two-stage Workshop of which an initial 2-day Workshop would be held immediately before the 2005 Scientific Committee meeting. The primary task of the initial Workshop was to identify information about the markets that would assist in evaluating market sampling approaches and allow a review of their relative precision. It was held 27-28 May 2005 in Ulsan, Republic of Korea (SC/57/Rep4).

The objectives of the two-stage Workshop were:

- (1) to review available methods that have been used to provide estimates of large cetacean bycatches via market samples, including consideration of their associated confidence intervals in the context of the RMP;
- (2) to identify information about the markets that would be required for a market sampling approach; and therefore,
- (3) to provide advice as to whether market-sampling-based methods can be used to reliably estimate bycatch for use in addressing the Commission's objectives regarding total removals over time and if so, the requirements for such methods.

The initial Workshop concluded that market sampling is a potentially useful method to supplement bycatch reporting schemes. It also agreed that bycatch estimates from market surveys would be improved considerably if carried out in conjunction with the use of data from DNA registers on whales entering the market. Whilst the Workshop recognised the political sensitivity of market-related issues in an IWC context, it respectfully requested relevant governments to consider a collaborative effort to investigate these methods as a potentially valuable source of information for management and use in the RMP.

Mae reiterated the position of the Government of Japan that market related issues are a domestic matter and in view of this the contribution from Japan to these discussions will be limited. He noted the complexity of the Japanese market and that the distribution system in Japan is dynamic and constantly changing. In view of these issues of market complexity, and the likely costs involved in obtaining appropriate sample sizes, some members doubted the conclusion of the Workshop that market sampling was a promising approach. Kim noted that, at last year's Commission meeting, Korea had reserved its position on the

decision of holding the Workshop. Accordingly, the Government of Korea was not represented at the initial Workshop. Therefore, some texts in the workshop report (SC/57/Rep4) do not necessarily reflect the views of scientists from the Korean delegation.

Others noted that the discussions at the Workshop drew attention to the ways in which estimates from market surveys could be improved through a collaborative approach using a combination of official statistics, register data and market surveys. If data from DNA registers were available then the statistical precision of estimates would be improved considerably and only a relatively low level of sampling would be required. In addition, market surveys would not need to be conducted continuously, particularly if the estimates were in agreement with the reported figures.

The initial Workshop only considered the first two of objectives (1)-(3). Although the view of some members was that market surveys would not provide reliable estimates of bycatch, the Committee **agrees** that the planned follow-up Workshop would be valuable in order to evaluate this fully. The Committee also **agrees** that such a Workshop should only be held when the Steering Group determines that sufficient progress has been made on addressing the data requirement needs, and on developing simulation frameworks for sensitivity analyses and to test sampling designs prior to the Workshop (financial implications are discussed under Agenda Item 21). The Committee **agrees** to the proposal for a follow-up Workshop as described in Annex J. There are no financial implications for the Workshop itself.

7.2.2 Develop recommendations regarding use of market based approaches in an RMP context

A preliminary analysis of concordance between labelling and genetic identification of whale products on the Japanese market was presented. This had been conducted following a recommendation by the initial Workshop. The Committee welcomed the preliminary analysis and looks forward to further data at next year's meeting. It was noted that the presented breakdown by species of concordance between labels and genetic analysis would allow these data to be incorporated in simulation trials to test the extent to which product selection based on labelling might assist with market survey design. Mae stated that enforcement of food labelling regulations was the responsibility of the Government of Japan. However, the food labelling regulations were primarily designed for consumer protection and thus had not been introduced for the purpose of estimating bycatch.

SC/57/NMP6 provided an estimate of the proportion of J- and O-type common minke whale products purchased on Japanese markets from December 1997 to February 2004, using mixed-stock analyses. This approach was presented as an alternative to the capture-recapture analysis described in SC/57/BC5 (see below), for the purposes of estimating bycatch from market surveys. The authors concluded that if market proportions are also influenced by incidental takes of O-stock common minke whales, as assumed in past RMP simulations, then the estimated total bycatch would have to be several times larger than the scientific hunt to explain the observed market proportions.

In discussion in the Working Group, it was noted that previous analyses had demonstrated that some haplotypes (around 8%) are shared by whales in the Sea of Japan and Pacific Ocean and that the results of statistical tests would

have been affected depending on whether these haplotypes were assumed to be J or O stock. The authors noted that the mixed-stock analysis used in SC/57/NMP6 is not biased by the existence of shared haplotypes but the precision of estimates is affected. Kim reiterated concerns about interpretations of population structure based on market samples where the locality and timing of origin was not known.

SC/57/BC5 used a series of market surveys in Korea to make inferences on the numbers of common minke whales entering the market, based on an updated genetic capture-recapture analysis from last year. This update avoided problems associated with multiple samples of meat from the same shop. The results yielded estimates of total supply for the five-year period 1999-2003 of 679 (SE=241) common minke whales using between-survey recaptures only, and 827 (SE=164) using both within- and between-survey recaptures. Although the standard errors of these estimates were relatively high, the authors noted that estimates of the number of individuals entering the market were significantly higher than the reported bycatch figure for this period.

Kim reiterated his concern over the uncertainty surrounding these estimates and therefore any implications from them.

The Government of Japan has conducted its own market research that started in 1995 when approximately 50 samples were collected. Subsequently, market surveys of around 600 samples a year have been conducted since 1999, including species identification and some individual identification. Mae drew attention to the position of Japan on these issues and noted that Japan would not be prepared to submit information from DNA registers for comparison with market samples. Kim reported that the Government of Korea had also conducted market surveys since 2003, but no decision had yet been made as to what data would be made available.

Some members noted that although market sampling techniques showed potential, further progress was unlikely to be made without the co-operation of national governments with respect to use of their DNA registers. Others referred to the results in SC/57/BC5 that had been obtained without access to such data that the precision of these methods would improve with increased sample sizes. Nevertheless, the Committee agrees that the power of the approach and the efficiency of market surveys would be improved considerably with collaboration with DNA registers. Access to diagnostic DNA registers would also reduce the need to understand market structure, although it is still necessary to understand the different pathways that products from reported and unreported sources might follow.

The Committee **agrees** that all the approaches to market sampling under discussion would be most effective if conducted with collaboration from national governments with respect to data from DNA registers. It respectfully requests such co-operation, although it recognises the political sensitivity of market related issues in an IWC context. The planned follow-up Workshop is intended to allow further discussion of data sharing and collaboration on methodology and all members are encouraged to participate.

7.3 Empirical analysis of the functional relationships between bycatch levels, fishing effort and population abundance

SC/57/NPM7 suggested methodology for the assessment of the J stock of North Pacific common minke whales. An integral component of the approach was the estimation of bycatch for years for which this information is not available. This was based on the assumption that the expectation for bycatch each year was proportional to the product of the population size with an annual index of effort of fixed-gear fisheries in which bycatches occur (effectively that bycatch-per-unit-effort is proportional to population size). The Bayesian structure of the model allowed for variation of bycatch about the level predicted by this model to be taken into account.

Kim presented data on fishing effort of stationary gear which consists of set, fyke and pound nets along the eastern coast of Korea. These data did not include gillnets and account for around 34% of the common minke whale bycatch along the east coast of Korea reported to the IWC.

The Committee notes that there is a need for a better understanding of the nature of bycatch in order to assess the reliability of the assumptions related to bycatch rates such as those used in SC/57/NMP7. This needs to include temporal and spatial information on the distribution of different types of gear as well as data on the seasonal and geographical distribution of bycatch. Soh indicated that the Korean authorities could consider collaboration on this work in a balanced way.

7.4 Information on and methods for estimation of cetacean mortality caused by vessel strikes

SC/57/BC1 presented two case studies of lethal collisions with large container ships involving a Bryde's whale in Ecuador and a sei whale off West Africa. Other information on ship strikes in the southeast Pacific and the eastern tropical Atlantic was reviewed. Unless whales become wrapped around the bow and are inadvertently taken into port, whale collisions with large ships often go unnoticed by crew members. Under-reporting of ship strikes is compounded by the absence of obligatory reporting, a deficiency in awareness of ship strikes and the lack of systematic necropsies of beached whale carcasses. The author noted that detailed examination of carcasses could assist in estimating the probability that a whale struck by a vessel would become draped on the bow.

The Committee agrees on the need to improve awareness of vessel strikes and reporting systems in order to gather more data. Concerns were expressed that in some countries, such as the USA, the penalty system may act as a deterrent to reporting of ship strikes. Matilla noted that the Hawaiian National Marine Sanctuary authorities were investigating systems for anonymous reporting of ship strikes. A recent US workshop on vessel collisions has been held and the report is available⁴.

SC/57/WW8 reviewed collisions between whale-watching boats and whales. Collisions that either killed animals or caused serious injuries were more frequent with larger vessels, especially those travelling at speeds higher than 18 knots. In order to assess the risks to whales, information on the extent of the industries and the size and

speed of the vessels involved would be helpful. This information could be collected in co-operation with the sub-committee on whalewatching. Many of the reported collisions occurred while whalewatching vessels were in transit and these data could be used to estimate likely collision rates for other vessels of similar size that regularly transit through whale habitats.

As in previous years, the Committee reviewed the information on ship strikes presented in national progress reports. It was noted that for at least one of these reports, the carcass involved had shown no external marks and it was only when it was flensed to the bone that the shattered skull revealed evidence of a collision with a ship. This further emphasised that flensing to the bone is often necessary in order to reveal that a stranded whale has been killed by ship strike. In Korea, a genetic sample of tissue left on the propeller of a vessel involved in a collision had been analysed and found to be from a common minke whale. It was noted that such analysis was a useful method for obtaining data on collisions with vessels.

ACCOBAMS is planning a Workshop on ship strikes, to be held in Monaco in November 2005. One reason for the Workshop had been the recognition of the threat to fin whales in the Mediterranean from vessel strikes. Panigada confirmed that he would be attending the Workshop and that the Workshop would also be addressing the question of how to estimate the number of whales involved in collisions with vessels. He also agreed to present the report of the Workshop to the Committee at next year's meeting. ASCOBANS is also collecting data on high-speed ferries within the region covered by the agreement. Kock agreed to contact ASCOBANS to find out the status of these investigations and report back any relevant information to the Committee.

7.5 Information on and methods for estimation of cetacean mortality caused by other human activities

At the 2004 meeting, the Committee had agreed that consideration of possible mortalities due to acoustic sources should be closely co-ordinated with the Standing Working Group (SWG) on environmental concerns. Although some data on the effect of seismic surveys on cetaceans had been presented at this year's meeting, there were no reports of mortalities.

7.6 Work plan

The work plan agreed by the Working Group on estimation of bycatch and other human-induced mortality is given as Annex J (item 10). The Committee's overall work plan is discussed under Item 19.

8. ABORIGINAL SUBSISTENCE WHALING MANAGEMENT PROCEDURE AND STOCK ASSESSMENT (SEE ANNEX E)

This Item continues to be discussed as a result of Resolution 1994-4 of the Commission (IWC, 1995). The report of the SWG on the Development of an aboriginal whaling management procedure (AWMP) is given as Annex E. The Committee's deliberations, as reported below, are largely a summary of that Annex, and the interested reader is referred to it for a more detailed discussion. Last year (IWC, 2005a), the Committee presented the Commission with its recommended *Gray Whale Strike Limit Algorithm (Gray Whale SLA)*. The Commission endorsed the *Gray Whale*

⁴ http://hawaiihumpbackwhale.noaa.gov/special_offerings/sp_off/Vessel_collision_wkshp.html.

SLA (IWC, 2005a, pp.10-11), which will now be used to provide management advice on eastern North Pacific gray whales (see Item 9.2). The primary issues at this year's meeting comprised:

- (1) all aspects of the management of Greenlandic fisheries for common minke and fin whales;
- (2) preparations for an *Implementation Review* for the bowhead whale; and
- (3) management advice for the humpback whale fishery of St. Vincent and The Grenadines.

8.1 Greenlandic fisheries and the Greenland Research Programme

The urgent need for a Greenland Research Programme had been first identified in 1998. This is primarily due to the lack of recent abundance estimates and the poor knowledge of stock structure (IWC, 2004c, p.191). The Committee had informed the Commission that it would be extremely difficult, if not impossible, to develop an *SLA* for the Greenlandic fisheries that will satisfy all of the Commission's objectives. This is particularly important in the light of the Committee's grave concern at its inability to provide management advice for these fisheries (e.g. IWC, 2004c, p.191).

8.1.1 Stock structure, range and movement

8.1.1.1 GENETIC INFORMATION

The main questions for both common minke whales and fin whales off West Greenland revolve around how the abundance estimates derived from sightings made during surveys relate to the true number of animals 'available' to the hunters. It has been generally accepted for both species that the animals found off West Greenland probably do not comprise the total stocks (e.g. see review in Donovan, 1991; Born, 1999; IWC, 2000c). However, there is no information on the extent of these total stocks.

The Committee welcomed the report of the simulation studies funded last year (see Annex E, item 2.1.1 for a full discussion of this work). The Committee **agrees** that the currently available data have low power to reject any West Greenland samples as belonging to the putative West Greenland population (Annex E, Appendix 2). The SWG discussions developed into a broader examination as to how genetic studies may help it in its work.

The Committee **agrees** that the most valuable contribution genetic methods can make is if they can provide a lower bound for the size of the West Greenland common minke whale population (or rather the population or populations potentially available to be hunted in West Greenland), which can then be compared with estimates from sightings surveys and lower bounds from population models where total abundance may be estimated from the sex ratio of the hunt (see Annex E, item 3.1). Such genetic estimates would provide independent estimates of abundance (which would be valuable even if only a lower bound can be estimated).

The Committee therefore **recommends** that an assessment of the statistical power of various genetic approaches to estimate abundance be conducted interessionally. Palsbøll, Skaug and Waples agreed to undertake this for four different approaches (Annex E, table 1) that use genetic data to infer abundance (either census population size or effective population size) given a realistic range of sample sizes, genetic markers and abundance

estimates. Details are given in Annex E (Appendix 3) and the financial implications are discussed under Item 21.

The Committee then reviewed the available information on West Greenland fin whales (e.g. see SC/57/PF14; Bérubé *et al.*, 1998). Although there is a reasonable amount of genetic information available from the North Atlantic, at present it is insufficient to determine whether the animals found off West Greenland comprise the total population or are part of a larger population.

8.1.1.2 CATCH DISTRIBUTIONS

Information on the distribution of catches of fin and common minke whales for the period 1990 to 2004 was reviewed (SC/57/AWMP10). Takes appeared to be clumped in the vicinity of the larger communities, although this was more evident for fin whales, with three major groupings (northern, central and southern), than common minke whales which showed more groups with less clear boundaries. Catches were generally in inshore waters for both species although in the central area fin whales were also caught offshore. For fin whales, there appeared to be more catches early in the year in the northernmost group; for common minke whales, the catch season was shorter further north. Overall there was some indication that the sex ratio of caught common minke whales changed slightly with latitude, with a higher proportion of males further north. Overall, the sex ratio for the common minke whale catch in West Greenland was constant over the period from 1990-2004 at about 76% female⁵.

The Committee **agrees** that the results in SC/57/AWMP10 do not suggest marked differences in the sex ratio of the catch along the west coast of Greenland, although there is some evidence that it differs among communities. The question of the use of the sex ratio data in population assessment is discussed further below (see Item 8.2.2).

8.1.2 Abundance and trends

8.1.2.1 METHODS

The Committee received an analysis of the results of the photographic aerial strip-transect surveys carried out in 2002 and 2004 (and the experimental survey carried out in 2003). A considerable amount of time was spent by the SWG in discussing the methods used to read the photographs and analyse the results to arrive at population estimates. These detailed discussions can be found in Annex E (item 2.1.2).

One key feature of the analyses is the determination of the average time animals are visible at the surface. The SWG examined the approach given in SC/57/AWMP1 and modified the analysis as shown in Annex E (Appendix 4). The Committee **agrees** with the revised estimated average time of 6.9 seconds ($CV=0.052$), whilst noticing that this is probably slightly negatively biased.

There was considerable discussion in the SWG about the process used to examine the photographs from both the experimental survey in Faxaflói, Iceland⁶ and from the surveys themselves⁷ (see Annex E, Appendix 5 and the discussion of SC/57/AWMP2 in that Annex). The

⁵ Sex data first became available in 1955, although in many years there were relatively high proportions of animals of unknown sex recorded. Over the period 1955-2004, the percentage of females in the catch (excluding animals of unknown sex) has almost always been over 60% with an overall (simple) average of about 72% (from data in Appendix 7).

⁶ Some 22,000 photographs.

⁷ Some 73,700 photographs.

Committee identified a number of issues with the process as described in SC/57/AWMP2 and 3 that it believed must be improved before it could consider the results from the photographic surveys acceptable from a methodological viewpoint. To this end, it developed the protocol for the examination of the photographs given in Annex E, Appendix 5. This is discussed further below.

8.1.2.2 SURVEY RESULTS

SC/57/AWMP3 described the results from an aerial digital photo-based strip-transect survey for marine mammals off West Greenland that was carried out over a total of 4.5 months in the late summers and autumns of 2002 and 2004. About 3.7% of the area was covered by images taken at sea state three or less. Photographs of two common minke whales and seven fin whales were found (other species were also seen). The author presented uncorrected estimates of animals at the surface of 46 ($CV=0.74$) common minke whales and 250 ($CV=0.48$) fin whales. He applied corrections for whales missed by observers and for animals not at the surface to arrive at an estimate of 510 ($CV=0.75$) common minke whales, which is significantly smaller than the revised estimate of 6,390 ($CV=0.41$) whales in 1993 (Hedley *et al.*, 1997). He corrected the fin whale estimate for animals not at the surface and obtained an estimate of 980 ($CV=0.48$) whales, which is similar to the estimate of 1,100 (95% CI 520-2,100) whales in 1987-88 (IWC, 1992, pp.595-644).

The Committee did not consider these estimates acceptable for a number of reasons related to both the examination of the photographs and the appropriateness of the correction factors applied.

As noted above, a protocol was developed for examination of the photographs. The Committee noted that whilst following the protocol will give more confidence in the number of whales identified on the images and the estimate of the area covered by the photographs, unless there are appreciably more sightings, in particular of common minke whales, any abundance estimates based on only a few more identified whale images on the photographs would constitute enormous extrapolations and probably be considered unacceptable. It noted that given the different sizes of common minke and fin whales, it believed that the problem of readers missing whales was greater for common minke whales. This is discussed further under Item 8.2.3.2.

The Committee also reviewed the surfacing rate estimate used to correct abundance estimates for West Greenland common minke whales both with respect to photographic and cue-counting surveys. SC/57/AWMP3 had used the value of 53 surfacings hour⁻¹ with no associated variance used previously by the Committee and in conformity with corrections previously applied to visual aerial surveys. Details of the review are given in Annex E (item 2.1.2.2 and Appendix 6). The SWG had discussed whether estimates of surfacing rates should be based on data only for the area to which they will be applied. There was general agreement that this was the case, providing sufficient data are available. However, it was noted that when there are few data, there is great value in using comparable data for other areas. In its review, there was considerable discussion as to the appropriate way to quantify uncertainty from quite different studies.

The Committee **recommends** that if possible, the original data on which the preliminary estimate given in Annex E is based (and any other data on surfacing rates for

common minke whales in the Northern Hemisphere) should be obtained and re-analysed to determine the various components of variance and hence the most appropriate measure of variance of surfacing rate to be used when estimating abundance. The SWG had not had time to thoroughly review the basis for the estimated correction factor used in SC/57/AWMP3 for fin whales. The Committee also **recommends** that this be reviewed, updated and re-analysed as possible. An intersessional Working Group under Kingsley was established with a view to providing the SWG with appropriate estimates (including variance) for both species at the next annual meeting.

While the Committee has identified a number of problems with these particular surveys, it **agrees** that if these can be overcome, in principle the photographic strip-transect method has potential value and can avoid several difficulties associated with visual surveys.

8.1.3 Preliminary consideration of management procedures

The Committee was pleased to receive a paper (SC/57/AWMP6) that outlines a multi-stock age- and sex-structured population dynamics model that allows for dispersal among putative populations. This model could form the basis of an operating model to evaluate candidate *SLAs* for common minke whales off West Greenland and hence explicitly models regions other than West Greenland. Further details are given in Annex E (item 2.2). This is somewhat different from SC/57/AWMP4 that has no explicit geographical structure but attempts to estimate the fraction of the West Greenland stock that is found in a larger area than just West Greenland using the sex ratio in the catches.

The Committee **agrees** that these papers will prove valuable in its attempt to develop an *SLA* for the Greenlandic fisheries.

8.2 Annual review of catch data and management advice for common minke and fin whales off Greenland

8.2.1 Catches

SC/57/AWMP4, 5 and 10 presented information on catches and the complete catch history is given in Annex E (Appendix 7). Catches of common minke whales from West Greenland in 2004 were 44 males, 129 females and two of unknown sex (four additional animals were struck and lost). Catches of fin whales were five males and six females (two additional animals were struck and lost). In 2003 the equivalent catches were 58 males, 117 females (seven additional animals struck and lost) for common minke whales and two males, four females (two additional animals were struck and lost) for fin whales.

8.2.2 Assessments

Two Bayesian assessment papers were presented. SC/57/AWMP4 provided a Bayesian assessment for the common minke whale stock of the West Greenland fishery. The primary feature used in this assessment was the fact that the fraction of females in the West Greenland catch has remained around 0.72 since the beginning of the hunt in 1948. This fraction is incompatible with abundance estimates from aerial surveys if West Greenland common minke whales comprise a single stock. More details of the analysis can be found in Annex E (item 3.2). The author estimated an equilibrium abundance of 17,500 (95% CI=13,700-21,800) individuals, a current depletion of 0.92 (95% CI=0.79-0.96), and an *MSYR* of 0.09 (95% CI=0.04-

0.10). He concluded that while there was no evidence that a West Greenland harvest at current levels poses a threat to the overall stock, the proposed assessment will not necessarily identify local depletion in West Greenland.

SC/57/AWMP5 provided a Bayesian assessment for West Greenland fin whales, using the historical catches and three abundance estimates from 1988 to 2003 in an age- and sex-structured population dynamics model. The model assumes density-regulated dynamics, and a population in dynamic equilibrium in 1922. It projects the population from 1922 to 2015 under the influence of the historical catches. Again, details of the analysis can be found in Annex E. The author estimated production in 2005 to be 12 (CI=11-17) and 2005 abundance to be close to equilibrium population size with depletion estimated to be 0.96 (CI=0.43-0.99).

The SWG also examined the results of some preliminary work carried out using a Schaeffer model. The results for common minke whales suggest that the estimates of stock status are highly sensitive to assumptions regarding the *CV* for the 2003 abundance estimate. The results for fin whales suggest that the data are uninformative about key model outputs such as the *MSYR*, current depletion and current replacement yield, and that Bayesian analyses for fin whales are very sensitive to the priors selected for the parameters of the model, particularly that specified for the extent of additional variance.

In reviewing the assessment work, the SWG made the following observations.

- (1) The results of the Bayesian analyses are very sensitive to choices of priors, specifically the upper bounds for the priors for *MSYR* and the extent of additional variance for the survey estimates of abundance.
- (2) The high values for the extent of additional variance imply that the model assigns little weight to the estimates of abundance. The results are therefore determined primarily by the assumed prior distributions and in the case of SC/57/AWMP4, the sex ratio data.
- (3) The realised priors for some model parameters in Bayesian analyses differ substantially from the specified priors owing to the impact of the constraints imposed by the model structure. The low information content of the data implies that these constraints are the key reason why the posteriors for some parameters such as *MSYR* differ from the specified priors.
- (4) The approach used in SC/57/AWMP4 to make use of the data on the sex ratio of the catch has the potential to determine a lower bound for the abundance of the total stock (rather than just that component that feeds off West Greenland). However, at present, the fits to the data on sex ratio are poor.
- (5) The penalty imposed on equilibrium abundance in SC/57/AWMP4 is highly influential, including on the lower bound of equilibrium abundance and *MSYR*, but the tuning levels are essentially arbitrary.
- (6) The production model assessments assume that the estimates of abundance pertain to absolute population size although this assumption is likely to be invalid to some (possibly substantial) extent.
- (7) In the case of the fin whale assessment, the fits to the data on 1+ abundance are poor.

The Committee recognised the considerable effort expended by the authors in attempting to provide assessments for common minke and fin whales off West Greenland.

However, it **agrees** that in the light of the observations listed above, none of the preliminary assessments can be used as the basis for management advice. It recalled the difficulty it had last year when it noted that it had advised that in the absence of an agreed abundance estimate for fin whales from the 2004 survey, it would likely recommend that the take of fin whales of West Greenland be reduced or eliminated. Some commented that under such circumstances and given the discussion under the abundance estimates, consideration should be given to suggesting that the fin whale catch be eliminated until an agreed abundance estimate is reached. This was taken into account in the discussion of management advice given below.

The Committee also **agrees** that the sex-ratio data should be incorporated into future attempts at assessments because they can in principle provide information about the lower bound for the total abundance of the stock. However, any assessment based on these data must examine the sensitivity of the results to assumptions associated with their inclusion. An intersessional Working Group (Annex P(5)) was established to develop and undertake appropriate analyses related to the inclusion of sex ratio data in assessments and hence to determining a lower bound for the abundance of the stock as soon as possible. The group should also consider similar issues for fin whales.

The Committee noted that use of such data depends critically on whether hunters are able to correctly determine sex of caught animals. It was informed that although there may be some errors when assigning sex to the catch, estimates of sex ratio by hunters and biologists are similar when comparisons have been made. The Committee **recommends** that if sex ratio data are to be used as the basis of assessments/management advice or for a future *SLA*, genetic methods should be used to confirm sex.

8.2.3 Management advice

8.2.3.1 INTRODUCTION

As it has stated on many occasions, the Committee has never been able to provide satisfactory management advice for either the fin or common minke whales off West Greenland. This reflects the lack of information on stock structure and abundance, and the absence of appropriate assessments. This is the reason the Committee first called for the Greenland Research Programme in 1998.

Despite receiving preliminary estimates of abundance from photographic surveys carried out in 2002 and 2004, the Committee **agrees** that, once again, it is in the deeply unfortunate position of being unable to provide satisfactory management advice on safe catch limits; **it views this as a matter of great concern**. The present uncertainties over the preliminary abundance estimates are such that the Committee does not consider them acceptable estimates. Although it has suggested further work with respect to the data collected on the photographic surveys, it cautions that there is no guarantee that this further work will result in significantly greater values, or, in the case of common minke whales, an agreed estimate. It notes that the Commission has set catch limits for the West Greenland fisheries of up to 175 common minke whales struck in each year for the period 2003-2007 with a provision that up to 15 strikes may be carried over from one year to the next and a catch of up to 19 fin whales for the same period.

8.2.3.2 COMMON MINKE WHALES

Taken at face value, the preliminary (and not accepted) estimate of abundance for common minke whales suggests

that about a 90% decline has occurred since the previous survey in 1993. However, the Committee has considerable doubts over this estimate (see Annex E, item 2.1.2.1) and there are several indications that such a decline has probably not occurred (e.g. the consistently high predominance of females in the catch suggests that the abundance estimate does not represent the total number of animals available to the fishery). Nonetheless, the Committee urges that considerable caution be exercised in setting catch limits for this fishery because it has no scientific basis for providing advice on safe catch limits. It noted that if an Aboriginal Subsistence Whaling Scheme (AWS) (see Item 8.5) was in place, this fishery would be at or near the place where the grace period would begin. This management advice will be re-evaluated next year in the light of the intersessional work recommended.

Given this, the Committee **strongly recommends** that a re-examination of the existing photographs be undertaken as a matter of urgency, according to the protocols given in Annex E, Appendix 5. **In conjunction with this, it strongly recommends** that preparations be made to carry out a cue-counting survey in the summer of 2006 targeted especially at common minke whales, so that if the intersessional group overseeing the re-examination of the photographs concludes that this will not result in an acceptable estimate, a survey can be carried out. The Committee recognises that the prevailing weather conditions in Greenland mean that there is no guarantee that a survey will result in sufficient coverage to allow an abundance estimate to be obtained in any one survey.

The Committee also **strongly recommends** that the sex ratio data be fully investigated *inter alia* to determine whether they can be used to obtain at least a minimum estimate for the total stock and be incorporated into an assessment model (see Item 8.2.2 above).

8.2.3.3 FIN WHALES

In 2004, the Committee had expressed special concern over the absence of an abundance estimate for fin whales since 1987/88 and had advised that in the absence of an agreed abundance estimate for fin whales from the 2004 survey, it would likely recommend that the take of fin whales off West Greenland be reduced or eliminated. This year the Committee had received a preliminary estimate (that was not considered acceptable, see Item 8.1.2.2 and the recommendation for reanalysis of the photographs given above) from the photographic surveys that was not appreciably different from the previously accepted estimate. Despite the fact that the Committee has more confidence in this preliminary estimate than it has for the common minke whale estimate (see above), it is not in a position to provide satisfactory management advice on safe catch limits. It therefore **urges that considerable caution be exercised in setting catch limits for this fishery**. Mindful of its recommendation of 2004 (see above), as interim *ad hoc* advice, the Committee advises that a take of 4-10 animals (approximately 1% of the lower 5th percentile and of the mean of the estimate of abundance) annually was unlikely to harm the stock in the short-term, particularly since this does not take into account the possibility that the fin whale stock extends beyond West Greenland (see Item 8.1). This advice will be re-evaluated next year in the light of the intersessional work recommended.

8.2.3.4 OTHER RESEARCH RECOMMENDATIONS

Last year, the Committee repeated its strong recommendation that samples for genetic analysis be collected from the catch as a matter of high priority and urged the Committee to encourage the Government of Denmark and the Greenland Home Rule authorities to assist with logistical and, if necessary, financial support. The Committee **repeats** its recommendation this year. It was pleased to be informed that 103 common minke whale samples, 8 fin whale samples and 4 samples of unreported species had been collected last year. The Committee **strongly recommends** that these samples be analysed in accordance with the advice of the intersessional Working Group on genetics.

The Committee **reiterates its great concern** at its continued lack of ability to provide management advice on these stocks, with serious implications for both the hunt and for the stocks involved. It **strongly urges** the relevant authorities to provide the necessary funds to allow all of the research recommendations given under Item 8.2 to be carried out. Should the necessary funding not be put in place to allow both (1) a re-examination of the photographs and (2) a cue-counting survey to occur if recommended by the Steering Group, it **agrees** that priority should be given to carrying out the survey.

8.3 Annual review of catch data and management advice for humpback whales off St. Vincent and The Grenadines

In recent years, the Committee has examined the stock structure of humpback whales in the North Atlantic in the context of the fishery of St. Vincent and the Grenadines. It has stated that the most plausible hypothesis is that the whales from St. Vincent and the Grenadines are part of the West Indies breeding population, numbering around 10,750 animals in 1992, but has encouraged the collection of additional data. This year, two papers were received providing more consideration of stock structure in this area.

SC/57/AWMP9 provided an update on a new assessment of North Atlantic humpback whales. A total of 3,615 biopsy samples were collected. The sample processing and data analysis should be completed in time for high-precision estimates of abundance to be available by 2007. The paper also hypothesised that the demographic population structure of this stock is probably complex, with whales from more than one feeding ground perhaps sharing the same winter breeding ground, or separate but uncertain breeding grounds.

The Committee was pleased to receive this report and expresses its continuing support for this programme.

SC/57/AWMP7 reported that one humpback whale landed at St. Vincent and the Grenadines in 1999 was matched to a specific catalogued individual photographed in the Gulf of Maine. This is the first direct stock assignment from this fishery and the most southeasterly sighting of a Gulf of Maine humpback whale. Based on its length, the authors believed that the second animal landed at the same time was probably a calf and, if so, a member of the same population.

The Committee welcomed this paper, noting that this strong additional information to that considered previously, strongly suggests that the animals found off St. Vincent and The Grenadines are part of the West Indies population.

The Committee also welcomed the updated report on catches submitted to the Secretariat. In 2004, there were no whales taken. In February 2005 there was a single male humpback whale taken, measuring 35ft in length.

The Commission has adopted a total block catch limit of 20 for the period 2003-07. The Committee agrees that particularly given the new information presented this year in SC/57/AWMP7, this catch limit will not harm the stock. The Committee also **repeats its recommendations** of previous years that wherever possible photographs and genetic material are collected from the catch. It was pleased to hear that two photographs (one from the 2003 catch and one from the 2005 catch) have been obtained and that arrangements will be made to send the photographs to the North Atlantic catalogue.

8.4 Planning for a bowhead whale *Implementation Review* in 2007

The Committee discussed planning for the 2007 *Implementation Review* for the Bering-Chukchi-Beaufort (B-C-B) Seas bowhead whales (*B. mysticetus*). The purpose of an *Implementation Review* is to determine whether any new information that has become available indicates that the present situation is outside the region of parameter space tested during *SLA* development. If this is the case, additional trials will be developed to test the performance of the *SLA* in this new region. If performance is found to be unacceptable under these new trials, revisions to the *SLA* will be required. In the case of the bowhead whale, a variety of new hypotheses concerning genetic population structure have been developed that have implications for management. Although there is little firm basis yet for assessing the plausibility of these hypotheses (see Item 9.1), they represent an untested region of parameter space. There is no new evidence that any other biological or demographic factors lie outside the region previously tested. The questions regarding stock substructure have stimulated considerable relevant research and analyses are expected to be completed in time for formulating management advice in 2007. Therefore, the Committee **agrees** to aim to complete the *Implementation Review* at the 2007 meeting whilst recognising that this did not preclude delaying completion to 2008 or later if circumstances warranted.

The Committee **agrees** to the following approximate timeline (more details are given in Annex E, item 4).

- (1) *First intersessional Workshop*. This meeting will be held in or around March 2006. Its task will be to specify the basic structure and types of simulation trials needed for the *Implementation Review*. This meeting will also initiate discussions on the ranges of parameter values to be tested, but not the specific choices.
- (2) *2006 Annual Meeting*. This meeting will review progress on trial design and coding. It seems appropriate that the stock structure discussions should occur in joint sessions of the AWMP and the BRG sub-committees, with this leading to a refinement of the trial structure and parameter value ranges.
- (3) *Second intersessional Workshop*. This meeting will be held in or around October 2006. Coding of the trials must be completed before this Workshop. The purpose of this meeting is to review the coding of trials and their behaviour within the agreed parameter ranges. The Workshop will finalise trial structure.

- (4) *Data availability*. In accordance with the Committee's Data Availability Agreement (DAA), all data relevant to management advice for the 2007 meeting should normally be submitted 6 months in advance of that meeting (i.e. probably in December 2006). However, given the collaborative nature of the analyses being undertaken, the Committee **agrees** that provided all collaborators concur, consideration should be given to allowing an extension to this deadline should it be required.
- (5) *Third intersessional Workshop*. This meeting will be held in or around March 2007. The purpose of the workshop is to select specific parameter values for the designed trials, after confirming that the trial structure and coding revisions are satisfactory. After this meeting, the trials will be run by the Secretariat in advance of the 2007 Annual Meeting.
- (6) *2007 Annual Meeting*. The primary task at this meeting will be to assess the relative plausibility of the trials chosen, examine the trial results, and evaluate continued management under the *Bowhead SLA*. If the Committee determines that the completed review indicates unsatisfactory performance of the *Bowhead SLA*, it will develop a workplan for its revision.

This timeline cannot be met without the imposition of certain deadlines. The Committee **agrees** that the trial structure and parameter ranges will be based only on evidence available at or before the 2006 Annual Meeting. Furthermore, the Committee **agrees** that choices for parameter values and trial plausibility judgments shall be based upon only the data available in advance of the 2007 Annual Meeting (see point 4 above). Decisions will be based on evidence that meets these deadlines. If new evidence becomes available subsequent to the applicable deadline, it shall not be used for the present *Implementation Review* unless completion of the *Implementation Review* is postponed to 2008 or later.

The financial implications of this plan are discussed under Item 21.

8.5 Scientific aspects of an Aboriginal Subsistence Whaling Scheme

In 2002, the SWG developed scientific aspects of an AWS intended for use in conjunction with the *Bowhead SLA* (IWC, 2003b, pp.154-5). These proposals were agreed by the Scientific Committee (IWC, 2003a, pp.19-23) and reported to the AWMP sub-committee of the Commission. At the 2003 and 2004 meetings, the Chair of the SWG discussed such matters with interested commissioners and representatives of the hunters. The Commission has not yet adopted the AWS and in particular the USA has expressed some concerns (IWC, 2005a, p.13). There was some discussion of this item by the SWG (Annex E, item 5).

The Committee again **recommends** the scientific components of an AWS to the Commission, noting that it forms an integral part of the long-term use of *SLAs*.

8.6 Work plan

The Committee **agrees** that the items below should be given priority during the intersessional period.

8.6.1 Greenland

- (1) The photographs from the 2002 and 2004 surveys should be re-examined and advice be provided

throughout the process (a) on whether a survey should be undertaken in summer 2006 (see below) and (b) to develop an agreed method to obtain acceptable abundance estimates from the data, if possible. An intersessional e-mail group to provide such advice was established (Annex P(3)).

- (2) The data on which the estimate of surfacing rate in Annex E, Appendix 4 is based (and any other data on surfacing rates for fin and common minke whales in the Northern Hemisphere) should be obtained and re-analysed to determine the various components of variance and hence the most appropriate measures of variance of surfacing rate when estimating abundance. An intersessional group to co-ordinate this was established (Annex P(4)).
- (3) Preparations should be made to carry out a cue-counting survey in summer 2006 (see Item 8.2). A final decision on whether to conduct the survey will be taken by the intersessional group established under (1) above.
- (4) The sex ratio data for common minke whales should be fully investigated *inter alia* to determine whether it can be used to obtain at least a minimum estimate for the total stock and be incorporated into an assessment model. An intersessional group to forward this work was established (Annex P(5)). This information should be provided to the intersessional group established under (1).
- (5) An assessment of the statistical power of various genetic approaches to estimate abundance (Annex E, Appendix 3) should be completed. This will be carried out by Palsbøll, Skaug and Waples. Financial implications are dealt with under Item 21.

8.6.2 Bowhead whales

To meet the goal of finishing the bowhead *Implementation Review* at the 2007 Annual Meeting, two Workshops will be required (see Item 8.4), one in the forthcoming intersessional period. The USA has offered to host that Workshop in either Seattle or La Jolla in or around March 2006. The Workshop will specify the basic structure and types of simulation trials needed for the *Implementation Review*.

There is also a considerable amount of Secretariat computing work involved (Allison primarily). Given the unknown nature of the final stock structure hypotheses, it is difficult to estimate accurately the amount of Secretariat time required for the *Implementation Review*. This could be up to 15 months for the entire process (i.e. to the end of the 2007 review); it may be up to eight months between the first and second intersessional Workshops. This needs to be taken into account in the overall Committee work plan (see Item 19).

8.6.3 Priority topics for the 2006 meeting

- (1) Review progress on the Greenlandic research programme (especially with respect to abundance, stock structure and the use of sex data in assessments) and attempt to provide management advice.
- (2) Review progress on and refine design of trial specifications and coding for bowhead whales.
- (3) Review information on the St. Vincent and The Grenadines fishery and provide management advice.

The Committee noted that this is a particularly heavy workload for the 2006 Annual Meeting. It notes that unless the SWG on the AWMP has a pre-meeting, it will require

considerably more sessions than normally allocated at an annual meeting. This is discussed further under Items 18 and 19.

9. ABORIGINAL SUBSISTENCE WHALING STOCK ASSESSMENTS ON BOWHEAD, RIGHT, AND GRAY WHALES (SEE ANNEX F)

9.1 Bering-Chukchi-Beaufort Seas bowhead whale stock identity

The Committee considered the results of a USA-sponsored Workshop on B-C-B bowhead whale stock structure held in Seattle, February 2005 (Anon., 2005). The Workshop considered five stock structure hypotheses:

- (1) the one-stock model presently accepted by the IWC;
- (2) one stock with generational gene shift (GGS);
- (3) two stocks with temporal segregation;
- (4) two stocks with spatial segregation; and
- (5) the two-stock Chukchi Circuit (CC) hypothesis.

The latter is a new hypothesis based on inference from Russian sighting and oceanographic data. It assumes a primary population that migrates from the eastern Bering Sea to the Beaufort Sea in spring, returns by a similar route in autumn, and is subject to harvest at Barrow in both seasons, with a second population that leaves the Bering Sea in late May and June and follows the Chukotka coast northward to the northern Chukchi and western Beaufort Seas. In this hypothetical scenario, the second population would be vulnerable to harvest at Barrow in autumn, but not during spring.

SC/57/BRG10 re-examined the 'Oslo bump', a significant increase in genetic difference between pairs of whales sampled approximately one week apart at the Barrow autumn migration versus those sampled at other time intervals (Jorde *et al.*, 2004). Genetic data from 117 Barrow whales were screened for quality and analysed in generalised additive models. Pair-wise comparisons detected no significant effects in the spring migration. In the autumn migration, there was a significantly elevated genetic difference in pairs of whales taken about a week apart in the hunt.

SC/57/BRG4 carried out an analysis that was parallel to SC/57/BRG10, but adjusted for whale ages in a manner that was argued to be more appropriate. It found a weaker pattern of elevated gene difference in pairs taken about a week apart, which was no longer statistically significant at the 5% level. SC/57/BRG4 also emphasised that the effects of whale ages and spatio-temporal whale positions during migration are highly confounded, making it difficult to isolate the genetic patterns associated with each. The paper concluded that it was premature to reject any major hypotheses until more and better data become available. The importance of additional samples was emphasised, as the detection of the 'Oslo bump' was based on only 54 samples from the autumn migration. Further, genetic structure might be the result of a combination of factors and so not entirely explained by a single proposed hypothesis.

The Committee **agrees** that the 'Oslo bump' appears to be a real feature of the limited available data. However, additional data are necessary to confirm whether this pattern reflects a real characteristic of the B-C-B bowhead population. No single explanation has emerged to explain the effect.

SC/57/BRG19 described the development of a new and expanded panel of microsatellite loci from bowhead whales. The goal of the work was to produce at least 25 loci from bowhead whales that are variable, reliable and can be consistently scored, even in samples that are not of optimal quality. Preliminary assessments of variability suggest that as many as 20 of an initial set of 33 possible loci might be suitable for use.

SC/57/BRG21 reported recent progress on B-C-B Seas bowhead whale stock structure research, as requested by the Scientific Committee during its 2004 meeting (Øien, 2004, pp.23-4). Research was directed towards testing proposed stock structure hypotheses. The Committee expressed its appreciation to the USA for its Seattle Workshop and research programme. However, some concerns were raised as to whether the working schedule would allow for new data to become available for review prior to the 2006 meeting. If there is sufficient evidence against a single stock, then it will be important to identify the implications of that structure so that the new trial structure can assess the potential effects.

The Committee **agrees** that the focus of this extensive work programme should be to provide advice that is of direct relevance to the development, if necessary, of a revised trial structure for testing the *Bowhead SLA*.

SC/57/BRG16 provided an update on recent aerial photographic surveys of bowhead whales for photo-identification and photogrammetry. Surveys were conducted near Point Barrow, Alaska, during the spring migrations of 2003 and 2004. The photographs from these studies will provide a capture-recapture abundance estimate for comparison with the most recent estimate from ice-based counts, as well as more precise estimates of bowhead whale life-history parameters such as survival. A survey near St. Lawrence Island in the Bering Sea in 2005 was designed to photograph bowheads during the second half of the spring migration when most well marked medium- and large-sized whales are seen. The location was chosen to maximise the possibility of photographing whales from a Bering Sea stock that may not migrate past Point Barrow in spring, if such a stock exists.

SC/57/BRG17 described a preliminary characterisation of the external morphology of bowhead whales caught by Alaskan Eskimos. Such external morphometric data may be useful for stock structure investigations.

9.2 Catch data and management advice for the Bering-Chukchi-Beaufort Seas bowhead whale

9.2.1 Catch information

SC/57/BRG15 reported catch information for the 2004 Alaskan subsistence harvest. A total of 43 bowhead whales was struck resulting in 36 animals landed. The efficiency (the ratio of the number landed to the number struck) of the hunt was 84%, which is higher than the mean efficiency over the past 10 years (78%). Of the 36 whales, 13 were males, 22 were females and the sex was not determined for one whale. Of the 22 females, seven were presumably mature (>13.4m in length). Four of these were examined closely. Two were pregnant, one with an 11cm foetus and the other with a 409cm foetus, while the other two were not pregnant.

SC/57/BRG24 reported that one 12m male bowhead whale was taken as part of the Russian subsistence harvest in 2004. The weight of the animal was estimated at

30,400kg. The author confirmed that the length of the whale was exact, but that the weight was estimated from the amount of meat that was distributed. The Committee **recommends** that every effort be made to obtain genetic samples from Russian catches.

9.2.2 Management advice

The Committee **agrees** that the *Bowhead SLA* remains the most appropriate tool for providing management advice for this harvest, at least in the short-term. The results from the *Bowhead SLA* show that no change is needed to the current block quota for 2003-07.

The Committee also repeated last year's recommendation that an *Implementation Review* focusing on stock structure should be conducted with the goal of completing it at the 2007 annual meeting so that management advice at that meeting is based on the best science available then. The *Bowhead SLA* was developed and tested under a single-stock hypothesis. The review will examine the robustness of the *Bowhead SLA* with respect to plausible stock hypotheses via simulation trials. If shown to be necessary, this may result in changes to the *Bowhead SLA* (and see Item 8.4).

9.3 Catch data and management advice for the eastern North Pacific gray whale

9.3.1 Catch information

A total of 110 eastern North Pacific (ENP) gray whales (43 males and 67 females) were harvested by the native people of the Chukotka Autonomous Region in 2004 (SC/57/BRG24). Of the total, one gray whale was lost during towing and six exhibited a strong chemical (iodic) odour. The latter were not used for any purpose and tissue samples have been analysed to determine the cause. Harvested whales ranged in length from 8.0-14.0m (average 10.1m). The weight ranged from 6.0-23.0 tons (average 11.9 tons).

The Makah Indian Tribe was unable to conduct whaling on this stock in 2004 because of domestic litigation. A court ruled in 2004 that the Makah Indian Tribe needs a waiver of the US Marine Mammal Protection Act (MMPA). The Tribe applied for that waiver in February 2005.

SC/57/BRG6 was a preliminary report of the re-analysis of catch data from the Soviet aboriginal fishery of eastern Pacific gray whales from 1980-91. Data for this period have been summarised on an annual basis in previous reports to the Scientific Committee. However, SC/57/BRG6 re-analysed biological and technical parameters based on a large total sample of 520 females, 248 males and 89 foetuses. The Committee welcomed this report and **agrees** that this information should be considered at the next *Implementation Review*.

9.3.2 Management advice

Last year, the Commission endorsed the *Gray Whale SLA* for use in providing management advice. In this meeting, the Committee reaffirmed that the *Gray Whale SLA* remains the most appropriate tool for providing management advice for this harvest. The Secretariat has calculated strike limits for this stock given the agreed abundance estimate and catch history. The results show that no change to the current block quota is needed for 2003-07. An *Implementation Review* is scheduled for 2009.

9.4 Implications of the special pre-meeting on sea ice and whale habitat

SC/57/E13 and SC/57/E5 had been presented in the joint Workshop on high-latitude sea ice environments (SC/57/Rep5). Both papers addressed the potential effect of variability in sea ice cover on B-C-B bowhead whales and are summarised under Item 12.1.

Three important issues were identified in the Workshop:

- (1) the effect of loss of sea ice on the census of B-C-B bowhead whales (related to the loss of the shorefast ice platform from which the census is conducted and the potential opening of commercial shipping routes in the Arctic);
- (2) the possible importance of sea ice in structuring habitat for bowhead and gray whales either directly or indirectly through potential for competition between gray and bowhead whales and via the potential northward shift of other mysticete species (competition) and killer whales (predation); and
- (3) the best way to incorporate large whale research, specifically IWC-related work into the International Polar Year (IPY) and Second International Conference on Arctic Research Planning (ICARPII) programmes (see Item 12.1).

Overall, the Committee was encouraged that there had been no apparent negative effect of global warming on bowhead whales. However, they also found it difficult to predict how bowhead whales might be affected by large-scale oceanographic changes in the future. Several areas of concern were discussed, including thermoregulatory issues and increased exposure to killer whale predation, competition with other species, ship traffic, noise, pollution and fisheries interactions. In addition to potential impacts on the census, a reduction in sea ice would probably affect the logistics of the harvest.

9.5 Catches by non-member countries

There were no catches of bowhead whales in the eastern Canadian Arctic in 2004. The carcass of one juvenile bowhead whale washed ashore near Arctic Bay in 2004, apparently the victim of a killer whale attack (Cosens, pers. comm.).

9.6 Work plan

The following work plan was proposed for the coming year:

- (1) review new information on the stock structure of the B-C-B Seas stock of bowhead whales and on the progress of on-going research; and
- (2) perform the annual review of catch information and new scientific information for the B-C-B Seas stock of bowhead and ENP stock of gray whales in order to advise the Commission as requested in Schedule Paragraph 13(b)(1) and (2).

10. WHALE STOCKS

10.1 Southern Hemisphere Antarctic minke whales (see Annex G)

10.1.1 Estimate abundance of Antarctic minke whales

10.1.1.1 THE 2004/05 SOWER CRUISE

SC/57/IA1 presented the report of the 2004/05 SOWER cruise. This was the 27th annual Antarctic cruise and represented the start of a new phase of research following

the completion of the third circumpolar series of surveys (CPIII). The research region was in Area III (0°-70°E) and lasted 65 days. The Committee expressed its gratitude to the Government of Japan for providing the vessels to conduct the survey. It also thanked the officers and crew of the vessels, the Cruise Leader, Senior Scientist and the other researchers for their efforts to ensure a successful cruise. The main purpose of this cruise was to conduct experiments that address problems encountered with the analysis of or interpretation of previous IWC/SOWER cruises.

One such experiment was presented in SC/57/IA7, which is a report of the collaborative studies with the Japanese icebreaker, *Shirase*. The SOWER vessels surveyed for Antarctic minke whales in the near-ice area (35°-50°E) while the *Shirase* surveyed in the pack ice zone (40°-50°E). The Committee thanked the Government of Japan and the Japanese Antarctic Research Expedition for conducting this study.

If the data from the SOWER and icebreaker cruises are to be used to estimate the proportion of Antarctic minke whales within the ice field that are not accessible to the IWC/SOWER survey vessels, care must be taken to account for the fact that the design and search effort for the two types of vessels were different.

Other experiments conducted on the SOWER cruise included Antarctic minke whale visual dive time trials, trials of the Buckland-Turnock (BT) survey method, trials of adaptive line transect sampling, and addressing effects of the CPII track design on the abundance estimates as compared to the CPIII track design. A direct electronic data acquisition program was also evaluated. The Committee considered that all the experiments had been useful.

Insufficient sea time had been available to properly evaluate the BT mode experiment. However, there was some concern expressed that the high-powered binoculars used for tracking in BT mode were difficult to use. The results from a BT mode experiment is an estimate of $g(0)$ that accounts for animal reactive behaviour, if any, that does not rely on assumptions of surfacing rates and patterns. Given the potential value of the BT mode experiment in assisting in interpreting previous results, the Committee **recommends** that the BT mode experiment be continued.

Practical aspects of the protocol of adaptive sampling were easily implemented but due to time constraints and the low density of animals when conducting these experiments, data collected were too limited to analyse. However, the Committee **agrees** that adaptive sampling is of greater benefit for species that are found in low densities (e.g. blue and fin whales).

Sufficient data had been collected during the dive-time experiments. The Committee **recommends** that these data be coded and analysed intersessionally by an intersessional Working Group (Annex (P14)).

The automatic data entry system was also found to be successful so the Committee **recommends** such a system be more fully developed and tested during the next cruise.

Good coverage was achieved for two-thirds of the study area of the experiment to investigate effects of the CPII track design on the abundance estimates but it is not clear whether this level of coverage is sufficient to try to compare the two designs, particularly given inter-annual variation.

10.1.1.2 RESULTS FROM SIMULATED DATA

Last year, the Committee identified four additional factors that could potentially reflect heterogeneity in the real International Decade of Cetacean Research/SOWER

(IDCR/SOWER) data and should be added to the already existing simulation scenarios. SC/57/IA2 outlined how these factors have been incorporated into the simulated data, which have been provided to the IWC Secretariat. These data were used to examine the robustness of some of the methods under development: the integrated model method by Cooke (2002); and the hazard probability model by Okamura (SC/57/IA4), as well as more established analysis methods, the standard method (SC/57/IA14) and the direct duplicate method (SC/57/IA15). For all these methods, the percentage relative bias of estimated density of whales was small. The integrated model and hazard probability model had the smallest biases; these tended to be positive. The standard and direct duplicate methods had larger biases that were negative. The Committee welcomes these encouraging results.

The highest priority task for next year is to produce estimates of Antarctic minke whale abundance and thus the Committee **agrees** that analysing the standard dataset of the actual IDCR/SOWER data should be given higher priority than analysing further simulated datasets. However, these estimates will need to be assessed on the basis of the performance of the methods obtained from the simulation study. The Committee established an intersessional email correspondence group (Annex P(10)) on analysis methods used to estimate abundance of Antarctic minke whales using IDCR/SOWER data. The group should further develop the list of factors that should be simulated and the combinations of these factors that should be used, taking into account of the high priority allocated to analysing the standard dataset. Factors to consider including in future simulations are: varying the sample sizes, reducing the value of $g(0)$, cue dependent detection functions combined with other factors, and varying amount of effort within the study area that may be correlated with weather conditions. See additional terms of reference for this correspondence group in Item 10.1.1.3.

10.1.1.3 RESULTS FROM CRUISE DATA

The 2003/04 SOWER cruise surveyed the eastern part of Area V including the Ross Sea. SC/57/IA11 presented estimates of Antarctic minke whale abundance using standard IWC methods (Branch and Butterworth, 2001). The mean school sizes in the northern, middle and Ross Sea strata were 1.13 ($CV=11.1\%$), 3.95 ($CV=12.2\%$) and 1.35 ($CV=7.0\%$), respectively. The abundance of Antarctic minke whales was estimated to be 77,120 ($CV=30.8\%$) for closing mode and 101,766 ($CV=23.3\%$) in independent observer (IO) mode. The combined estimate, having corrected for closing mode, was 98,522 ($CV=18.9\%$). An updated estimate of R (the factor used to convert closing mode estimates to pseudo-passing mode) was calculated. This value, including all data from 1998/99, was estimated to be 0.88.

The Committee noted that on the 2003/04 survey the mean school size and sighting rates were higher in the middle stratum than in the Ross Sea southern stratum, which was considered unusual. Several members suggested that the unusual distribution of larger schools could have been related to ice conditions. An examination of satellite derived ice motion was currently being undertaken by Ensor, Matsuoka and others in an attempt to identify the processes involved.

The Committee **recommends** that the relationship between abundance and distribution of Antarctic minke whales and the ice extent be examined using data from the

2002/03 and 2003/04 surveys, and those of JARPA, which covered similar areas.

SC/57/IA16 presented preliminary estimates of abundance for CPI, CPII and CPIII obtained using a slightly modified standard method (Branch and Butterworth, 2001). When results from closing mode and IO mode were combined, the circumpolar abundance estimates were 594,000 ($CV=12.8\%$), 769,000 ($CV=9.4\%$) and 362,000 ($CV=8.0\%$) for CPI, CPII and CPIII respectively. These estimates are negatively biased because some Antarctic minke whales may be north of 60°S , or inside the pack ice during the surveys and because some whales on the trackline were likely to have been missed. After simple extrapolation to account for differences in the latitudes surveyed during each circumpolar set (but not for increasing proportions of 'like minke' sightings), the ratio of the circumpolar estimates was 0.92:1.00:0.39, echoing previous preliminary findings of appreciably lower CPIII estimates. Estimates for each IWC Management Area also had low CPIII:CPII ratios (between 0.17 and 0.62), except for Area VI where the CPIII estimate was higher than in CPII.

SC/57/IA3 examined consistency over time of SOWER environmental covariates. It was clear that the method of determining 'visibility' has changed during CPII/CPIII, and a correction is necessary. Four simple ways were investigated, of which two were considered successful.

To facilitate the estimation of abundance using the CPI to CPIII data in the standard dataset, the Committee **recommends** that the intersessional email correspondence group on analysis methods (see Annex P(10)) assists the analysers (Branch, Bravington, Cooke, and Okamura) by developing what should be presented, what diagnostics are required and to create a set of rules, for example specifying how duplicates should be treated, how to pool the data, and other such data selection decisions. In addition, this group should determine diagnostics to ensure the comparability between DESS and the standard dataset.

10.1.1.4 ADDITIONAL VARIANCE

SC/57/IA5 presented the proposed statistical model for estimating additional variance, which is based on a combination of the methods in Punt *et al.* (1997) and Skaug *et al.* (2004). The performance of the additional variance estimation for IDCR/SOWER type surveys was investigated through simulation studies. The study found that estimates of the amount of random variation may be biased if the area-effects change systematically (and not randomly) between two circumpolar surveys.

The Committee **agrees** that consideration of the residuals over time might be used to assist in detecting spatial and temporal trends and the data from JARPA could possibly also be used to estimate additional variance. It also agrees that SC/57/IA5 was valuable and that the methods should be applied to the abundance estimates that will be presented at next year's meeting.

10.1.1.5 ESTIMATION OF ABUNDANCE USING JARPA DATA

SC/57/IA18 compared abundance estimates of JARPA survey data obtained using standard line transect methods and spatial modelling methods. Several vessels take part in the JARPA survey, where one vessel acts as a dedicated sighting vessel (SV) and the other vessels as sighting and sampling vessels (SSV). Vessels operate in closing mode, thus, in high-density areas effort is reduced. Standard line transect methods may be biased since effort is assumed to be located independent of density. The spatial model makes

no such assumption, but relies on good coverage throughout a study region. Results from four years of survey data in Area V were compared and found to be broadly similar.

It was suggested that combining all surveys together and including year as a factor might produce a more robust model. Concern was expressed that the variance of the sighting rate may be underestimated and that the moving ice edge could cause problems. It was also suggested that if this method was to be used in the future, the spatial model should be applied to simulated data to investigate the model's robustness.

Hakamada *et al.* (2005) investigated the effects of sampling activities, including 'skipping' (not covering the full daily distance planned in high density areas) and the use of closing mode, on abundance estimates when using data collected from SSV and SV. To correct for bias due to under-surveying high-density areas, the method developed by Haw (1991) was used. The consequent corrected abundance estimates averaged about 50,000 for Area IV and about 200,000 for Area V. No statistically significant change in abundance was detected.

In discussion, concern was expressed that the correction factors might change over time in response to variations in whale density and the extent of skipping. The most appropriate method of estimating variance in the sighting rate from the SSV was also discussed, as the SSV vessels surveyed relatively close to each other. The authors responded that they had checked for dependence of the correction factor on density and had not found any significant effect (Hakamada *et al.*, 2005). More details on these and other concerns, and responses to those are provided in Appendices 2 and 3 of Annex H.

10.1.2 Reasons for differences between Antarctic minke abundance estimates from CPII and CPIII

The Committee had planned to update the table on possible hypotheses explaining the differences between abundance estimates from CPII and CPIII (IWC, 2003d). However, there was insufficient time to complete this task. It is expected that updated abundance estimates from CPII and CPIII will be available next year and the Committee agrees to update the table after the abundance estimates become available.

10.1.2.1 IMPLICATIONS OF SEA ICE AND WHALE HABITAT

SC/57/IA6 used a GAM-based spatial model to account for environmental variables when estimating the abundance of Antarctic minke whales within a polynya present in Area II (0°E-60°EW). This analysis indicated that there appears to be a more complex response of the Antarctic minke whale distribution to environmental variables than what was believed before (e.g. high concentrations around the ice edge and decreasing towards the north). It was proposed that the oceanographic conditions associated with the Weddell Gyre in Area II could also be influencing the distribution of Antarctic minke whales instead of just sea surface temperature (SST) and sea ice extent as postulated by Kasamatsu *et al.* (1998).

Concerns were expressed about predicting density in a region outside the range of the observed data. The Committee suggested that this work be continued by including other environmental variables, if available, investigating the effects of using environmental variables alone, investigating the fit of the model by comparing the predicted patterns of abundance to the observed patterns of abundance in areas where there are data, considering

combining data from all years to develop the predictive model and developing estimates of variance for the extrapolated abundance estimate. In addition, it was noted that if this method is to be used in the future, its robustness should be investigated by applying it to simulated data. The Committee **encourages** further work on this difficult issue.

10.1.2.2 POPULATION DYNAMIC MODEL METHOD TO ESTIMATE TRENDS AND POSSIBLE DIFFERENCES

10.1.2.2.1 REPORT FROM INTERSESSIONAL WORKING GROUP

At its 2002 meeting and each year after, the Committee established an intersessional Working Group to address issues concerning catch-at-age analyses for Antarctic minke whales in Areas IV and V. Results of work completed so far on the integrated statistical catch-at-age (SCAA) model are in SC/57/IA9 and results from the Adaptive Framework Virtual Population Analysis (ADAPT-VPA) model are in SC/57/IA17 (both discussed later). Two of the outstanding tasks that remained before final results could be obtained were addressed during this Scientific Committee meeting: a set of plausible stock structure hypotheses for Areas IV and V was developed, and a set of environmental time series was identified (details in Appendix 4 of Annex G). That Appendix also lists remaining issues that require consideration and intersessional work.

The Committee **agrees** that having results from both the ADAPT-VPA and integrated SCAA was extremely valuable and encouraged continued work on both approaches. It also **agrees** that the Working Group should continue as an intersessional e-mail group (Annex P(13)). The Committee further **agrees** that a request for data be made under Procedure B of the Data Availability Protocol to allow work identified in Appendix 4 of Annex G to proceed.

10.1.2.2.2 ABUNDANCE ESTIMATES FROM SOWER AND JARPA USED IN POPULATION DYNAMIC MODELS

The intersessional Working Group **agreed** that for this year, abundance estimates by Branch (2003; pers. comm.) be used for the IDCR/SOWER cruises and estimates by Hakamada *et al.* (2005) be used for the JARPA cruises. In the longer term, completion of the population modelling work is dependent upon the finalisation of a set or sets of abundance estimates for both these cruises.

10.1.2.2.3 RESULTS FROM PRELIMINARY ANALYSES

SC/57/IA9 reported on the statistical catch-at-age model, which is a general population dynamics model applied to Antarctic minke whale data from Areas IV and V that allowed for: multiple fleets; age- or length-based selectivity; different shaped selectivity patterns which can change by time, sex and fleet; ageing error; and changes over time in carrying capacity. The reference case analysis indicated a substantial increase in recruitment between 1930 and 1960, then a decrease between 1960 and the mid-1980s and relatively constant recruitment subsequently. Correspondingly, abundance increased until around 1970 and then declined. These results are similar to those obtained by Butterworth *et al.* (1999). The estimate of K in 1960 was higher than in 1930 by a factor of 10. K was estimated to have decreased roughly by half between 1960 and 1980.

Sensitivity analyses showed the following: a significantly better fit was achieved when allowing for changes in K over time; selectivity varied with length or age for the JARPA catches; and apparent inconsistencies between the JARPA age composition data and the commercial age-length keys. Problems were encountered if the assumption was made that growth had not changed over

time. Hatanaka commented that growth rate may have changed over time and that the commercial catches were closer to the ice edge, which may have influenced their selectivity.

SC/57/IA17 reported advances in the application of ADAPT-VPA to Antarctic minke whales in Areas IV and V. They had applied the methodology of Butterworth *et al.* (1999) to abundance estimates (from both IDCR/SOWER and JARPA surveys) and catch-at-age data (both commercial and scientific) for Areas IV and V. The primary focus was a joint analysis of the two Areas under the assumption that there was a single stock, with year-to-year variability in how it was distributed. The model was most sensitive to the value of the natural mortality M . This was linked to the IDCR/SOWER survey trends suggesting higher estimates of M , and the JARPA survey trends suggesting lower estimates.

The trends in recruitment and population size in SC/57/IA17 agreed well with the corresponding reference case results in SC/57/IA9. However, some differences between results of the ADAPT-VPA (SC/57/IA17) and the SCAA (SC/57/IA9) were noted. For example, omitting the JARPA abundance data had a large effect in the ADAPT-VPA but not in the SCAA. The difference between the trends indicated by the revised JARPA and IDCR/SOWER abundance estimates for Area IV is clearly of concern. Further, the ADAPT-VPA approach needs to be extended to take account of the differences in selectivity patterns between the Japanese and Russian fleets indicated by SC/57/IA9. In addition, possible differences in selectivity patterns at large ages between JARPA and the commercial catches need to be investigated further.

The authors of SC/57/IA9 commented that their model's estimates of recent trends are dependent upon assumptions about temporal changes in carrying capacity (K) and the relative weight given to different data sources. Thus such models are unlikely to entirely resolve differences between CPII and CPIII.

10.1.2.3 OTHER

SC/57/O21 examined whether predator-prey interactions alone could broadly explain observed population trends of the major species without resorting to environmental change hypotheses. As a first step, a model was developed that included krill, four baleen whale species (blue, fin, humpback and Antarctic minke) and two seal species (Antarctic fur and crabeater). The study inferred that:

- (i) species interaction effects alone can explain observed predator abundance trends, although not without some difficulty;
- (ii) it was necessary to consider predator species other than baleen whales to explain the observed trends, with crabeater seals being particularly important and in need of improved abundance and trend information;
- (iii) the Atlantic/Indian region showed major changes in species abundances, in contrast to the Pacific which was much more stable;
- (iv) baleen whales need relatively high growth rates to explain the observed trends; and
- (v) the previous estimate of some 150 million tons for the krill surplus (Laws, 1977) may be too high since his calculations omitted density-dependent effects on feeding rates.

The Committee recognised that investigating interactions between species is important and welcomed contributions on this issue. The considerable discussion on the issues related to this model and the interpretation of its results is summarised in Annex G (item 3.3.3). These discussions include: the inclusion of other species in the model; pooling over the two species of krill; incorporating inter-annual changes and a correlation between the level of competition and good and poor krill years; the fit of the data; the effects of setting bounds on the parameters; the interpretation that the crabeater seal box also represents all other krill predators; the effect of assuming a top-down model in contrast to a bottom-up model; and the effect of the restriction of the study area which is only part of the habitat for some species in the model. It was noted that just because one model is consistent with the data, this is not a reason to accept its underlying hypotheses as the only plausible hypothesis. Many other hypotheses may also lead to models that fit the data, including a combination of top-down and bottom-up hypotheses.

The Committee noted that in many regions, assessments of numerous species are starting to be considered within an ecosystem framework. To consider an ecosystem framework for assessments of large whales, topics such as ecosystem models, competition between different large whale species and between large whales and other species must be discussed. The Committee also recognises the need for collaboration with other organisations to ensure that the Committee has the necessary expertise available. The Committee recalled the views of its previous workshop (IWC, 2004g) and **agrees** that ecosystem modelling should be added to the agenda next year and invites members to contribute papers on this issue (and see Item 19).

10.2 In-depth assessment of western North Pacific common minke whales, with a focus on J stock

10.2.1 Report from intersessional Steering Group

SC/57/NPM4 reported the activities of the intersessional steering group that were preparing for an in-depth assessment of western North Pacific common minke whale, with a focus on the J-stock. The Group met at the end of last year's meeting to discuss data availability issues and ways to proceed with the intersessional work (IWC, 2005h). The intersessional work focused on three areas: update of information and data; availability of data under Procedure B; and analyses conducted. Papers resulting from these preparations are discussed in detail in Annex G (item 4) and summarised below.

10.2.2 Distribution and abundance

In response to a request from last year, SC/57/NPM15 investigated the relationship between common minke whale distribution and oceanographic conditions in Korean waters. Data from commercial whaling records and sightings surveys around the Korean Peninsula from March to October during 1977-2004 show that common minke whales occur in areas with an annual mean SST range of 12-20°C. Common minke whale distribution was in the temperature range 13-25°C from March to July in the seas to the south and east of the Korean Peninsula. It was also noted that the abundance of common minke whales may be influenced by the abundance of prey organisms such as anchovy and zooplankton.

The Committee welcomed this review.

SC/57/NPM13 reported an investigation of the distribution and abundance of common minke whales based on catch and effort data from whaling in the waters around the Korean peninsula from the 1960s to the mid 1980s. Abundance indices were generally high from March to June with a peak in May. A lower secondary peak occurred in September. Potential migration paths and relative densities are discussed in detail in Appendix G.

SC/57/NPM3 and SC/57/NPM8 provided provisional abundance estimates of common minke whales from Korean surveys. The Committee welcomed this information along with a cruise report from April-May 2005. These are discussed in detail in Annex G (item 4.2) and the Committee looks forward to receiving revised estimates in the future.

A historical review of changes in the large whale species targeted by hunting off the Korean peninsula was presented. It suggested that the waters off Korea were historically abundant whale habitats as featured in the Bangudae petroglyphs from prehistoric times, various logbooks of foreign whaling vessels that harvested in Korean waters in the 19th century and bycatch data after 1990. Large whale species declined before the ban on whaling.

The Committee thanked the authors for this review and noted the plan to bring a revised version to a future meeting.

SC/57/NPM1 reported the results of a sighting survey in the Sea of Japan in spring 2004. Permission to survey in the Russian Exclusive Economic Zone (EEZ) was not granted so, during 11 May-29 June 2004, the research vessel, *Shonan-maru* No.2, covered the same area as in 2003. Abundance estimates are not yet available.

In discussion, it was noted that the large number of strata included in the survey design may lead to higher variances than are appropriate. Future survey design should aim to maintain equal coverage in the survey blocks so that, if appropriate, data can be pooled over blocks during analyses. This should minimise problems with large variance estimates and provide greater flexibility in analysis.

The Committee noted that the data from Japanese surveys conducted prior to 2002 had not been analysed to provide estimates of abundance. As shown in IWC (2005f, p.225), all these surveys had very low numbers of primary sightings, at least in part due to the timing and the small size of the areas surveyed. From 2002, the number of vessels used on surveys was increased, leading to improved coverage and to data that were sufficient for analysis. The Committee **encourages** that these data be analysed and presented at the next meeting.

10.2.2.1 PLANS FOR FUTURE SURVEYS

SC/57/NPM2 presented a plan for sighting surveys in the North Pacific to be conducted in summer 2005 and spring 2006. Permission to survey in the Russian EEZ to the east of the Kuril Islands and the Kamchatka Peninsula has been granted by the Russian Federation for summer 2005. The last survey in the Russian EEZ east of the Kuril Islands was in 1990; this will be the first time that a dedicated sightings survey has been conducted in the waters east of the Kamchatka Peninsula. Two research vessels will survey from 23 July to 20 September 2005. A survey is also planned in the northern Sea of Japan in spring 2006. Japan will make an application to survey in the Russian EEZ before the acceptance deadline. The survey is planned to be in standard IO passing mode with the priority species being the common minke whale. The tentative dates are 12 May to 30 June 2006.

The Committee thanks the Russian Federation for granting permission to conduct the sighting survey in their waters during 2005 and **requests** that permission is also granted for the 2006 survey. The Committee **encourages** the development of practical ways to investigate movements of animals from the Sea of Japan into the Sea of Okhotsk and North Pacific. The Committee noted that Miyashita, a highly experienced scientist on sighting surveys, would be in charge of the cruises and **agrees** that he should act as the Committee's representative for the purposes of oversight under the RMP.

SC/57/IA21 reported Korean plans to conduct a sightings survey using the vessel *Tamgu* 3, 10 April-29 May 2006, following recommendations from the Committee. Standard one-team IWC methods for conducting sighting surveys will be employed. If circumstances allow, biopsy sampling will be undertaken. The Committee was pleased to see these plans and noted that the timing was appropriate. As only one platform is being used $g(0)$ cannot be estimated. It was suggested that the survey should focus on blocks that have not yet been surveyed or had received little coverage. The Committee noted that Sohn and An, who are experienced in conducting sighting surveys, would be on the cruise and **agrees** that they should act as the Committee's representatives for the purposes of oversight under the RMP.

The Committee noted that it is still in the process of preparing for an in-depth assessment and it **encourages** that all work to generate abundance estimates continue so that it will be in a position as soon as possible to conduct the assessment. In this respect, a number of issues were raised.

Despite the completion of a number of surveys in recent years, the Committee noted the low survey coverage, particularly in sub-areas 6 (50%) and 10 (20%). The Committee **recommends** that future surveys fill these gaps. The Committee also **recommends** that the Commission requests the relevant authorities of the Russian Federation to grant permission for survey vessels to enter EEZ and territorial (coastal) waters. The Committee **encourages** collaboration between Russian, Japanese and Korean scientists to facilitate conducting surveys in as much of these sub-areas as possible. In addition, although the surveys being conducted are providing increasing coverage of the area, some unsurveyed areas are likely to remain and consideration needs to be given as to how such areas will be treated. For example, it is difficult to survey the waters very close to the Korean and Japanese coasts.

A review of the timing of all the surveys is also needed to avoid problems when combining estimates. Consideration will also need to be given as to how the data will be used to estimate trends in abundance.

10.2.3 Stock structure

SC/57/NPM10 updated previous studies of haplotype diversity in the mitochondrial control region using 305 samples from common minke whales bycaught in Korean waters 1998-2005. PCR/direct sequencing data revealed that:

- (1) haplotype frequencies showed no difference across the years analysed;
- (2) the haplotype diversity and nucleotide diversity were 0.898 and 0.00670, respectively; and
- (3) with no pooling there were no significant local differences, whereas using two haplogroup classifications based on single nucleotide partitions, referred

to as A4 and A5, differences were significant. Preliminary results from analyses of genetic diversity using six microsatellite loci from samples from bycaught common minke whales from Korea were also presented. These results show the possibility that there are two or more subpopulations, in accordance with the mitochondrial DNA analyses.

It was noted that care is needed in interpretation of the results of these studies because of the small sample sizes. The F_{ST} values in the microsatellite study seem too small to be significant and application of Bonferroni corrections may show that the results are not actually significant. In addition, the basis and reasons for the definition of groupings A4 and A5 was questioned.

SC/57/NPM5 presented results of genetic investigations into the population structure of western North Pacific common minke whales from coastal waters of Japan and the Republic of Korea based on products purchased on the retail markets between 1999 and 2004, updating analyses presented in Lavery *et al.* (2004). Comparisons between the two market divisions (Japan and Korea) and among the four market/stock divisions (J and O haplogroups within each market) contradicted a number of assumptions about stock structure and incidental takes used in previous RMP *ISTs*. The authors concluded that the results support the hypothesis of multiple coastal stocks in the waters of Korea and Japan.

Other members reiterated their previously expressed concerns about the use of market samples to make inferences about stock structure due to the lack of data on the origin of the market purchase (i.e. the date and location of where and when the animal was bycaught). They also referred to methodological problems with the analysis. This and related issues are discussed further in Annex G (item 4.3).

In conclusion, some members of the Committee believed that the results presented at this year's meeting provided evidence of population structuring within J-stock. Others disagreed and believed that it was too early to come to such a conclusion. The Committee **agrees** that further work is required and believes that collaborative studies would be the most productive way to further understanding of stock structure of common minke whales in this area.

The Committee was informed that some collaborative studies between Korea and Japan are ongoing and it **encourages** further collaborative work between Japanese and Korean scientists. The Committee looks forward to the presentation of results from genetic analyses of animals from Korean and Japanese bycatch at next year's meeting.

The Committee also noted that a large difference in the peak of conception for animals in the J- and O-stocks has been shown. This and other non-genetic information will need to be taken into account when considering stock structure.

10.2.4 Biological parameters

SC/57/NPM12 presented an investigation into variations in length and sex ratio by location, using data from 320 common minke whales bycaught in Korean waters from 1998 to 2004. The authors concluded that there is probably some spatio-temporal segregation by length and sex, in that most bycaught animals are small in size but their sex ratio differs by month and year.

The Committee **agrees** that the strongly varying sex ratio by season is indeed suggestive of segregation by sex, and

thus integrating genetics into studies of variation in length and sex by month/year and location would be informative.

SC/57/NPM14 presented a study of age and growth in common minke whales bycaught in Korean waters from April 2002 to May 2004. This is discussed further in Annex G (item 4.4).

10.2.5 Total takes

SC/57/BC5 reported on a mark-recapture estimate of the total number of common minke whales entering the Korean market, regardless of their source. The best estimate was 827 whales (SE=164), which suggests that more animals are entering the market than from recorded bycatch alone. The difference between the total market supply and the recorded bycatch is imprecisely estimated and could be improved by comparing the results with data from DNA registers. Further discussion of this paper and points arising from it are in Annex J.

SC/57/NPM6 provided an estimate of the proportion of J- and O-type common minke whale products purchased on Japanese markets from December 1997 to February 2004, using mixed-stock analyses, to set plausible bounds of total takes over time. This paper is discussed in more detail in Annex J. Based on grouping the market individuals into mtDNA haplogroups as described previously by Baker *et al.* (2000), the proportion of J-stock individuals on the Japanese market was estimated to be 45.5% (SE=4.3%) over the seven-year study. There was no significant difference in this proportion after the 2001 change in regulations controlling the sale of bycatch. A minimum total take of 616 J-stock common minke whales over the seven-year survey period was estimated using the estimated stock proportions and the known Special Permit take of 740 from the O-stock.

Responses to this paper are given under Item 7.2.2.

10.2.6 Assessment methodology

SC/57/NPM7 put forward a Bayesian framework for the assessment of the J-stock of common minke whales. The approach makes use of catch and commercial Catch Per Unit Effort (CPUE) information and, in particular, applies a set net effort-based model to estimate bycatch in years for which these data are not available. Pending finalisation of the actual data that might be used for input, an illustrative application of the approach was provided. The results were shown to be particularly sensitive to the commercial CPUE data used.

The Committee noted that the assessment model would need to be updated with the new data on abundance and total takes and adapted in the future depending on the results of discussions on stock structure. Work is currently being undertaken to provide these new data.

The Committee discussed the use of catch or bycatch per unit effort (CPUE) as an index of abundance for assessment. The Committee **agrees** that actual data on fishing effort from each fishery with significant bycatch should be used, and that these would need to be disaggregated by season, area and gear type. The bycatches themselves should also be disaggregated to the extent possible, such that a Generalised Linear Model (GLM) standardisation of the kind commonly used in the analysis of fishery CPUE data could be applied. The Committee **recommends** that the required data be made available. GLM standardisation is also important for the commercial CPUE data, but in particular disaggregation by area is required, given the shift in effort from the Sea of Japan to the Yellow Sea between

the earlier and later years of the series. The Committee recalled the extensive discussions of the use of CPUE data in earlier years and the potential problems when using this type of data, and **agrees** that the problems identified in the report of the 1987 Workshop on the Use of CPUE Data (IWC, 1989) should be considered before further developing a CPUE-based assessment. It was noted that CPUE series had nevertheless been analysed and effectively used for common minke whales in the Barents Sea using indices for individual vessel.

Estimates of absolute abundance are critical for the in-depth assessment. As recommended in Annex G, item 4.2, future surveys should aim to cover as wide a range as possible to improve coverage. Information on the proportion of animals moving from the Sea of Japan into the Sea of Okhotsk, about which there is great uncertainty, would be very valuable.

The Committee **agrees** that any decision on the most appropriate assessment method should wait until a range of such methods have been evaluated.

10.2.7 Other

In response to a request from the intersessional Steering Group, Kim provided a brief summary of the historical trends in Korean stationary fishing gear. There have been dramatic increases in both the number and the area covered by fishing gears since the early 1990s, but sharp decreases since the early 2000s, due to restructuring of the fisheries industry to reduce fishing effort in Korea. The Committee **welcomes** this information.

10.2.8 Future work

The Committee **agrees** that the material presented at this meeting was a significant advance and thanked Korean scientists in particular, for their hard work during the previous year. However, it was clear that large information gaps still remain. For example, the CPUE data are limited and difficult to interpret, there are large gaps in coverage in sighting surveys that provide estimates of abundance, stock structure is still unclear, and there is no information on bycatch in countries other than Japan and Korea. The Committee recognises that a quantitative assessment may be several years away. However, there was a need to proceed with some urgency, particularly because of the Committee's concern about the effect of bycatch on the status of the J-stock. Some members noted that evidence presented to date showing relatively low abundance and high bycatch had not allayed this concern.

The Committee **recommends** that the work identified in its report continue as expeditiously as possible. The results of the Steering Group's (Annex P(11)) deliberations on a future work plan can be found in Annex G, Appendix 6.

10.3 Southern Hemisphere whale stocks other than Antarctic minke and right whales (see Annex H)

10.3.1 In-depth assessment of Southern Hemisphere humpback whales

The Comprehensive Assessment of Southern Hemisphere humpback whales has been discussed since 1999 (IWC, 2000d). At this meeting, substantial progress has been made and the Committee expects to complete the assessment in 2006.

The Committee had discussed whether to associate the historical feeding stocks of Southern Hemisphere humpback whales (Areas I–VI) with the more recently assigned breeding ground classifications (A–G, X; IWC, 1998a).

Since no consensus on the appropriate association was reached, the Committee **agrees** at present to continue to refer to the feeding grounds by their number and the breeding grounds by their stock letter.

10.3.1.1 REPORT OF THE INTERSESSIONAL GROUP

The Committee received a report from the intersessional group to summarise the state of knowledge of Southern Hemisphere humpback whale stocks (Annex H, Appendix 7). It thanked the group and **recommends** that its work continues until the Comprehensive Assessment of this species is completed. It also **agrees** that the table (SC/57/SH11) with summarised information be published on the Commission's website⁸.

10.3.1.2 DISTRIBUTION AND ALLOCATION OF HISTORIC CATCHES

The Committee examined information on humpback whale historic catches in the Southern Ocean during the period following World War II with emphasis on IWC Areas IV, V and VI (SC/57/SH6).

Last year, the Committee proposed that the allocation of historic catches from the Antarctic Peninsula be investigated in light of new information on stock structure (IWC, 2005g, p.244). After some discussion, the Committee agreed that the A/G border in the feeding grounds requires modification. Two scenarios were suggested. The first apportions all catches to the west of 50°W and south of 60°S to breeding stock G, while the second apportions all catches to the west of 50°W and south of 50°S to G (fig. 1 in Annex H). The Committee **agrees** that the 100°W–70°W core area for stock G be extended eastward to 50°W.

The key remaining issue for the catch series is to assign the 1959/60 and 1960/61 catch information presented in SC/57/SH6 to the correct stocks. Currently, they have been allocated based on the proportion of the reported catches. It was suggested that all catches provided in SC/57/SH6 be compared with the IWC database, with resolution of any differences in either catch numbers or area assignments. It is probable that the IWC database requires updating in terms of positional information (at the highest resolution possible) for the 1959/60 and 1960/61 *Slava* and *Sovietskaya Ukraina* catches; the breakdown of these catches into smaller areas will be possible for some, but not all, catches. The likelihood of determining the locations of the 7,177 Soviet catches from the *Slava*, *Sovietskaya Ukraina* and *Sovietskaya Rossia* expeditions for which there are currently no location data requires investigation.

The Committee noted that funding is already available for a meeting of a small group (Annex P(1)) to finalise the incorporation of the Soviet catches into the IWC database. The Committee **recommends** that this meeting take place within the next six months and that the existing group of scientists proposed last year be expanded to include Clapham and Findlay. This meeting should further review and verify the fleet cruise tracks, so that the feasibility of apportioning unknown humpback whale catches on cruise tracks can be assessed. The Committee **recommends** that the humpback whale catch series should be finalised by January 2006 and made available on the IWC website for use in the population dynamics modelling (see Item 10.3.1.4).

10.3.1.3 NEW INFORMATION ON ABUNDANCE, RATES OF INCREASE AND STOCK STRUCTURE

10.3.1.3.1 ANTARCTICA

The Committee received a number of papers on this topic. These included the examination of the movements of humpback whales around the Antarctic Peninsula (SC/57/SH2), a genetic analysis of the relationship between two feeding areas (west coast of the Antarctic Peninsula and the Magellan Strait) and breeding stock G (SC/57/SH3), and a study of the relationship of humpback whale density and chlorophyll-a concentration in the Gerlache Strait (SC/57/SH8).

An update on data collection from IDCR/SOWER humpback whale samples from Areas I, II and III was provided to the Committee. A total of 92 samples are available and analysis should be completed and presented by the next annual meeting. The sample sizes that exist for Areas I, II and III are relatively small. If the genetic data contrasting wintering regions and potential corresponding feeding grounds are to be useful for the assessment of Southern Hemisphere humpback whale stocks, it is necessary that biopsy sampling during future Antarctic cruises be given the highest priority. Recognising the complexities and issues of survey design and priorities for cetacean work by the IDCR/SOWER cruises in the Antarctic environment, the Committee **urges** that the collection of tissue biopsy samples from Antarctic humpback whales be given greater priority than at present.

It was noted that a proposal for access to samples collected during IDCR/SOWER cruises from Areas IV, V and VI was approved some time ago. In 2003, it had been agreed that half of all of the IDCR/SOWER samples would be transferred to the Southwest Fisheries Science Center in the USA (IWC, 2004b, p.50), although the samples have not yet been shipped. The Committee **recommends** that priority be given to the transferring of these samples (Zerbini will oversee this process).

A summary of the genetic analyses of 287 humpback whale samples obtained during JARPA surveys at the feeding grounds of Areas III, IV, V and VI was presented (Pastene *et al.*, 2005). Focus was given to testing the geographical ranges proposed by the Committee for stocks C, D, E and F⁹ in the Antarctic feeding grounds (IWC, 2005g, p.236). Results of mtDNA analysis showed that whales in these geographical ranges are genetically differentiated, suggesting some structure of the humpback whales in the feeding grounds. However, analysis based on six microsatellite loci, while exhibiting some degree of genetic heterogeneity, was unable to discriminate among these potential stocks. It was suggested that different degrees of fidelity to breeding areas between females and males could explain such results. Analysis of mtDNA suggests that the historical sector of mixing between stocks D and E at 110-130°E has been occupied more by the D stock in recent years.

Estimates of abundance and rates of increase for humpback whales from JARPA cruises were presented (Matsuoka *et al.*, 2005). There was substantial discussion on issues related to potential sources of bias from JARPA data (Annex H, item 6.3.1), with different views being expressed (Annex H, Appendices 2 and 3). It was noted that the JARPA review is currently scheduled for mid- to late-2006

(SC/57/O2). The Committee **agrees** that issues associated with the interpretation of the JARPA data should be considered at the JARPA review meeting. However, it also encourages submissions that will help inform the discussion and consideration in the meantime.

Details on the discussion of these papers are found in Annex H, item 6.3.1. The Committee welcomed them and **recommends** that these studies be continued in the future.

10.3.1.3.2 SOUTH AMERICA

The Committee received two papers from South America. These included the first photographic matching of a humpback whale from Brazil to South Georgia (SC/57/SH1). Information from photo-identification data showed that whales feeding in the Magellan Strait migrate to Ecuador, Costa Rica and Panama with strong site fidelity to the latter locality (SC/57/SH10). Details of these studies can be found in Annex H, item 6.3.2. The Committee welcomed the presentation of these papers and **recommends** that these studies be continued in future years.

10.3.1.3.3 AFRICA

The Committee received SC/57/SH13, which evaluated the significance of the division of breeding stocks between regions in the South Atlantic and Western Indian Ocean (stocks A, B, C and X). As discussed in Annex H (item 6.3.3), the situation is complex and at present no change to the sub-region nomenclature is recommended. There is no value in trying to redesign the boundaries without clear definition and degree of gene flow for the various sub-regions. Based on the total evidence and on the direct observation of dispersal of identified individuals, it seems that in at least some localities gene flow is ongoing across present boundaries. The minimum gene flow that is required between two localities in order to include them within a single management unit has not been established. The Committee welcomed the work presented and **recommends** that these studies be continued in future years.

10.3.1.3.4 OCEANIA

The Committee received three papers under this item. The report of the 6th Annual Meeting of the South Pacific Whale Research Consortium (SC/57/SH9), noted numerous new matches made between existing catalogues in this region, demonstrating a significant degree of interchange between over-wintering grounds. Of particular interest was the discovery of matches between French Polynesia and other areas of the South Pacific: Cook Islands (1), Tonga (5) and New Caledonia (1). A new catalogue from American Samoa provided new matches with French Polynesia, the Cook Islands and Tonga, despite a relatively small number of fluke photos. This further demonstrates the complexity of interchanges between the various populations of humpback whales in the South Pacific region.

The Committee received an updated analysis of the population structure of South Pacific humpback whales and the origin of the eastern Polynesian breeding grounds (Olavarria *et al.*, 2005). The significant geographic differentiation reported supports the recognition of at least five subpopulations (breeding grounds) of humpback whales across the South Pacific, each one corresponding to a specific winter breeding ground. The most isolated humpback whale subpopulation within the South Pacific is found in waters off Colombia. The differentiation of mtDNA diversity between the Indian Ocean breeding ground (Western Australia) and the South Pacific grounds (except with Colombia) was low. The significant

⁹ According to the sub-committee's decision (Annex H, item 6), these are equivalent to Areas III, IV, V, VI.

segregation observed among breeding subpopulations is partially consistent with the six IWC Antarctic management stocks, largely corresponding with one or more tropical breeding ground, supporting a further division of breeding stock E at least into two units. The question of the origin of the breeding areas in eastern Polynesia remains unresolved.

SC/57/SH12 presented preliminary new abundance ($6,555 \pm 389$ whales) and rate of increase ($10.6 \pm 0.5\%$) estimates for the eastern coast of Australia. The rate of increase agrees with those previously obtained for this population and demonstrates the continuation of a strong post-exploitation recovery. It was noted that there was no expectation that the Committee would accept the estimate but rather that it would provide feedback to the authors of the paper, who would then bring a final estimate to the Committee next year.

Further discussion of these papers is described in detail in Annex H, item 6.3.4. The Committee welcomed these papers and **recommends** that these studies be continued in the future.

10.3.1.4 POPULATION DYNAMICS MODELLING

Four papers were presented under this item. SC/57/SH15 presented a Bayesian assessment of breeding stocks D and E (western and eastern Australia) using a model that allows for mixing on their feeding grounds. The Base Case estimates current abundance relative to the pre-exploitation population size (K) to be 0.46 for stock D and 0.29 for stock E. Projections into the future assuming a zero harvesting scenario show (in terms of the median) near complete recoveries to pristine levels in some 15 years for stock D and some 20 years for the currently more depleted stock E. A posterior distribution for the maximum growth rate parameter r was developed. It was suggested that this prior be used for similar Bayesian assessments of other Southern Hemisphere humpback whale populations for which little or no information on increase rates is available. Two other papers used this prior to assess the status of the stocks B (western Africa), C (eastern Africa), G (western coast of South America) (SC/57/SH16) and A (eastern South America) (SC/57/SH17). Current abundance estimates for breeding stocks A, B and G are low ($0.25K$, $0.09K$ and $0.25K$ respectively), whilst the current abundance estimate for breeding stock C is much further recovered at $0.79K$. Projections under a zero harvesting strategy estimate breeding stock C to be fully recovered by 2020, whilst breeding stocks A, B and G will be fully recovered only by about around 2030. Details on the discussion of these papers are to be found in Annex H, item 6.4.
