ABSTRACT: The western North Pacific (WNP) population of gray whales *Eschrichtius robustus* is redlisted by the IUCN as Critically Endangered. As part of a long-term study on whales off Sakhalin Island, Russia, photo-catalog comparisons of gray whales in the western and eastern North Pacific (ENP) were undertaken to assess population mixing. These comparisons involved 2 approaches: (1) a systematic comparison of the WNP 'Sakhalin Catalog' to an ENP 'Pacific Northwest Catalog' that consisted of images from the northwest coast of North America and (2) a non-systematic comparison of the WNP 'Sakhalin Catalog' to an ENP 'Laguna San Ignacio Catalog' that consisted of images from central Baja California, Mexico. The Sakhalin to Pacific Northwest comparison consisted of 181 and 1064 whales, respectively, and resulted in 6 matches (3 males, 2 females, and 1 whale of unknown sex). All sightings of 'Sakhalin whales' in the Pacific Northwest occurred off southern Vancouver Island, British Columbia, Canada. The Sakhalin to Laguna San Ignacio comparison consisted of 181 and 2514 whales, respectively, and resulted in 4 matches (2 males and 2 females). As the Pacific Northwest and Laguna San Ignacio catalogs represent only a small fraction of the total estimated number of individuals in the ENP population (~19 000), it is likely that more WNP/ENP exchange has occurred than was detected by these photo-catalog comparisons. Although these matches provide new records of movements between the WNP and ENP, recent observations of gray whales off Japan and China suggest that not all gray whales identified in the WNP share a common wintering ground.

Once thought to be extinct, an endangered western North Pacific gray whale breaches off Sakhalin Island, Russia.

Pacific (WNP) and eastern North Pacific (ENP) populations (LeDuc et al. 2002, Lang 2010, Lang et al. 2011). The ENP population ranges from calving areas off Baja California, Mexico, to feeding areas in the Bering, Beaufort, and Chukchi Seas. The WNP population feeds in the Okhotsk Sea off Sakhalin Island, Russia, and in nearshore waters of the southeastern Kamchatka Peninsula (southwestern Bering Sea). Little is known about the current migratory routes and wintering areas of the WNP population, but historic evidence indicates that the coastal waters of eastern Russia, the Korean Peninsula, and Japan were part of the migratory route and that areas in the South China Sea were used as wintering grounds (see review by Weller et al. 2002).

Both populations were dramatically reduced by commercial whaling during the 19th and 20th centuries (Henderson 1984, Weller et al. 2002, Reeves et al. 2010). The ENP population was removed from the U.S. List of Endangered and Threatened Wildlife in 1994 and is currently estimated to number approximately 19 000 individuals (Laake et al. 2009). At the single species-level unit, gray whales are redlisted by the International Union for Conservation of Nature (IUCN) as being of Least Concern (Reilly et al. 2008). The WNP subpopulation, however, is redlisted by the IUCN as Critically Endangered (Reilly et al. 2008). The most recent assessment of the Sakhalin population, using a Bayesian individual-based stage-structured model, resulted in a median 1+ (non-calf) estimate of 130 individuals (90% Bayesian CI = 120–142) in 2008 (Cooke et al. 2008).

Research on gray whales in the WNP has been ongoing since 1995, predominantly on the primary feeding ground off northeastern Sakhalin Island (Weller et al. 1999, Bradford et al. 2008, Lang et al. 2011), and more recently off southeastern Kamchatka (Vertyankin et al. 2004, Tyurneva et al. 2010, Burdin et al. 2011). These studies monitor gray whales using photo-identification methods, as gray whales are individually identifiable based on unique, permanent pigmentation features (Darling 1984). Such monitoring on the Sakhalin feeding ground has documented (1) pronounced seasonal site fidelity and inter-annual return of known individuals, (2) consistent use of the area by adult females when pregnant, resting (i.e. when not pregnant or lactating), and accompanied by calves, and (3) annual return by many individuals that were first identified there as young-of-the-year (Weller et al. 1999, 2002, Bradford et al. 2008, Bradford 2011).

Whales associated with the Sakhalin feeding area can be absent for all or part of a given feeding season (Bradford et al. 2008), indicating that they probably use other areas during the summer and fall feeding period. Some of the whales identified feeding in the coastal waters off Sakhalin, including reproductive females and calves, have also been documented off the southern and eastern coast of Kamchatka (Tyurneva et al. 2010, Burdin et al. 2011). Further, whales observed off Sakhalin have been sighted off the northern Kuril Islands in the eastern Okhotsk Sea and Bering Island in the western Bering Sea (Weller et al. 2003). Finally, Lang (2010) reported that 2 adult individuals from the WNP, sampled off Sakhalin in 1998 and 2004, matched the microsatellite genotypes, mtDNA haplotypes, and sexes (1 male, 1 female) of 2 whales sampled off Santa Barbara, California, USA (Area 3 in Fig. 1) on 20 and 23 March 1995. The study by Lang (2010) was the first to suggest that some level of interchange might be occurring between the WNP and ENP.

While information regarding the summer feeding areas of gray whales in the WNP has become increasingly available in the past decade, current data from the historic migratory corridor(s) are limited and data from the presumed wintering area(s) are essentially unavailable. There have been only 13 known sightings or strandings in Japanese waters since 1990 (Nambu et al. 2010). Between 2005 and 2007, 4 female gray whales were fatally entrapped in set nets along the Pacific coast of Honshu, Japan. One of these females, entrapped in January 2007, was matched to earlier photographs of it as a calf (with its mother) while on the Sakhalin feeding ground in July and August 2006 (Weller et al. 2008). This match provided the most contemporary link between the summer feeding ground off Sakhalin and a winter location along the coast of Asia.

In an effort to obtain more information about the southern migration route(s) and wintering area(s) of gray whales in the WNP, a satellite telemetry project was undertaken in 2010 by a team of Russian and American scientists (Mate et al. 2011). While the objective of that study was to document gray whale movements in the WNP, the only whale tagged was tracked from the WNP to the ENP. The result of this telemetry study, together with the genetic matches reported by Lang (2010), provided the impetus for WNP/ENP photo-identification catalog comparisons, which we conducted to further assess population mixing.

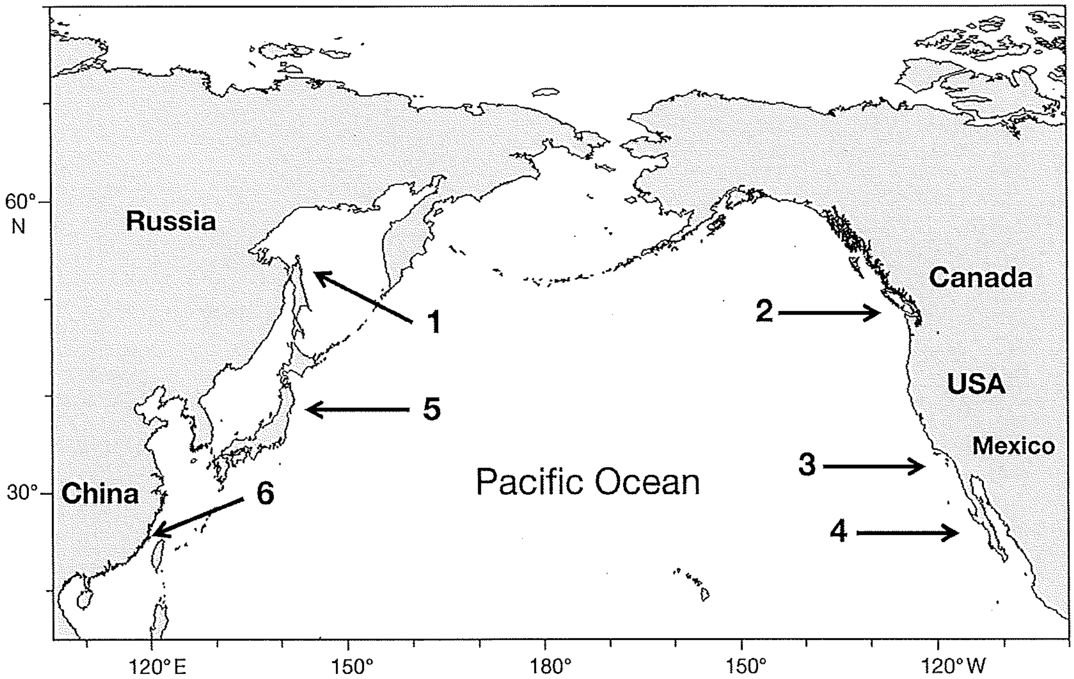

Fig. 1. *Eschrichtius robustus*. North Pacific Ocean, showing: (1) Western North Pacific (WNP) feeding ground off Sakhalin Island, (2) Eastern North Pacific (ENP) region off Vancouver Island where 6 photographic matches to Sakhalin individuals were found, (3) ENP region off California where 2 genetic matches were found (Lang 2010), (4) ENP region off Baja California where 4 photographic matches to Sakhalin individuals were found, (5) WNP region of Japan where a photographic match was found (Weller et al. 2008), and (6) WNP region of China where a gray whale stranded in November 2011 (Zhu 2012)

MATERIALS AND METHODS

Photo-identification images of 181 Sakhalin gray whales (the Sakhalin catalog, hereafter SAK catalog) collected off Sakhalin Island (Area 1 in Fig. 1) between 1994 and 2009 by a joint Russia-U.S. research program (Weller et al. 1999, 2002) were compared to a catalog of 1064 'Pacific Northwest gray whales' (hereafter, PNW catalog) identified by Cascadia Research Collective and collaborators working in U.S. and Canadian waters from California to Alaska (Area 2 in Fig. 1) primarily between 1998 and 2009 (Calambokidis et al. 2002, 2010). The PNW catalog focuses on gray whales that feed during summer and fall in coastal waters between northern California and the Gulf of Alaska, referred to as the Pacific Coast Feeding Group (PCFG), but also includes some migrating whales identified in the spring (March to May) during their northward passage to high-latitude feeding grounds.

Of the 181 whales in the SAK catalog, all were represented by a right-side dorsal flank image, and 179 were associated with a left-side dorsal flank image. Of the 1064 whales in the PNW catalog, 845 were represented by a right-side dorsal flank image, and 898 were associated with a left-side dorsal flank image. Each individual in the SAK catalog was compared in numerical order to all individuals in the PNW catalog as follows. First, the left-side dorsal flank of each individual in the SAK catalog was compared to the left-side dorsal flank of all individuals in the PNW catalog. This process was then repeated using the right-side dorsal flank and ventral aspect of the tail flukes. Comparisons were made by a single analyst (A.K.), but resulting matches were confirmed by 3 independent researchers skilled in gray whale photo-identification (including A.L.B. and J.C.).

Similarly, photo-identification images of 181 whales in the SAK catalog were compared to an online catalog of 2514 'Laguna San Ignacio gray whales' (hereafter, the LSI catalog) identified between 2006 and 2010 in Baja California, Mexico (Area 4 in Fig. 1). This assessment was not comprehensive or systematic, as was the case for the PNW catalog, because the LSI catalog represented a collection of 'annual working catalogs' rather than a single multi-year catalog of known individuals. Thus, the comparison to the SAK catalog reported herein was undertaken opportunistically. A single analyst (A.L.B.) conducted the appraisal, with identified matches confirmed by 2 additional observers (including D.W.W.).

RESULTS

The comparison of the SAK catalog to the PNW catalog resulted in a total of 6 confirmed matches of individuals, including 3 males, 2 females, and 1 whale of unknown sex (Table 1). None of these 6 whales is a known PCFG animal, and, to date, each one has only ever been photographed a single time during either April or May.

Remarkably, all 6 of the matches were from only 2 days of effort, with 3 whales identified on 2 May 2004 and 3 on 25 April 2008. The 3 whales identified on 2 May 2004 were together in a single group, while the 3 whales recorded on 25 April 2008 were in 2 separate groups but in close proximity. All of the sightings of Sakhalin whales in the Pacific Northwest occurred near Barkley Sound off the west coast of southern Vancouver Island, British Columbia, Canada.

Three of the 6 whales were first identified as calves (with their mothers) on the Sakhalin feeding ground during 1997 (no. RUS-U.S. 032/CRC 1045), 2003 (no. RUS-U.S. 119/CRC 1040), and 2004 (no. RUS-U.S. 135/CRC 1042; Table 1). Interestingly, a genetic analysis of paternity classified one of the matched males (no. RUS-U.S. 035/CRC 0809) as the putative father of 2, or possibly 4, calves identified off Sakhalin (Lang 2010). All 6 whales had sightings off Sakhalin prior to their respective sightings off Vancouver Island, and 5 (83%) had sightings off Sakhalin subsequent to their Vancouver sightings. Four whales were sighted off Vancouver Island and Sakhalin in the same year: 3 in 2004 and 1 in 2008. Of the 3 whales identified off Vancouver Island on 2 May 2004, 2 were resighted off Sakhalin on 31 July 2004, while the third was first resighted on 6 August 2004. Whale no. RUS-U.S. 032/CRC 1045 was sighted off Sakhalin in 2007 during July (29), August (4,18,25), and September (7,8,9), off southern Vancouver Island on 25 April 2008, and then back off Sakhalin on 19 July 2008. This whale is the same individual satellite-tracked from Sakhalin to the ENP in 2010/2011 (Mate et al. 2011).

The comparison of the SAK catalog to the LSI catalog resulted in a total of 4 confirmed matches of individuals, including 2 males and 2 females (Table 2). Three of these 4 whales were photographed in Laguna San Ignacio in only 1 year, while whale no. RUS-U.S. 052 was identified in both 2007 and 2010. All 4 whales had sightings off Sakhalin prior to their respective sightings in Laguna San Ignacio, and 3 (75%) had sightings off Sakhalin subsequent to their lagoon sightings. Two whales were sighted in Laguna San Ignacio and Sakhalin in the same year: one in 2008 (no. RUS-U.S. 063) and one in 2010 (no. RUS-U.S. 052).

One of the 4 whales (no. RUS-U.S. 020) was first identified as a calf on the Sakhalin feeding ground

[a] Same whale satellite-tagged in 2010 (Mate et al. 2011). First identified off Sakhalin as a calf in 1997. [b] Putative father of 2 (strict criterion) or 4 (relaxed criterion) Sakhalin calves (for definitions see Lang 2010). Years that these calves were first identified are: 1998, 2001, 2002, and 2003. [c] First identified off Sakhalin in 2003 as a calf. [d] First identified off Sakhalin in 2004 as a calf

during 1997 (Table 2) and photographically matched to the Commander Islands in June 2000 (Weller et al. 2003). A genetic analysis of paternity classified 1 of the matched males (no. RUS-U.S. 052) as the putative father of a calf identified in 1998 off Sakhalin (Lang 2010). Both of the matched females were identified as mothers with calves while in Laguna San Ignacio. Whale no. RUS-U.S. 042 was identified as a mother with a calf in 2009 but has never been seen with a calf off Sakhalin. Whale no. RUS-U.S. 063 was identified as a mother with a calf in 2008 and was also observed with a calf off Sakhalin (in 1998).

DISCUSSION

The photographic matches reported here provide new information that is of broad significance to understanding the migration patterns and mixing of gray whales in the North Pacific. The high number of matches made between the SAK and PNW catalogs is particularly intriguing given that the PNW catalog used for comparison focuses on PCFG whales and thus greatly underrepresents individuals that pass off the Pacific Northwest during the spring migration. Limited numbers of whales in the PNW catalog have been photographed during the spring off the coast of Vancouver Island where the 6 matched whales were observed (n = 26 for southern Vancouver Island; n = 48 for all of western Vancouver Island). Thus, 6 of the 74 (8.1%) whales identified off Vancouver Island in the PNW catalog were known Sakhalin individuals. Given that the PNW catalog contains only a small fraction (1064) of the estimated total number of individuals (~19 000) in the ENP population, it is likely that more WNP/ENP exchange has occurred than was detected during this comparison.

The high match rate observed between the SAK and PNW catalogs suggests a spatio-temporal behavioral factor that makes Sakhalin whales more likely to have been identified in the small PNW spring sample. The fact that all the matches came from sightings made on only 2 days, mostly in the same groups and in localized areas, indicates that whales from the Sakhalin feeding ground associate, at least to some degree, even when utilizing migratory routes in the ENP. These 6 whales were sighted in an area where some whales tend to linger and feed during the northbound migration (Darling et al. 1998). Feeding whales are often found in more nearshore waters and over extended periods of time, potentially making them more likely to be photographed than animals rapidly migrating past the area (Darling et al. 1998, Calambokidis et al. 2010). The long distance and potential open water crossing required for transit from the ENP to the WNP may make it advantageous for whales to spend time feeding in the Pacific Northwest (e.g. Vancouver Island) prior to undertaking a westerly passage to Sakhalin.

The preliminary comparison of the SAK and LSI catalogs revealed 4 additional matches. Since the SAK to LSI catalog comparison was conducted in a non-comprehensive manner, relying on long-term familiarity with whales in the WNP catalog, it is probable that additional matches exist. Given the importance of conducting further comparisons to the wintering lagoons of Baja California, Mexico, a systematic and comprehensive comparison of the SAK catalog to a recently compiled multi-year catalog from LSI and Laguna Ojo de Liebre (Scammon's Lagoon) is presently underway (see IWC 2011).

When the 10 WNP/ENP photo-identification matches reported here are combined with the 2 genetic matches noted by Lang (2010), a total of 12 gray whales (6 males, 5 females and 1 whale of unknown sex) identified in the WNP off Sakhalin Island have been matched to 3 locations in the ENP (Vancouver Island, Southern California, Laguna San Ignacio), providing evidence that both sexes, in approximately equal numbers, move between the WNP and the ENP. Despite this level of mixing, significant mtDNA and nuclear genetic differences between whales utilizing the Sakhalin feeding ground and those summering in the ENP support the continued recognition of Sakhalin animals as a distinct genetic unit (Lang et al. 2011).

Adding to the complexity of mixing between the WNP and ENP are contemporary records of gray whales off Japan and, to a lesser degree, China. As previously mentioned, there have been only 13 records of gray whales in Japanese waters since 1990 (Nambu et al. 2010). One of these reports includes a whale first identified as a calf accompanied by her mother on the Sakhalin Island feeding ground in July and August 2006 that was later fatally entrapped in a set net off the Pacific coast of Honshu (Area 5 in Fig. 1) in January 2007 (Weller et al. 2008). While observations of gray whales in Japan have been made between November and August, most of these records are concentrated between March and May. This March to May period coincides with the sightings in the ENP of the 10 matched whales described here. Observations of gray whales in China are exceptionally rare. Only 24 sightings and/or strandings have been recorded since 1933, including observations of 2 mother–calf pairs (Wang 1984, Zhu 2002). However, a 13 m female gray whale stranded in the Taiwan Strait near the town of Baiqingxiang (Pingtan County), China (Area 6 in Fig. 1), in November 2011 (Zhu 2012). These findings, in combination, suggest that not all gray whales identified in the WNP share a common wintering ground.

The use of photo-identification methods, together with genetic and telemetry techniques, is essential to furthering our understanding of gray whale population structure. We recommend that other existing photo collections and tissue samples of gray whales in the WNP and ENP (e.g. those from Sakhalin, Kamchatka, Chukotka, Mexico, and Japan) be used to further examine gray whale movement patterns and population mixing within the Pacific. Ideally, a collaborative Pacific-wide study should be undertaken, similar in scope to those conducted for humpback whales in the Atlantic and Pacific (Smith et al. 1999, Calambokidis et al. 2008).

Acknowledgements. We thank all who have contributed photographs and data to the WNP and ENP catalogs. D. DeMaster and R. Wulff were instrumental in securing funding for this comparison. J. Cooke, G. Donovan, R. Reeves, and W. Perryman provided valuable insight and encouragement throughout this project. The IWC granted permission for use of photographic data from 2010. The National Marine Mammal Laboratory provided support for portions of the PNW photo-identification studies. The Protected Resources Division, Southwest Fisheries Science Center, National Marine Fisheries Service, National Oceanic and Atmospheric Administration provided support for the participation of R.L.B., A.R.L., and D.W.W.

ABSTRACT

Within the North Pacific, gray whales (*Eschrichtius robustus*) are recognized as distinct eastern and western populations. Although both populations were severely reduced by whaling, the eastern population is generally considered to have recovered while the western population has remained highly depleted. Previous studies have documented genetic differentiation between the two populations on the basis of mtDNA haplotype frequencies. Since mtDNA represents only maternal inheritance patterns, the present study used bi-parentally inherited microsatellite markers (n=13) to measure differentiation between populations as well as to compare levels of nuclear genetic diversity retained in each. Mean levels of genetic diversity, as measured by the microsatellites, were similar between the eastern and western populations, indicating that the western population has retained relatively high levels of nuclear genetic diversity despite its small size. Comparison of microsatellite allele frequencies confirmed that eastern and western populations are genetically distinct. Although highly statistically significant, the level of differentiation between the two populations is relatively low, and sex-specific analyses suggest that some amount of male-biased dispersal may occur between populations. While these results suggest some movements between the eastern and western populations may take place, the maintenance of genetic differences between the two populations supports their recognition as separate eastern and western populations. Future efforts should focus on elucidating the nature and extent of any dispersal which is occurring in order to better understand factors potentially influencing the recovery of the small western population.

INTRODUCTION

Although gray whales (*Eschrichtius robustus*) once inhabited the North Atlantic Ocean (Mead and Mitchell 1984), the current distribution of the species is limited to the eastern and western margins of the North Pacific (Rice and Wolman 1971). Within this region, gray whales are recognized as having distinct eastern and western populations. Eastern gray whales winter in the lagoons and adjacent waters of Baja California, Mexico and then migrate north along the west coast of North America to feed in the Bering and Chukchi Seas during summer (Rice and Wolman 1971), with a small number of animals remaining in more southern waters between northern California and southeastern Alaska during summer months (Darling 1984, Calambokidis *et al.* 2002). For western gray whales, the primary feeding ground is in the coastal waters off northeastern Sakhalin Island, Russia (Weller *et al.* 1999, 2002). The location of the wintering ground(s) for this population remains unknown, but limited information from sightings, strandings, and catches shows that some animals winter in the coastal waters of southern China (Wang 1984, Henderson 1990, Zhu 1998).

Both gray whale populations were greatly reduced by intensive commercial whaling during parts of the 19th and 20th centuries, but the two populations have exhibited different trajectories in abundance following exploitation. Commercial whaling for eastern gray whales ceased in 1936 (Brownell and Swartz 2006), and the population's size has increased since that time (Rugh *et al.* 2005). Eastern gray whales were removed from the U.S. List of Endangered and Threatened Wildlife and Plants in 1994, and recent abundance estimates indicate that the population contains approximately 22,000 animals (Punt and Wade 2010). In the western population, however, hunting continued through at least 1966 (Brownell and Chun 1977). This population was reduced to a much smaller size than the eastern populations and was considered by some to be extinct as recently as the 1970s (Bowen 1974). Today western gray whales exist only as a small remnant population. Recent population assessment utilizing a Bayesian individually-based stage-structure model and photo-identification data collected between 1994 and 2007 projected a median non-calf population size of 130 individuals in 2008, assuming current demographic and population trends continue (Cooke *et al.* 2008). This population was listed as Critically Endangered by the IUCN in 2000 (Weller *et al.* 2002, Baillie *et al.* 2004), and its continued survival is jeopardized by problems associated with small population size (reviewed in Clapham *et al.* 1999), as well as by a wide range of potential anthropogenic threats, including the rapid expansion of oil and gas development on its summer feeding ground off Sakhalin Island, Russia (Weller *et al.* 2002, Reeves *et al.* 2005, IISG 2006) and mortality due to net entrapment while on the migratory route off Japan (Brownell *et al.* 2007, Weller *et al.* 2008b).

Concern for the conservation status of the western population led to the initiation of a joint Russia-U.S. research program in 1995. This program is based on the summer feeding ground off Sakhalin Island, Russia and has incorporated both photo-identification studies and biopsy sampling (Weller *et al.* 1999, 2002). Photo-identification research has shown that most whales demonstrate high rates of annual return and pronounced seasonal site fidelity to the Sakhalin feeding ground (Weller *et al.* 1999, 2002). The majority (83% of identified whales (n=169) have also been genetically sampled, allowing a male bias (58% males) to be documented among sampled individuals (Weller *et al.* 2002, 2008). This male bias is particularly pronounced in individuals first identified as calves, of which 66% are males (Weller *et al.* 2008).

Biopsy samples collected between 1995 and 1999 have been used to show that the eastern and western populations are genetically distinct based on mitochondrial DNA (mtDNA) haplotype frequencies (LeDuc *et al.* 2002). This study found that western gray whales have retained a relatively high number of mtDNA haplotypes for such a small population. Genetic differentiation between the eastern and western populations was based on differences in the frequency distributions of haplotypes within each population. While haplotypes were apportioned relatively evenly among the eastern gray whale samples, the haplotype distribution found within the western gray whale samples was highly skewed, with two haplotypes found in very high frequencies and the remaining haplotypes identified in only one or two individuals (LeDuc *et al.* 2002).

The work presented here used thirteen microsatellite markers to further examine population structure of gray whales. Unlike mtDNA, which is maternally inherited and provides information about historic gene flow of females only, microsatellites are nuclear bi-parentally inherited markers and reflect gene flow of both males and females. The primary goal of this study was to examine genetic differentiation between eastern and western populations using microsatellites, as well as to assess factors which might contribute to that differentiation. Secondarily, levels of nuclear genetic diversity were compared between the two populations to determine if substantial genetic variability has been lost in the much smaller western population and could thus be affecting its ability to recover. Finally, since additional western gray whale samples have been collected since the LeDuc *et al.* (2002) study, further analysis of population structure and genetic diversity using mtDNA was also conducted.

MATERIALS AND METHODS

Sample collection and DNA extraction

One hundred forty-two western gray whale samples were collected between 1995 and 2007 via biopsy darting of free-ranging whales on the population's feeding ground off Sakhalin Island, Russia. All except for one of the western gray whale samples are linked to a photographically identified animal, and this sample set represents 83.4% of all animals (n=169) identified on the western feeding ground through 2007. One hundred thirty-seven eastern gray whale samples obtained from the archive at the Southwest Fisheries Science Center were used for comparison to the western population. These samples were taken primarily from stranded animals (n=105), with some samples obtained from directed subsistence takes (n=12), fisheries bycatch (n=3), and biopsies (n=17) from free ranging whales. Collection locations ranged from southern California north to the Chukotka Peninsula in Russia.

DNA had been previously extracted for 120 of the eastern gray whale samples and 45 of the 142 western gray whale samples (those collected between 1995 and 1999) for use in an earlier study (LeDuc *et al.* 2002). For the remaining samples, whole genomic DNA was extracted using either the QIAGEN DNeasy™ tissue kit or the Corbett Robotics X-tractor Gene robot with the recommended protocols.

Molecular sexing and mtDNA control region sequencing

For those samples (n=114) not analyzed in the prior study by LeDuc *et al.* (2002), molecular sexing and mtDNA control region sequencing were conducted. For all of the eastern gray whale samples as well as the western gray whale samples which were collected prior to the 2006 season (n=94), a polymerase chain reaction (PCR) was used to determine sex utilizing primers described in Fain and Lemay (1995) and following the methods described in Gilson *et al.* (1998). For western gray whale samples collected in 2006 and 2007 (n=20), the protocol described in Morin *et al.* (2005) was used to determine the sex of individuals.

PCR was used to amplify a 523-base-pair fragment from the mtDNA control region using the primers 5'-TACCAAATGTATGAAACCTCAG-3' (H00034, Rosel *et al.* 1995) and 5'-CCTCCCTAAGACTCAAGGAAG-3' (L15812, Escorza-Trevino *et al.* 2005). Amplification products were cleaned through purification columns (QIAquick, Qiagen) and then sequenced using standard protocols with ABI-PRISM® Dye-DeoxyTerminator Big Dye™ v3.1 (Applied Biosystems) and the same primers. Following ethanol precipitation, sequenced products were run on an ABI 3100 or ABI3130 capillary sequencer. Consensus sequences for both strands were generated using ABI SEQSCAPE v2.5 software.

Microsatellite genotyping

Thirteen microsatellite loci isolated from other cetacean species were used to genotype the samples (*Table 1*). Reactions were performed in 25-uL volumes containing approximately 100 ng of genomic DNA and 2.5 uL of 2.0 mM $MgCl_2$ buffer, 1.5 uL of 10 mM dNTPs, 0.75 uL of each primer (at 10uM concentrations, with the forward primer of each pair fluorescently labeled), and 0.25 uL Taq. The thermal cycling profile included an initial hot start of 94°C for 2 min followed by 35 cycles of 94°C for 45 s, 1 min at the annealing temperature (see *Table 1*), and 1.5 min at 72°C, with a final 5-min extension at 72°C. Amplified products were mixed with a size standard and loaded onto an ABI 3100 or ABI 3130 sequencer. Sizing and binning of allele fragments using ABI GENESCAN and GENOTYPER analysis software were automated and relied on the use of internal lane standards, with subsequent manual evaluation of all labeled peaks.

Microsatellite scoring errors and identification of replicate samples

Prior to inclusion in this study, photo-identification data collected during biopsy sampling was used to identify and remove any duplicate samples (*i.e.,* samples taken from the same individual) from the western population sample set. Genotypic data were used to search for duplicates within the eastern gray whale sample set using MS Excel Toolkit v3.1 (Park 2001); one duplicate was identified and removed prior to analyses, leaving a total of 136 eastern gray whale samples. Microsatellite data were also examined for signs of large-allele dropout and null alleles using MICRO-CHECKER v2.2.1 (van Oosterhout *et al.* 2004).

Genetic variability within populations

ARLEQUIN v3.01 (Excoffier *et al.* 2005) was used with the mitochondrial control region data to calculate standard indices of genetic variation (nucleotide diversity, π, and haplotype diversity, *h*; Nei 1987) for each population. Genetic diversity at the nuclear level was characterized by generating the number of alleles, observed heterozygosity, and expected heterozygosity for each microsatellite locus in each population using ARLEQUIN. Within each sample set, a Markov-chain approximation of an exact test, as implemented in GENEPOP v3.4 (Raymond and Rousset 1995a), was used to test for departures from Hardy Weinberg expectations and for linkage disequilibrium between all pairs of loci.

Bottleneck analyses

Populations which have undergone recent bottlenecks are expected to exhibit genetic signatures characteristic of a reduction in effective population size (Cornuet and Luikart 1996, Luikart and Cornuet 1998, Luikart et al. 1998, Garza and Williamson 2001). One such signature is a transient excess of heterozygosity (H_e) relative to that expected in a population of constant size, which results from the rapid loss of rare alleles contributing little to overall heterozygosity (Cornuet and Luikart 1996). Here we utilized the program BOTTLENECK v1.2 (Piry *et al.* 1999) to determine if the gray whale microsatellite data demonstrated evidence of population bottlenecks. As recommended (Piry *et al.* 1999), a two-phase model assuming 95% single-step mutations and 5% multiple-step mutations was employed, with the variance among multiple steps set to 12. The distribution of gene diversity at equilibrium was estimated using a coalescent process with 10,000 simulations, and a one-tailed Wilcoxon test was used to determine if an excess of heterozygosity, relative to that expected in populations at equilibrium, was present (Cornuet and Luikart 1996).

The loss of rare alleles during a population bottleneck may also result in gaps in the size distribution of microsatellite alleles. This can be measured as the mean ratio (*M*) of the number of alleles to the allele size range across all loci (Garza and Williamson 2001); bottlenecked populations demonstrate reduced *M* values. Here we used ARLEQUIN to calculate *M* for both gray whale populations and then compared our values to those reported for reduced and stable populations by Garza and Williamson (2001).

Genetic differentiation among populations:

Two approaches were used to assess the degree of genetic differentiation between the two sampling regions. In the first approach, samples were divided *a priori* into populations based on the geographic location in which they were collected. The extent of genetic differentiation between populations was then examined using both mtDNA sequences and microsatellite data. For mtDNA data, an analysis of molecular variance (AMOVA, Weir and Cockerham 1984, Excoffier *et al.* 1992) was used to generate frequency-based (F_{ST}) estimates of differentiation using the program ARLEQUIN (20,000 permutations were used to test for significance). For microsatellite loci, genetic differentiation was examined using an AMOVA (ARLEQUIN) and allelic frequencies (with 20,000 permutations to test for significance) to generate F_{ST} values (Weir and Cockerham 1984). Modified exact tests based on genotype counts, as implemented in GENEPOP v3.4 (Raymond and Rousset 1995b), were also utilized to measure levels of differentiation. Significance was tested using 10,000 permutations. Since the western gray whale sample set included 57 mother-calf pairings, analyses of genetic differentiation were repeated after removal of the sample representing the calf in each pair, in order to avoid biasing the results by including known first-degree relatives.

As an alternative to *a priori* stratification of samples by geographic location, population structure was also explored using a Bayesian model-based clustering approach (STRUCTURE v2.2, Pritchard *et al.* 2000) with the microsatellite data. STRUCTURE assumes that within a set of samples there are K populations, each of which is characterized by allele frequencies at each locus. The program then divides all samples into K genetically distinct clusters by assigning individuals to putative populations such that Hardy-

Weinberg and linkage disequilibrium are minimized within each group. Five independent runs of K=1-5 were performed with a burn-in period of 50,000 iterations followed by 100,000 Markov-chain Monte Carlo repetitions, using a model based on admixture with correlated allele frequencies (Falush *et al.* 2003). After averaging across runs, the log probability of the data given K (Ln P(X|K) was used as the criterion to infer the number of clusters (K) most compatible with the our data.

Detection of sex-biased dispersal

The potential for sex-biased dispersal between populations was investigated using the microsatellite data with the methods described by Goudet *et al.* (2002) and implemented in FSTAT v2.9 (Goudet 2001). Since the signal of sex-biased dispersal disappears with mating (Goudet *et al.* 2002), animals first sampled as calves in the western population were omitted prior to analysis. This program generates a number of statistics aimed at identifying patterns of sex-biased dispersal. The statistics utilized here were 1) F_{st}, the proportion of genetic variation among populations; 2) the mean corrected assignment index (mAIc) and 3) the variance around the assignment index (vAIc) (Favre *et al.* 1997, Mossman and Waser 1999). The p values were estimated using 10,000 randomizations, and a one-tailed test was utilized based on the expectation that, as in most mammals, dispersal is biased toward males. F_{st} and mAIc are expected to be higher in the more philopatric sex, while vAIc should be lower (Goudet *et al.* 2002).

To further explore the potential for sex-biased dispersal between populations, sex-specific estimates of genetic differentiation were generated using the methods outlined above with both the mtDNA and microsatellite data. In addition, values of cluster membership (Q) produced by the STRUCTURE model assuming K=2 clusters were compared between males and females.

RESULTS

Genetic diversity

Forty haplotypes defined by 39 variable sites were identified from the 278 gray whale samples. Thirty-five haplotypes were found among the eastern gray whale samples, while 22 haplotypes were found in the western gray whale sample set. Seventeen haplotypes were shared between the two populations. The frequency of haplotypes in each population is shown in *Table 2*. When all samples were combined, nucleotide diversity (π) was 0.018 (SD=0.0092), while haplotypic diversity (*h*) was 0.89 (SD=0.012). When subdivided by population, nucleotide diversity was relatively similar in both populations (π=0.016 ±0.0081SD, eastern population; π=0.018 ±0.0093SD, western population), while measures of haplotype diversity were higher in the eastern (*h*=0.95 ±0.006SD) than the western (*h*=0.77±0.025SD) population (*Table 3*). Sex-specific diversity measures indicated that although haplotypic diversity was similar between the male (*h*=0.96) and female (*h*=0.95) subsets of the eastern population, lower levels of haplotype diversity were found among the western female subset (*h*=0.77) when compared to the western male subset (*h*=0.83).

No signal of large-allele dropout or null alleles was identified by MICROCHECKER for any locus in either of the two populations. No deviation from Hardy-Weinberg Equilibrium was detected in either population after controlling for the False Discovery Rate (FDR, Benjamini and Hochberg 1995). After correcting for the FDR, only one loci combination was found to be in significant linkage disequilibrium in the eastern population. However, significant linkage disequilibrium was detected for eight loci combinations in the western population. Given that the same loci pairs were not in disequilibrium in both populations, it is unlikely that this result was derived from physical linkage. Linkage disequilibrium can result from inclusion of related individuals within a sample set. Therefore, known relatives were removed and the tests were rerun on the remaining genotypes. Six loci combinations remained out of linkage disequilibrium after controlling for the FDR.

After averaging across loci, measures of microsatellite diversity were higher in the eastern population (H_o=0.74, H_e=0.74, K=9.8) than in the western population (H_o=0.71; H_e=0.70, A=8.8); however, these differences were relatively small (*Table 4*). A total of 18 private alleles were observed in the eastern population, while only 5 private alleles were found in the western population.

Statistical analysis of the microsatellite allele frequency data using the program BOTTLENECK did not detect evidence of a recent (2-4N_e generations) bottleneck in either population. Under the model utilized, heterozygosity excess was not observed in the eastern (Wilcoxon test, *P*=0.989) or the western population (Wilcoxon test, *P*=0.999). In addition, the calculated *M* values (0.823±0.15and 0.808±0.17) in the eastern and western populations, respectively) were more consistent with those described for stable populations and were considerably higher than the upper bound (0.70) that Garza and Williamson (2001) derived for reduced populations.

Genetic differentiation among populations

Significant genetic structuring between eastern and western populations on the basis of both mtDNA haplotypes and microsatellite allele frequencies was observed (*Table 5*). Similar results were also observed for the microsatellite data when genetic differentiation was assessed using the exact test; the overall results were significant ($p \leq 0.001$), with 11 of the 13 loci showing significant differences when analyzed independently (data not shown). These comparisons remained significant ($P \leq 0.001$) after known relatives (n = 57 calves which had sampled mothers) were removed from the analysis (*Table 5*); however, only three of the thirteen loci showed significant differences when analyzed independently.

STRUCTURE analyses (Pritchard *et al.* 2000, Falush *et al.* 2003) supported the presence of two populations (P ~1.0), with a clear increase in the log-likelihood of the data for K = 2 when compared to that for other numbers of clusters (*Table 6*). The probability that the data contained only one cluster was < 0.001, suggesting that eastern and western populations are not panmictic. When Q values, which represent the proportion of each individual's genotype that can be attributed to each of the clusters, were used to assign individuals into clusters, 80% (n = 109 of 136) of animals sampled in the east were grouped into the same cluster while 65% (n = 92 of 142) of animals sampled in the west were grouped into a cluster (*Figure 1*). However, average source population Q values were relatively low for both populations; they averaged 0.69 (± 0.209SD) for animals sampled in the east and 0.60 (± 0.296SD) for animals sampled in the west.

Sex-specific comparisons

Sex-specific estimates of differentiation were much more marked among females than among males. Using mtDNA haplotype frequencies (*Table 5*), both the male and female comparisons were highly significant, although the F_{st} value estimated for females ($F_{st} = 0.078$) was more than twice as high as that estimated for males ($F_{st} = 0.033$). Interestingly, while the male-specific comparisons remained significant (P = 0.029) in the microsatellite exact test, F_{st} estimates based on microsatellite allele frequencies suggested no significant differences between eastern and western males. The sex-biased dispersal tests in FSTAT also supported greater philopatry among females when compared to males. While difference in males and females were not significant for the mean assignment index (*P* = 0.365) or the variance in the mean assignment index (*P* = 0.9262), females demonstrated significantly higher F_{st} values (*P* = 0.0176).

Results of the STRUCTURE analysis provided further evidence that male-biased dispersal may be occurring. After removing animals first identified as calves, average Q values were similar between eastern males ($Q_{EM} = 0.70 \pm 0.211$SD) and females ($Q_{EF} = 0.67 \pm 0.208$SD, *P* = 0.26, t-test); 80% and 87% of males and females were assigned to their source population. In contrast, average Q values were lower for western males ($Q_{WM} = 0.47 \pm 0.339$SD) than for western females ($Q_{WF} = 0.63 \pm 0.250$; *P* = 0.010, t-test). Only 40% of western males had $Q \geq 0.50$ for the cluster representing the western population, in contrast to 75% of western females.

DISCUSSION

Genetic variability

Populations reduced to small sizes can suffer from a loss of genetic diversity, which in turn may compromise their ability to respond to changing environmental conditions (Willi *et al.* 2006) and negatively influence long-term viability (Spielman *et al.* 2004, Frankham 2005). Although little is known about the level of genetic diversity maintained in the western gray whale population prior to its depletion by commercial whaling, comparison of the levels of diversity found in this small population with those maintained in the much larger population in the eastern Pacific can provide some insight into whether reduced genetic diversity may influence its recovery. Previous studies utilizing mtDNA indicated that while the western gray whale population had retained a relatively high number of mtDNA haplotypes and levels of nucleotide diversity which were concordant with those found in the eastern population, the population had reduced haplotype diversity when compared to its eastern counterpart (LeDuc *et al.* 2002). Our results, using an extended sample set that included ~83% of photographically identified western gray whales, support these earlier findings. As previously noted, the reduced haplotype diversity found in the western population was not a reflection of the number of haplotypes present but rather of the skewed distribution of those haplotypes (LeDuc *et al.* 2002). This skew was even more marked with the added samples. While the frequencies of the two most common haplotypes changed little, new low frequency haplotypes were added, with 14 of the 22 western gray whale haplotypes being found in only one or two animals.

While approximately half (49%) of the mtDNA haplotypes identified in the eastern population were shared with animals sampled in the western North Pacific, a much larger proportion (77%) of the mtDNA haplotypes found in the western population were also identified in eastern animals. Given the relatively thorough sampling of animals on the western feeding ground, it is likely that most if not all haplotypes present in that area have been identified, indicating that the mtDNA haplotypes found only in the eastern Pacific are likely to be unique to that population. In contrast, the low proportion of animals sampled in the eastern population suggests that those haplotypes currently identified only among western animals (n=5) might also be discovered in the eastern population with additional sampling.

Although the relationship between population size and mtDNA diversity is not straightforward (Bazin *et al.* 2006; Nabholz *et al.* 2008), the number of haplotypes (n=22) found in the western gray whale population is surprising given its small size and history of exploitation. In a similar study of endangered North Atlantic right whales (*Eubalaena glacialis*), which are thought to number approximately 400 individuals, only five haplotypes have been documented (n = 180 samples, Malik *et al.* 2000). While sampling in other populations has been less comprehensive, similar patterns have been found in other small mysticete populations, including the Okhotsk Sea bowhead whale population (*Balaena mysticetus*), in which only four different haplotypes were found (n = 25 samples, LeDuc *et al.* 2005), as well as the Sea of Cortez fin whales (*Balaenoptera physalus*), in which three haplotypes have been identified (n = 56 samples, Berube *et al.* 2002). The number of haplotypes found in the western gray whale population is more consistent with numbers found in larger populations, such as the stock of right whales (*Eubalaena australis*) breeding off South Africa, which contains 21 haplotypes (n = 41 samples, Patenaude *et al.* 2007) and has an estimated abundance of 3400 animals (Best *et al.* 2005).

Although the number of haplotypes currently found in the western population is higher than might be expected, this pattern may not persist into the future. Eleven of the 14 haplotypes found in low frequencies have been identified only in a single male. Although little specific information is available on gray whale longevity, they are generally thought to live for approximately 40 to 60 years. It is possible that some of these “rare haplotype” males could be animals that escaped being killed by whalers which hunted gray whales until at least 1966. Given the maternal inheritance pattern of mtDNA, and assuming that these males are indeed the only animals in the population with these haplotypes, the eventual loss of these individuals has the potential to substantially decrease levels of mtDNA diversity in the future.

The level of nuclear genetic diversity found in the western population was slightly lower than, but very similar to, that found in the much larger eastern population. The number of microsatellite alleles found exclusively in the eastern population, however, was markedly higher than the number found in the western population. Given that the western population has been relatively thoroughly sampled, these results suggest that the western population’s depletion and continued small size may have resulted in the loss of rare alleles from the population. No genetic signature of a bottleneck was detected in the western population using the microsatellite data. However, simulations have shown that detection of bottlenecks using genetic methods is dependent on a wide range of conditions, including duration of the bottleneck, mutation rate, pre-bottleneck size, and post-bottleneck recovery (Williamson-Natesan 2005), and many studies have failed to detect the genetic signature of a bottleneck even when demographic data indicate population size collapse (*e.g.*, Queney *et al.* 2000, Spong and Hellborg 2002).

Overall, the western population appears to have retained relatively high genetic diversity despite its history of exploitation and continued small population size. In other populations, the maintenance of genetic diversity in the face of population decline has been attributed to long generation times (Dinerstein and McCracken 1990, Hailer *et al.* 2006, Lippe *et al.* 2006), which are characteristic of baleen whales and may have buffered the population against the rapid loss of variation. However, the relatively high level of genetic diversity that appears to have been maintained in the western population could also be the result of dispersal of eastern animals onto the western feeding ground. Even at low levels, dispersal has been shown to obscure bottleneck signatures (*e.g.,* Kellar *et al.* 2001, Busch *et al.* 2007) and genetically "rescue" populations from the loss of genetic diversity (Vila *et al.* 2003). Further exploration of this possibility is detailed below.

Population structure

The inclusion of additional samples to analyses employing mtDNA supported the previous conclusion that the two populations are genetically distinct (LeDuc *et al.* 2002). Nuclear differentiation estimates further confirm differences between the two populations and indicate that genetic separation between populations is not derived solely from female philopatry. These measures of differentiation remained significant after known first degree relatives (*i.e*., the calf from sampled mother-calf pairs) were removed from the dataset, suggesting that such differences are not solely an artifact of the inclusion of highly related individuals in the analysis.

Although highly significant, the degree of nuclear differentiation, as measured by F_{ST} values, between the two populations is relatively small. This pattern of differentiation is similar to that found in North Pacific bowhead whale populations, which also demonstrate a significant but small degree of differentiation between a smaller western population inhabiting the Okhotsk Sea and a much larger eastern population in the Bering-Chukchi-Beaufort Seas (LeDuc *et al.* 2005). The relatively small but highly significant genetic differences observed in gray whales, particularly when combined with the similar pattern observed in North Pacific bowhead populations, suggests that past Arctic environmental changes may have played a role in influencing patterns of historic mixing and separation of eastern and western animals. Both stranding records and radio-carbon dating of remains have indicated that changes in sea ice distribution may have mediated bowhead whale distribution in the Canadian Arctic (Dyke *et al.* 1996, SaVelle *et al.* 2000). Within the North Pacific, Arctic-wide cooling and glaciation brought on by the "Little Ice Age" (~400-750 years ago) may have resulted in a southern shift in sea ice distribution and reduced sea level (Overpeck *et al.* 1997), potentially facilitating mixing between eastern and western whales. Sea ice expansion during the Neoglacial (~4700 to 2500 years ago) may also have limited access to parts of the Bering Sea and has been hypothesized to have altered the distribution of North Pacific pinnipeds and cetaceans (Crockford and Frederick 2007).

A second explanation for the low level of differentiation is that some limited gene flow could be occurring between the two populations. Given the small size of the western population, it seems likely that even minimal gene flow from the eastern to the western population would quickly homogenize allele frequencies. However, genetic drift also acts more strongly on small populations, allowing differences between populations to develop more rapidly. As such, genetic drift could be acting to counterbalance some restricted degree of genetic interchange between populations.

A third scenario which might also explain our results involves dispersal of whales between feeding areas without genetic exchange. Since breeding in gray whales is thought to primarily occur along migratory corridors (Rice and Wolman 1971), movement between feeding regions does not necessarily imply gene flow between the populations. Given that all of the western gray whale samples were obtained on the feeding ground, low differentiation levels could potentially be generated by a small number of eastern gray whales traveling to the western gray whale feeding ground during summer months and consequently being sampled while mixed with members of the western population. If these eastern dispersers visit the western feeding ground but return to the eastern Pacific to breed, such extralimital movements would act to reduce measured levels of genetic differentiation between populations in the absence of significant gene flow.

Some support for a limited degree of dispersal and/or gene flow between populations can be derived from the results of the sex-specific comparisons. If the observed low level of differentiation were due to recent divergence, similar patterns of differences should be observed for males and females. Contrary to this expectation, all measures of differentiation were at least twice as high for female-only versus male-only comparisons. In addition, although comparisons between males remained significant for mtDNA, the F_{st}-based comparison of microsatellite allele frequencies did not identify significant differences among males, suggesting that some degree of male-biased dispersal may be occurring between populations. Such a pattern could also provide an explanation for the large proportion of mtDNA haplotypes (11 of 22) in the western population which are represented only by a single male. Given the higher diversity and number of mtDNA haplotypes found in the eastern population, any dispersers from the east would have a relatively high probability of carrying haplotypes considered "rare' in the west (LeDuc *et al.* 2002). Eight of the eleven haplotypes carried by only a single male in the west were also found in the east; given the low proportion of sampled animals in the east, it is plausible that the other three haplotypes would also be identified among eastern animals with additional sampling.

Although the analyses summarized here are not able to discriminate between gene flow and feeding ground dispersal, a combination of genetic assignment tests and parentage analysis in the future may be useful to distinguish between these two possibilities. In addition, simulation modeling could be utilized in the future to determine the degree of gene flow or feeding-ground dispersal which could occur while still allowing the two populations to maintain genetic distinctiveness.

Conclusions and conservation implications

The results presented here support past work indicating that eastern and western populations are genetically distinct, further highlighting the need for continued conservation and expanded protection of the critically endangered western gray whale population. Although highly statistically significant, the level of differentiation between the two populations is relatively low, which may reflect recent divergence of the two populations, perhaps mitigated by past environmental changes, but could also suggest that some limited degree of dispersal and/or gene flow may occur between the two populations. Discrimination between these proposed explanations is important, given that each scenario could have different effects on the recovery of the critically endangered western population. If a restricted amount of gene flow is taking place, that interchange could be important in providing "genetic rescue" for the western population, helping to maintain relatively high levels of genetic diversity in a small population which would otherwise likely suffer from inbreeding and a subsequent loss of fitness. However, if dispersal between feeding grounds without any gene flow is occurring, then any eastern dispersers are not contributing to the gene pool but could be artificially inflating our estimates of both genetic diversity and population size, which would suggest that the western population is even more vulnerable than currently thought. Given the wide range of threats, including entrapment in fishing nets as well as expanding oil and gas development, which challenge the recovery of the western gray whale population, further exploration of possible mechanisms of intermixing is needed to better understand the dynamics of this critically endangered population.

ACKNOWLEDGEMENTS:

Much appreciation goes to the many participants of the western gray whale research team, especially A. Bradford, Y. Ivashchenko, H.W. Kim, S. Reeve, M. Sidorenko, and G. Tsidulko. Support and funding for western gray whales studies have been provided by (in alphabetical order): Alaska SeaLife Center, Animal Welfare Institute, Exxon Neftegas Limited, the International Fund for Animal Welfare, the International Whaling Commission, the Marine Mammal Commission, the Marine Mammal Research Program at Texas A&M University at Galveston, the National Fish and Wildlife Foundation, the National Marine Fisheries Service, the NOAA Dr. Nancy Foster Scholarship Program, Ocean Park Conservation Foundation Hong Kong, Sakhalin Energy Investment Company, the U.S. Environmental Protection Agency, and the Washington Cooperative Fish and Wildlife Research Unit. This project was conducted as part of the

Marine Mammal Project under Area V: Protection of Nature and the Organization of Reserves within the U.S.-Russia Agreement on Cooperation in the Field of Environmental Protection.

ABSTRACT

Although the majority of Eastern North Pacific (ENP) gray whales spend their summers feeding in the Bering, Beaufort, and Chukchi Seas, a small number of individuals, referred to as the Pacific Coast Feeding Group (PCFG), feed in waters between northern California and southeastern Alaska during summer and fall. Many individuals identified within this southern feeding area demonstrate intra- and inter-seasonal fidelity to the region, suggesting that structure could be present among ENP gray whales utilizing different areas for feeding. Little is known, however, about patterns of site fidelity of individuals feeding in northern waters. We utilized samples collected from individual gray whales within both southern (n=100) and northern (n=106) feeding areas to assess possible stock structure using both mtDNA control region sequences and 8 microsatellite markers. Significant mtDNA differentiation was found when the subset of samples representing individuals (n=71) sighted over two or more years within the seasonal range of the PCFG were compared to the combined set of samples collected from the northern feeding area(s) (F_{ST}=0.01, p=0.005; Fisher's exact test, p=0.008) as well as when the PCFG samples were compared to only those samples which were collected off Chukotka, Russia (n=71, F_{ST}=0.01, p=0.012; Fisher's exact test, p=0.030). No significant differences were found for any of the comparisons utilizing microsatellites. These results indicate that structure is present among gray whales utilizing different feeding areas and suggest that matrilineal fidelity plays a role in creating such structure. The lack of differentiation detected using nuclear markers (χ^2 test, p=0.636, PCFG versus northern; p=0.753, PCFG versus Chukotka) suggests that individuals from different feeding areas may interbreed. These results are important in evaluating the management of the ENP gray whale population, especially in light of the Makah Tribe's proposal to resume whaling in an area of the Washington coast utilized by both feeding and migrating whales. Although the proposed hunt is designed to target whales migrating to/from the northern feeding grounds, the possibility of taking a PCFG whale cannot be eliminated. Increasing our understanding of recruitment into this group is needed to assess potential impacts of a hunt.

INTRODUCTION

The current distribution of gray whales is limited to the eastern and western margins of the North Pacific (Rice & Wolman, 1971), where a small western population (~130 individuals, Cooke *et al.,* 2008) and a much larger eastern population (~19,000 individuals based on surveys in 2006/2007, Laake *et al.,* 2009) are recognized. Much of what is known about the western population is derived from photo-identification and genetic studies of individuals on the population's primary feeding ground, which is located in the coastal waters of northeastern Sakhalin Island, Russia (Weller *et al.,* 1999; Weller *et al.,* 2008; LeDuc *et al.,* 2002; Lang *et al.,* 2010). Photo-identification studies have documented seasonal site fidelity and annual return of individuals to this feeding area (Weller *et al.,* 1999). Reproductive females are known to utilize the Sakhalin feeding ground in years when they are accompanied by calves as well as when they are pregnant or resting, and the return of many individuals first identified as calves accompanying their mothers has been documented (Weller *et al.,* 2009). Genetic comparisons of samples collected from gray whales feeding off Sakhalin with samples collected from whales in the eastern North Pacific (ENP) have supported recognition of the two populations as distinct, with differentiation in both mtDNA haplotype and microsatellite allele frequencies (LeDuc *et al.,* 2002; Lang *et al.,* 2010).

Gray whales in the ENP population feed in waters between California and the Bering, Beaufort, and Chukchi Seas during summer and fall. Most of the population then migrates south along the coast of North America to overwinter in the lagoons and coastal waters of Baja Mexico. Three primary calving lagoons are utilized, with some females known to make repeated returns to specific lagoons (Jones, 1990). Genetic studies have demonstrated small but significant mtDNA differentiation between females (mothers with calves) utilizing two of the primary calving lagoons and females sampled in other areas (Goerlitz *et al.,* 2003). An additional study, utilizing both mtDNA and microsatellites with samples collected from all three of the primary calving lagoons, also identified small but significant departure from panmixia between two of the lagoons using nuclear data, although no significant differences were identified using mtDNA (Alter *et al.,* 2009).

Sub-structuring within the feeding range of the eastern population could also be present. Although little is known about fidelity of gray whales feeding north of the Aleutians, a small number of individuals, referred to as the Pacific Coast Feeding Group (PCFG; IWC, 2010), are known to show fidelity to more southern feeding grounds located in the coastal waters between northern California and southeastern Alaska (Gilmore, 1960; Pike, 1962; Hatler & Darling 1974; Darling, 1984; Calambokidis *et al.,* 2002, 2010). Within these waters, photo-identification research, which commenced in the early 1970s, has identified some whales that demonstrate consistent return to specific areas within this larger region, although movements between areas within the region also occur regularly (Hatler & Darling, 1974; Darling, 1984; Calambokidis *et al.,* 2002, 2010). In addition, photographic evidence has shown that some whales considered part of the PCFG move at least as far north as Kodiak Island, Alaska (Calambokidis *et al.,* 2010, Gosho *et al*., 2011). Recent estimates of the annual abundance of the PCFG suggest that at most a few hundred individuals utilize this feeding area (Calambokidis *et al.,* 2010).

Satellite tagging studies of 18 whales off the coast of Oregon and California have provided additional information on the movements of individual whales considered part of the PCFG (Mate *et al.,* 2010). Although the duration of tag attachment differed between individuals, movement patterns of the tagged animals were variable, with some individuals remaining in a relatively small area within the larger PCFG seasonal range and others traveling more widely. Only two of the eighteen whales moved north of Washington while tagged; one of these animals traveled at least as far north as southeastern Alaska (Mate *et al.*, 2010). All six of the individuals whose tags continued to transmit through the southbound migration utilized the wintering area within and adjacent to Laguna Ojo de Liebre. Although this lagoon is by far the most heavily used of the three major wintering lagoons, these results raised the possibility that PCFG whales may demonstrate philopatry to this particular wintering area (Mate *et al.,* 2010).

Concern for the PCFG of gray whales has stemmed in part from recent interest in the resumption of whaling by the Makah Tribe in northwest Washington, an area used by migrating whales as well as by whales considered part of the PCFG. The current proposal by the Makah Tribe includes time/area restrictions which will limit the hunt to between 1 December and 31 May and will not allow hunting in the Strait of Juan de Fuca east of Cape Flattery. The Makah Tribe also proposes to compare photographs of any whales harvested in the hunt to a photo-identification catalogue of known PCFG whales and to suspend the hunt for the year if the number of known PCFG gray whales struck is equal to the annual allowable bycatch level calculated for the PCFG (Makah Tribal Council, 2011). These restrictions are designed to reduce the probability of killing a PCFG whale and to focus the hunt on whales migrating to/from feeding areas north of the PCFG. Nevertheless, it is impossible to ensure that no PCFG whales would be killed. Evaluating whether such kills would, over time, have the potential to deplete the PCFG requires an understanding of how individuals are recruited into the group. If recruitment into the area is exclusively driven by calves learning the location of feeding grounds from their mothers (i.e., internally), then a PCFG individual that is removed would not be replaced by immigration. However, if recruitment is largely external, such that some whales stop to feed during the migration and then return to the PCFG area as their primary feeding destination in subsequent years, then it is likely that any takes from the PCFG would be offset by immigration into the group by whales that in previous years fed in northern areas.

Understanding recruitment into the PCFG is relevant to management under the Marine Mammal Protection Act (MMPA). The goal of the MMPA is to maintain population stocks as functioning elements of their ecosystem. The National Marine Fisheries Service considers stocks to be demographically independent units, such that the population dynamics of the affected group is more a consequence of births and deaths within the group (internal dynamics) rather than of immigration or emigration (external dynamics). Thus, the exchange of individuals between population stocks is not great enough to prevent the depletion of one of the populations as a result of increased mortality or lower birth rates (NMFS, 2005).

Previous genetic studies of the PCFG whales have focused on evaluating patterns of recruitment. Initial work utilizing a simulation-based approach indicated that if the PCFG originated from a single recent colonization event in the past 40 to 100 years, with no subsequent external recruitment into the group, detectable mtDNA genetic differentiation would be generated (Ramakrishnan & Taylor, 2000). Subsequent empirical analysis, however, failed to detect such a signal when comparing 16 samples collected from known PCFG whales utilizing Clayoquot Sound, British Columbia, with samples (n=41) collected from individuals presumably feeding in more northern areas (Steeves *et al.,* 2001). Additional genetic analysis utilizing an extended set of samples (n=45) collected from whales within the range of the PCFG indicated that the level of genetic diversity and the number of mtDNA haplotypes identified were inconsistent with measures, based on simulations, which would be expected if recruitment into the group were exclusively internal (Ramakrishnan *et al.,* 2001). However, both simulation-based studies focused on evaluating only the hypothesis of founding by a single and recent colonization event and did not evaluate alternative scenarios, such as limited dispersal of whales from other areas into the PCFG, which could have implications for management (Ramakrishnan and Taylor 2000, Ramakrishnan *et al.,* 2001). More recently, Frasier *et al.* (In press) have shown significant levels of mtDNA differentiation when comparing samples collected from 40 individuals considered part of the PCFG with published data generated from 104 samples collected from ENP gray whales, most of which stranded along the migratory route (LeDuc *et al.,* 2002). These results suggest that matrilineally directed fidelity may play a role in use of this area and led the authors to support recognition of the PCFG as a distinct management unit.

The lack of available samples collected from gray whales feeding in northern areas has limited previous genetic studies from directly addressing the potential for demographic independence among whales utilizing different feeding regions within the ENP. Here we use samples collected from various locations north of the Aleutians as well as samples collected from within the seasonal range of the PCFG. A high proportion of the samples collected north of the Aleutians were collected from individuals harvested off Chukotka, Russia, where between 111 and 134 whales per year have been taken during aboriginal whaling over the last decade (IWC, 2010). We also increased the number of samples collected from whales within the seasonal PCFG range and, for those samples linked to photographed individuals, were able to further refine our representation of the PCFG by incorporating sighting histories of known individuals in some comparisons.

The primary goal of this study was to evaluate whether multiple demographically independent units of gray whales exist on feeding grounds, with a special focus on comparing PCFG whales with whales utilizing northern feeding areas. Although other scenarios are possible, here we test three hypotheses using data from both mitochondrial and nuclear markers (n=8 microsatellite loci):

1. No population structure (e.g., panmixia) is present among gray whales utilizing feeding areas in the ENP; individuals move between feeding areas and exhibit random mating. This hypothesis would be supported by a finding of no nuclear or mitochondrial differentiation between samples collected in northern versus southern feeding areas.
2. Utilization of feeding areas is influenced by internal recruitment, with calves following their mothers to feeding grounds and returning in subsequent years. Mating is random with respect to feeding ground affiliation. This hypothesis would be supported by a finding of significant differences in mtDNA haplotype frequencies when comparing samples collected on northern versus southern feeding grounds, but no significant differences are expected in microsatellite allele frequencies between groups of samples from specific geographic areas (i.e., "strata").
3. Utilization of feeding areas is influenced by matrilineal fidelity and mating is not random with respect to feeding ground affiliation. This hypothesis would be supported by a finding of significant differences in both mtDNA haplotype and microsatellite allele frequencies.

Support for the second hypothesis would indicate that groups of individuals feeding in northern and southern areas are demographically independent but not reproductively isolated, while support for the third hypothesis would provide support for both demographic independence and reproductive isolation.

METHODS

Sample Collection

A total of 277 samples were processed for this study. The majority of samples (n=185, including all samples collected between Northern California and British Columbia, Canada) were collected as biopsies from free-ranging individuals, with the remainder collected from individuals taken as part of the subsistence whaling (n= 75 samples from Chukotka) or from stranded individuals (n=17). Collection locations ranged from northern California to Barrow, Alaska and Chukotka, Russia (Figure 1).

For each of the biopsy samples collected, efforts were made to obtain a photograph of the biopsied whale. For whales biopsied between northern California and British Columbia, Canada, photographs were compared to photo-identification catalogues maintained by Cascadia Research Collective. This approach allowed sighting histories of individual individuals to be linked to samples and utilized (as described below) in the stratification of samples for comparisons.

Figure 1 shows that most of the PCFG samples utilized in this study came from the southern portion of the PCFG range. Although the original design of the study was to have both a Russian and a Barrow, Alaska strata, the sample size for the latter (n=14) was insufficient to characterize genetic frequencies from that area. We were therefore unable to directly address hypotheses about whether there are multiple demographically independent feeding units to the north of the Aleutian Islands.

Laboratory Processing

DNA extraction, PCR Amplification and Sequencing – DNA was extracted from samples using standard protocols. The 5' end of the hyper-variable mtDNA control region was amplified from extracted genomic DNA, using the polymerase chain reaction (PCR) and then sequenced using standard techniques (Saiki *et al.,* 1988; Palumbi *et al.,* 1991). DNA was amplified using a 25 ul reaction of 1ul DNA, 18.25 ul of water, 2.5 ul of buffer [10 mM Tris-HCl (pH 8.3), 50 mM KCl, 1.5 µl of 10 mM dNTP], 0.75 µl of each 10 µM primer, and 0.25 ul of Taq DNA polymerase. The PCR cycling profile consisted of 90°C for 2 min, followed by 35 cycles of 94°C for 50 sec, an annealing temperature of 60°C for 50 sec, and 72°C for 1 min, then a final extension of 72°C for 5 min. A 523 base pair region of the 5' end of the mtDNA control region was amplified using primers B (5'-TACCAAATGTATGAAACCTCAG - 3'; Rosel *et al.,* 1995) and TRO (5′- CCTCCCTAAGACTCAAGG-3′; developed at SWFSC). Both strands of the amplified DNA product were sequenced independently as mutual controls on the Applied Biosystems Inc. (ABI) model 3730 sequencer. All sequences were aligned using Sequencher v4.8

software (Gene Codes Corp., 2000). If discrepancies were found within the replication the sample was re-sequenced from extracted DNA. If the discrepancy was still not resolved, DNA was re-extracted from tissue and the sample was resequenced until the haplotype was confirmed. For a small number of samples (n=4), the mtDNA sequence contained an ambiguous base call which could not be resolved; these samples were excluded from the mtDNA analysis. In addition, if a sample was identified as having a mtDNA haplotype that was not found among any of the other samples, mtDNA amplification and sequencing was replicated to confirm the haplotype identity.

Nuclear DNA processing – Eight microsatellite loci isolated from other cetacean species were used to genotype the samples (Table 1). Extracted DNA was amplified using a 25 µl reaction of 1 µl of DNA, 18 µl of MilliQ water (Millipore, Bedford, MA), 2.5 µl of 10x PCR buffer (500 mM KCl, 100 mM Tris-HCl, pH 8.3, and 15 mM $MgCl_2$), 1.5 µl of 10 mM dNTP, 0.75 µl of each 10 µM primer, and 0.5 units of Taq DNA polymerase. The PCR cycling profile included 90 °C for 2.5 min, followed by 35 cycles of 94 °C for 45 sec, 1 min at the optimal annealing temperature (Table 1), and 72 °C for 1.5 min, then a final extension of 72 °C for 5 min. PCR products were assessed electrophoretically. Genotype data was generated on ABI's 3730 genetic analyzer and analyzed with ABI's Genemapper (version 4.0) software.

Sex determination - Samples were genetically sexed by amplification and Real-Time PCR (MX3000p, Stratagene Inc) of the zinc finger (ZFX and ZFY) genes. Sex was determined by the amplification pattern: males had two products and females had one (Morin *et al.,* 2005).

Quality Control – Quality control and sample tracking procedures, as detailed in Morin *et al.* 2010, were implemented for all laboratory processing by incorporating control samples (negative and positive) into all amplifications. In addition, a set of samples were randomly chosen to act as replicates for error tracking and error rate estimation. For these samples ("random replicates"), which represented ≥10% of all samples processed, the mtDNA sequence, sex, and microsatellite genotype were re-generated from DNA for each sample.

Analysis

Stratification of Samples – Two stratification hypotheses were tested in the analysis. The "Northern versus Southern" hypothesis assumed that individuals utilize each of these general regions in a relatively uniform manner such that sampling location within each stratum does not matter. The stratification used for the Northern-versus-Southern hypothesis included all samples described above (Figure 1). Those samples which were collected north of the Aleutian Island Chain were included in the "North" stratum, while all samples collected between northern California and southeastern Alaska (i.e. from within the described range of the PCFG) were included in the "South" stratum (Figure 1).

The second hypothesis is referred to as the "Fine-scale Feeding Aggregation" hypothesis. This hypothesis considers that there may be multiple feeding aggregations north of the Aleutians and hence sampling location within each stratum does matter. The only fine-scale area that was sampled adequately to capture genetic frequencies in the "North" stratum included the individuals hunted off Chukotka (Figure 2). The "Fine-scale Feeding Aggregation" hypothesis also used more stringent criteria than location and season to define individuals assigned to the PCFG stratum. The rationale for more stringent criteria is that photo-identification studies have indicated that whales utilizing the PCFG's seasonal range fall into two categories: 1) whales that return frequently and account for the majority of sightings, and 2) apparent stragglers from the migration that are sighted in only one year (Calambokidis *et al.,* 2010). The criteria for assigning samples to the PCFG stratum were intended to make this stratum representative of the first category of whales. Inclusion in the PCFG stratum for the "Fine-scale Feeding Aggregation" hypothesis relied on two criteria: 1) the sample was linked to a photographed animal with high or medium confidence, and 2) the photographed animal had been sighted two or more years within the season (June – November) and area representative of the PCFG.

Data Review – To avoid including duplicate samples, the Excel Microsatellite Toolkit (Park, 2001) was used to identify samples with identical genotypes, indicating that they may have been collected from the same animal. These sample pairs were then checked to see if they also shared the same mtDNA haplotype and sex, and, when possible, photo-identification records were used to confirm the genetic match. For all samples which shared identical mtDNA haplotypes, sexes, and genotypes, one sample from each pair was removed.

Genotyping Error Rate – For all plates of samples used to generate microsatellite genotypes, a random subset of samples, representing >10% of the samples on each plate, were assigned as replicates. Replicate and original genotypes were compared, and a per-allele error rate was calculated by determining the number of discrepant allele calls divided by the total number of allele calls compared across all loci.

Genetic Diversity – For the mtDNA, haplotypic diversity (h) and nucleotide diversity (π) were calculated using Arlequin 3.5.1.2 (Excoffier *et al.,* 2005). For the microsatellite data, the number of alleles per locus and observed and expected heterozygosities were calculated using custom R-code (eiaGenetics, available upon request[1]). Fstat (Goudet 1995) was used to calculate allelic richness for each stratum. Deviations from Hardy-Weinberg equilibrium (HWE) were assessed for each microsatellite locus using Genepop (version 4.0.11, Rousset 2008). Both the probability test (Guo & Thompson, 1992) and the test for heterozygote deficiency (Rousset and Raymond 1995) were conducted using the program defaults for the Markov chain parameters (10,000 dememorization steps, 20 batches, 5000 iterations/batch). Genepop was also used to test for linkage disequilibrium (LD) for each pair of loci. All tests were run for the combined dataset as well as for each stratum, and a sequential Bonferroni correction was applied across all tests for each stratum.

Genetic Structure – Pairwise estimates of genetic divergence were calculated using both F_{ST} and and Φ_{ST} (based on pairwise differences between sequences as the measure of genetic distance) for the mtDNA data as implemented in Arlequin 3.5.1.2 (Excoffier *et al.,* 2005). Statistical significance was assessed using 20,000 permutations. Fisher's exact test (Raymond & Rousset, 1995) was also used to test for mtDNA differentiation between strata using 100,000 replications to test for significance.

For the microsatellite data, F_{ST} (Weir &Cockerham, 1984), Jost's D (Jost, 2008), and a χ^2 test were used to assess genetic differentiation. These tests were implemented using custom code (eiaGenetics[1]) written in the statistical program language R (R Core Development Team, 2009). Statistical significance was determined from 10,000 permutations of each data set.

RESULTS

Data Review - Fifteen samples (including n = 11 samples collected from stranded whales) amplified at ≤5 microsatellite loci and were removed from the analysis. The remaining samples were genotyped for at least seven of the eight microsatellite loci. Fifty-six samples had microsatellite genotypes, mtDNA haplotypes, and sexes which matched at least one other sample in the dataset; these samples were removed from further analysis. No movements of animals between regions representing different strata were identified based on genetic matches (i.e., all samples sharing identical genetic profiles were part of the same stratum).

Genotyping Error Rate – Based on the samples randomly chosen for replication, a per-allele error rate of 0.16% was detected for the microsatellite data.

Genetic Diversity – Thirty-nine mtDNA haplotypes defined by 37 variable sites were identified from the 202 gray whale samples representing unique individuals (Table 2). Haplotype diversity (h) was high in all four strata ("Northern v. Southern" and "Fine-scale Feeding Aggregations") defined for the analysis (0.945 - 0.953). Nucleotide diversity (π) was also similar among the four defined strata (1.4 – 1.6%).

The frequency of each haplotype in the defined strata (including Barrow) is shown in Table 3. For the "Fine-scale Feeding Aggregations" strata, eighteen haplotypes were shared between Chukotka and the PCFG, with nine haplotypes found only in Chukotka and five haplotypes found only in the PCFG. For both Chukotka and the PCFG, many haplotypes were found in only one individual (n=12 haplotypes in Chukotka, n = 8 haplotypes in the PCFG).

The median-joining network shows the relationship among mtDNA haplotypes and their frequency in each stratum (Figure 4). MtDNA haplotypes from both Chukotka and the PCFG are dispersed throughout the network, and no phylogeographic pattern is apparent.

---

[1] Contact E. Archer @Eric.Archer@noaa.gov

A summary of microsatellite diversity for each locus is shown in Table 4. None of the tests for HWE were significant after the correction for multiple tests was applied. Significant linkage disequilibrium was found for only one pair of loci (EV14t and Gt023t) in the PCFG strata. No significant LD was found for these two loci in any of the other strata or for the combined dataset, so these loci were retained for the analysis.

Measures of genetic diversity for each stratum after averaging across loci are shown in Table 5. As in the comparisons of mtDNA diversity, nuclear diversity was similar across all strata.

Sex Ratio – A female bias was present among the samples, ranging from 1.3 – 1.5 females per male in each stratum (Table 6). This female bias is similar to that (1.47 females per male) described in Frasier *et al.* (In press) but contrasts with earlier studies (Steeves *et al.,* 2001; Ramakrishnan *et al.,* 2001). The male bias (1.7 males per female) described in Steeves *et al.* 2001 was based on a small sample size (n=16 samples). When the gender determination method utilized here was applied to the sample set used in the Ramakrishnan *et al.* 2001 study, only a slight male bias was identified (1.25 males/female). These results contrast with those presented in Ramakrishnan *et al.* (1.8 males/female) and indicates that an issue with the gender determination assay used at that time was responsible for falsely identifying some samples as males.

Genetic Structure – The results of the mtDNA comparisons are shown in Table 7. Low but statistically significant differences were detected when the PCFG stratum was compared with the North stratum (Φ_{ST} = 0.030, p= 0.0118; F_{ST}= 0.010, p=0.0052; Fisher's exact test p=0.0080) and with the Chukotka stratum (Φ_{ST} = 0.020, p=; F_{ST}= 0.012, p=0.0295; Fisher's exact test p = 0.0304). The F_{ST} comparisons for mtDNA were also significant when the North and South strata were compared (F_{ST}=0.007, p = 0.0272), although none of the other mtDNA comparisons involving the South stratum demonstrated significant differences. None of the comparisons across strata utilizing the microsatellite data were significant (Table 8), providing no evidence of nuclear structure among feeding areas.

DISCUSSION

The results presented here are consistent with the second hypothesis that was evaluated, indicating that utilization of at least some feeding areas is influenced by internal recruitment (e.g., matrilineal fidelity), but that individuals from different feeding grounds interbreed. The extent of differentiation, while significant, was low and was detected only in the mtDNA comparisons. Diversity within the PCFG strata was high and similar to that found among strata in the north.

The low level of mtDNA differentiation between strata, as well as the high diversity found in the PCFG, could be a reflection of relatively recent colonization (or re-colonization following depletion of the population by commercial whaling) of the PCFG area. If recruitment into the PCFG is driven exclusively by the return of individuals which followed their mothers to the area as calves, then over time those mtDNA haplotypes originally found only in males or non-reproducing females would be removed via genetic drift, while haplotypes found in females and their returning offspring would build to higher frequencies. By this process, genetic differences would develop between the PCFG and other feeding aggregations, and, given its small size, the PCFG would be expected to maintain low haplotypic diversity. However, if colonization of the PCFG area occurred relatively recently, strong mtDNA differences between the PCFG and individuals feeding further north may not have had time to develop, and the number and distribution of haplotypes in the PCFG may not yet have been affected by genetic drift.

The low level of mtDNA differentiation and high diversity is also consistent with a scenario in which the population structuring is largely driven by matrilineal fidelity (perhaps over longer time scales) but in which some low-level external recruitment also occurs. Some degree of external recruitment would slow the accumulation of genetic differences between the PCFG and northern individuals. As well, external recruits would likely carry haplotypes not previously found among PCFG individuals and would increase the number and diversity of haplotypes found.

These two explanations are not exclusive, and it is plausible that some combination of these scenarios (recent colonization and/or low-level external recruitment) may be occurring. The origin of the PCFG is unknown, and use of the area may date back to the "Little Ice Age" [ca. 1450-1850] when access to the Bering Sea feeding areas would have been limited by heavy ice and some whales may have started to use the PCFG range. Gray whales have been recorded feeding in the southern portion of the PCFG range as early as 1926, when a single gray whale, which was reported to have been feeding with four other whales, was taken by the Trinidad whaling station off the entrance to the Crescent City Harbor in July (Howell & Huey, 1930). The repeated return of individual whales to the area was first documented starting in the 1970s (Hatler & Darling, 1974; Darling, 1984). Photo-identification studies have identified some individuals that have consistently returned to the PCFG seasonal range over time, including some known reproductive females and their calves (Calambokidis *et al.,* 2010). However, "new" whales continue to appear annually and many are resighted in subsequent years (Calambokidis *et al.,* 2010). These new individuals may be internal recruits that were not sighted as calves, but could also be external recruits that return to the area following a successful feeding season. Even if some low-level external recruitment to the area is occurring, however, the differences in mtDNA haplotype frequencies observed in our comparisons indicate that matrilineal fidelity to the area does occur and is important in influencing population structure on the feeding grounds utilized by ENP gray whales.

Conception in gray whales is thought to primarily occur during a three week period between late November and early December (Nov 27 – Dec 13), although if no conception occurs during this first period, a second estrus may occur about 40 days later when whales are on or near their wintering grounds (Rice & Wolman, 1971). Rugh *et al.* (2001) estimate that the median (peak) sighting dates for the southbound migration are 12 December for Unimak Pass, Alaska, suggesting that many gray whales would be north of the PCFG seasonal range during the first mating period. In addition, of the eight individuals which had retained their satellite tags when they started the southbound migration, four (two males and two females) remained on the PCFG feeding ground after mid-December, with two staying until mid-January or later (Mate *et al.,* 2010). These findings raise the possibility that some segregation in breeding could occur based on feeding ground affiliation. However, while the results of the mtDNA comparisons indicate that matrilineal fidelity is generating structure among feeding areas utilized by ENP gray whales, the lack of differentiation found in the nuclear comparisons supports mixing of individuals from different feeding areas while breeding.

The genetic signal of matrilineal fidelity in the PCFG is less marked than that seen among gray whales feeding off Sakhalin Island in the western North Pacific (WNP). Although significant differences in F_{ST} and Φ_{ST} were observed in the mtDNA comparisons between the PCFG and the northern strata, the magnitude of differentiation is lower than that seen in the WNP versus ENP comparisons (F_{ST}=0.068, p≤0.001; Lang *et al.,* 2010). In addition, a pattern of matrilineal fidelity to the area is also reflected in the distribution of haplotypes among individuals in the western population, such that two haplotypes are found in very high frequencies (representing 36% and 31% of all sampled individuals, Lang *et al.,* 2010). This pattern would be expected if utilization of this area was driven in large part by the continued return over time of a small number of females and their offspring (and eventually their offspring's offspring), and examination of the haplotypes carried by individuals revealed that 16 of the 23 known reproductive females (between 1995 and 2007, Weller *et al.,* 2008) share one of these two common haplotypes (Lang, 2010). In the PCFG stratum, however, the three highest frequency haplotypes are found in only 10 to 13% of sampled individuals, which is consistent with more recent colonization of the PCFG area by a relatively large number of founders. In addition, genetic differentiation based on microsatellite allele frequencies was observed between the Sakhalin and ENP strata (F_{ST} = 0.009, p≤0.001; Exact test, p≤0.001), indicating that, unlike what has been suggested in the PCFG, some degree of reproductive isolation also occurs between these groups.

The results presented here are consistent with those presented in Frasier *et al*. (In press), which also found evidence of maternally driven structure when comparing samples collected from PCFG whales with samples from LeDuc *et al*. 2002, which were collected primarily from animals which stranded along the migratory route. The samples utilized in the Frasier *et al*. (In press) study were all collected from Clayoquot Sound, British Columbia. In contrast, the majority of samples representing the PCFG in this study were collected from animals in the waters off northern California, Oregon, and Washington, with only 11 samples collected from waters off British Columbia. Although some whales are known to move throughout the range of the PCFG, sightings of most whales are concentrated within subareas of the range (Calambokidis *et al*. 2010). This pattern is illustrated in Figure 7 of Calambokidis *et al.* (2010), which shows the distribution of latitudes of sightings for whales with 6 or more sightings after 1 June from 1998-2008. The patterns evident in this figure reveal that individual gray whales do not utilize the range of the PCFG randomly and indicate that, while there is likely overlap among the individuals sampled in Frasier *et al*. (In press) and the current study, neither represents random sampling across the range of the PCFG. To date, the photographs and/or genetic identities of sampled whales in the Frasier *et al*. (In press) study have not been compared with those used in the current study. In the future, such comparisons, along with the collection of additional samples from whales in the northern portion of the PCFG range, would be valuable in allowing sampling effort to be more evenly distributed throughout the range of the PCFG.

As aforementioned, the results presented here are consistent with the hypothesis that utilization of at least some feeding areas by ENP gray whales is influenced by internal recruitment. Within the PCFG, these findings are concordant with photo-identification records demonstrating site fidelity of individuals, including some known reproductive females and their calves, to the seasonal range (Calambokidis *et al.,* 2010). However, interpretation of the results is complicated by our lack of understanding of the potential for structuring within the northern feeding ground(s). If there is no structure on the feeding grounds north of the Aleutians, then the northern strata (both "north" and "Chukotka") can be considered representative of the genetic diversity of whales feeding throughout the northern feeding area. As such, the mtDNA differences observed here would be driven by fidelity of individuals to the PCFG seasonal range. However, if structuring is present among northern feeding areas, then the differences demonstrated here may be influenced by fidelity of individuals in either or both areas (Chukotka and PCFG). The collection of additional samples from northern feeding areas would be valuable in further elucidating the mechanisms creating the observed differences and in evaluating whether structuring is present among whales utilizing the northern feeding grounds.

Although the lack of nuclear differentiation found in our study indicates that gray whales from different feeding regions may be interbreeding, the significant differences in mtDNA haplotype frequencies that were identified in the study suggest that groups of gray whales utilizing different (northern versus southern) feeding regions are demographically independent. A similar pattern has been observed among humpback whales in the North Atlantic, where four feeding regions are present (Katona & Beard, 1990; Stevick *et al*., 2006). Within feeding regions, individuals demonstrate intra- and inter-seasonal site fidelity, with only low levels of interchange between regions (Stevick *et al*., 2006). Although most of the whales from these four feeding regions share a common mating ground in the West Indies (Katona & Beard, 1990; Clapham *et al.,* 1993; Palsbøll *et al.,* 1997; Stevick *et al.,* 1998), individuals utilizing the Gulf of Maine have been classified as a separate feeding stock, based on matrilineally-derived fidelity of individuals to this area and the assumption that, should this subpopulation be extirpated, repopulation by whales using adjacent areas would not occur on a management timescale (Waring *et al.,* 2000). It has been suggested that the timeframe for management should be, at most, decadal in scope (i.e., <100 years; Clapham *et al*., 2008).

Future Work - The low level of differentiation identified, as well as the high diversity found in the PCFG strata, may indicate relatively recent colonization of the PCFG but is also consistent with a scenario in which some low-level external recruitment into the PCFG may occur. Relatedness analysis, in which microsatellite genotypes are used to identify putative parent-offspring pairs, would provide insight into the proportion of internal versus external recruitment that is occurring. Such analysis would require genotyping additional microsatellite loci for sampled individuals and would benefit from the collection of additional samples from individuals within the PCFG.

As part of previous work exploring genetic differentiation between gray whales in the eastern and western North Pacific (Lang *et al.,* 2010), the genetic profiles of samples collected from individuals on the Sakhalin feeding ground (n=142) were compared to those generated from samples collected in the eastern North Pacific (n=136). Two individuals that were sampled off Sakhalin had matching genders, genotypes (n=13 loci), and mtDNA haplotypes to two individuals sampled off central California in 1995 (Lang, 2010). Although subject to caveats, these genetic matches may have represented movements of gray whales between the eastern and western North Pacific. Given that additional gray whale samples from feeding grounds in the ENP have been processed as part of this study, an expanded genetic comparison of all processed samples is currently underway to look for additional matches between the eastern and western populations.

ACKNOWLEDGEMENTS

Samples utilized in this project were collected under MMPA permit #14097 granted to the Southwest Fisheries Science Center and permit #540-1811 granted to John Calambokidis of Cascadia Research Collective. Samples collected in Russian waters were imported under CITES permit #1OUS77422319, held by the Southwest Fisheries Science Center. We thank Robin Abernathy, Billy Adams, Russ Andrews, Valentina Burkanov, Douglas Coleman, Dominick DeBari, Graeme Ellis, John Ford, Gary Friedrichsen, Brian Gisborne, Dawn Goley, Merrill Gosho, Ernie Grimes, Jeff Harris, Jason Herreman, Jeff Jacobsen, Barb Lagerquist, Rikki Manuel, Michael Murner, Carrie Newell, Sean Oliver, Nate Pamplin, Joe Scordino, Mikhail Shlemov, Tatiana Shulezhko, Debbie Steele, Rod Towell, Andrey Tretyakov, and Gina Ylitalo for their assistance with sample collection or contribution. Assistance in organizing sample collection efforts was provided by Paul Wade. All data for the analyses were generated in the SWFSC Genetics Laboratory, with assistance from Amanda Bowman and Jeremiah Minich. Gaby Serra-Valente and Nicky Beaulieu archived all samples. Eric Archer provided the R-code utilized for the microsatellite analysis, and Karen Martien provided help with analysis. Eric Archer, John Bickham, Karen Martien, Phil Morin, Wayne Perryman, and Dave Weller contributed to useful discussions on the analysis and interpretation of results. John Bickham, Bob Brownell, Donna Darm, Karen Martien, Steve Stone and Dave Weller provided helpful comments for improving the manuscript. Some of the work presented here was conducted as part of a National Research Council Postdoctoral Fellowship. Funding for the project was provided by the Northwest Regional Office of NOAA National Marine Fisheries and by a Species Recovery Grant for Tribes awarded to the Makah Tribe.

ABSTRACT

The western population of North Pacific gray whales (WGW), once thought extinct, is now estimated at 130 individuals and feeds primarily off northeastern Sakhalin Island, Russia, during summer. The population is critically endangered, facing anthropogenic threats throughout its range from nets, ships, and oil development, but present migration routes and wintering areas remain unknown. On 4 October 2010, a subcutaneous Argos tag was applied following protocols established by the International Whaling Commission to a 13-year-old male (named “Flex”) in good body condition off Piltun Lagoon, northeastern Sakhalin Island. Flex was first seen as a calf off Sakhalin in 1997. State-space modeling of fall near-shore movements for 68 days post-tagging identified a small home range foraging area within 45km of the tagging site. These data are unique as local weather conditions during this time generally prevent other forms of whale observation. On 11 December, Flex departed Sakhalin and began migrating across the Okhotsk Sea, Bering Sea, and Gulf of Alaska. By 5 February, Flex was within 20 km of the central Oregon coast, overlapping spatially and temporally with the last few weeks of the usual eastern gray whale southbound migration. Flex’s migration segments were linear, high speed (averaging 6.5 km/h), and included deep water far offshore, suggesting open-water navigation skills not previously attributed to gray whales, who are considered coastal and shallow-water oriented. State-space modeling (considering directionality and speed) identified the basin-wide movements as “migration” rather than “wanderings" associated with foraging behavior. Flex’s movements do not preclude other migration routes or winter destinations for WGWs. Additional WGW tagging is needed to identify other areas of use. The resulting data will have high conservation value and be useful in potential mitigation of anthropogenic activities.

BACKGROUND

The western population of North Pacific gray whales (Eschrichtius robustus, WGW) once thought to be extinct was re-discovery off northeastern Sakhalin Island, Russia and is critically endangered (IUCN, 2008). The population is estimated to contain about 130 individuals age one or older, of which only about 25 are reproductive females (Cooke et al., 2008), and it faces a number of anthropogenic threats throughout its range, including fatal interactions with coastal net fisheries off Japan (Weller et al., 2008; Bradford et al., 2009) along its presumed migration route(s) and oil development in and near its principal summer feeding area (IUCN, 2009). The wintering area of the present population is unknown but, based on the limited available information, has been suggested as south of Honshu, Japan, off the coast of southern China in the South China Sea and the Gulf of Tonkin (Weller et al., 2002), or possibly off North America (Ilyashenko, 2009).

Satellite telemetry has been proposed repeatedly as an efficient way to investigate the migratory routes and wintering grounds of western gray whales and scientists have been cautious about tagging because of the population's very low numbers. After considerable discussion by the IWC Scientific Committee from 2006-10 and various panels convened under the auspices of IUCN from 2006-8 (summarized for the U.S. Marine Mammal Commission and IUCN by Weller, 2008), the research tagging effort reported here was undertaken to tag and track up to 12 of whales during the late summer of 2010 to ascertain winter migration route(s) and reproductive area(s).

METHODS

We used Wildlife Computers Spot-5 Argos transmitters epoxy-cast in Stainless steel cylinders for nearly complete implantation. Insertion blades and attachments for WGWs were similar to those used on 18 eastern NP gray whales (EGW) in 2009/10 (Mate, 2010). The latter field study was an efficacy test prior to using the tags on WGWs. The tags were applied by using a modified air-powered ARTS applicator and specialty pushrods (Mate et al. 2007).

The research was based from the 50 m M/V Igor Maximov, which was at sea from 3 September to 7 October 2010. Although we encountered technical difficulties with the supplied small tagging vessel and significant weather problems (including remnants of two typhoons and two gales), we tagged a whale on the last field-operational day of the extended cruise.

We followed the protocols established by the IWC special steering committee on western North Pacific Gray whale telemetry, which required tagging only known adult males in good body condition. On 4 October 2011, we tagged a13 year old male known as Flex off the northeast coast of Sakhalin Island, Russia (Figure 1 inset), where the whale had first been seen as a calf in 1997. Although the tag was not completely deployed, it provided location data for 124 days.

RESULTS

Flex stayed along the Sakhalin Island coast within 45 km of the tagging site and within 5 km of shore for 68 days (Figure 1). These near shore movements suggest foraging behavior. In mid-December Flex crossed the Sea of Okhotsk to the west side of the Kamchatka Peninsula, went around the southern end of the peninsula and departed the east coast in early January. The tagged whale crossed the western and central Bering Sea in one week to arrive at the shallow shelf break near a major canyon and then proceeded south passed the Pribilof Islands and through the eastern Aleutian Islands before crossing the Gulf of Alaska and heading south 20-25 Km off the Washington and Oregon Coasts (Figure 2). He was last located by satellite 20 Km off Siletz Bay, Oregon (~45*N) on 5 February, which over-lapped with the last few weeks of the usual ENP gray whale southbound migration through this same area.

Despite ambiguities in the accuracy of many Argos location classes, the course heading across the western Bering Sea varied within just a few degrees for a week. Such linearity in the Argos track makes significant errors in the actual distance traveled unlikely compared to the Argos-derived path. The Argos track length may actually be a conservative estimate, but still resulted in sustained swimming speed estimates for various segments of travel (Table1) substantially higher than those normally observed for EGWs during their southbound migration (Herzing and Mate, 1989; Granite Canyon ref).

CONCLUSIONS AND DISCUSSIONS

The very liner movement of Flex so far from shore suggests good open water navigation skills not previously attributed to gray whales. ENP gray whales have been considered more coastal or shallow-water oriented. State-space modeling suggests the long-range movements of Flex across the Sea of Okhotsk, Bering Sea, and Gulf of Alaska are directed migration movements rather than “wanderings", usually indicative of foraging behavior. During the Bering Sea and North Pacific travel segments, the whale's average speeds were >6.5 km/h, 50% higher than average speeds observed for six 2009-tagged EGWs migrating south in 2010 (Mate, 2010).

Flex has previously visited the eastern North Pacific, confirmed by photo matching (Weller et al., IWC/SC63/BRG6) and two other WGWs have been genetically matched to southern California (Lang et al., IWC/S63/BRG10). The results demonstrated by this whale do not preclude other migratory destinations for other WGWs or even this whale during other winters. The possibilities identified from the tagging, genetics, and the photo-ID papers suggest additional WGW taggings would be useful to identify other possible winter migratory routes and/or destinations. We took 13 tags to Russia in anticipation of tagging 12 whales in 2010. The remaining 12 tags are still in Russia. We suggest tagging 12 more WG whales to increase the total sample size to 10% of the estimated population. The use of a mother ship would help assure our ability to move more widely if necessary to find adequate candidate whales for tagging. An improved tagging boat would increase the probability of success. An earlier tagging season would avoid seasonally predictable bad weather. Being able to tag both males and females would dramatically improve the probability of successfully deploying additional tags and develop information about possible sexual differences in: winter migratory routes; foraging area departure timings; reproductive destinations; wintering area arrival timings; the amount of time spent in wintering areas; turnover rates in wintering areas, and spring migration re-entry routes and timing back into the summer feeding areas. All of these issues might identify areas or specific anthropogenic activities that could be risks to WGWs, as well as mitigation possibilities.

ACKNOWLEDGEMENTS

This research was conducted under a permit issued to V. Rozhnov, Deputy Director of the A.N. Severtsov Institute of Ecology and Evolution of the Russian Academy of Sciences and funded via an IWC contract with support from Exxon Neftgas Limited, Sakhalin Energy Investment Company, and IUCN. We thank assistants C. Hayslip, L. Irvine, Y. Poltev, and the crew of the Maximov for their preparations and field work; O. Tyurneva for photo analyses; and Tomas Follett for data archiving and graphics preparations.

Western North Pacific gray whales (WGWs), once considered extinct, are critically endangered with unknown migratory routes and reproductive areas. We attached satellite-monitored tags to seven WGWs on their primary feeding ground off Sakhalin Island, Russia, three of which subsequently migrated to regions occupied by non-endangered eastern gray whales (EGWs). A female with the longest-lasting tag visited all three major EGW reproductive areas off Baja California, Mexico, before returning to Sakhalin Island the following spring. Her 22 511 km round-trip is the longest documented mammal migration and strongly suggests that some presumed WGWs are actually EGWs foraging in areas historically attributed to WGWs. The observed migration routes provide evidence of navigational skills across open water that break the near-shore north–south migratory paradigm of EGWs. Despite evidence of genetic differentiation, these tagging data indicate that the population identity of whales off Sakhalin Island needs further evaluation.

1. Introduction

Gray whales (*Eschrichtius robustus*) occur in both the eastern and western North Pacific Ocean [1]. Considered separate populations, both were severely depleted by commercial whaling. Eastern gray whales (EGWs) have recovered and are now thought to be near carrying capacity [2]. Western gray whales (WGWs), once thought to be extinct, currently number approximately 130 individuals and are listed as critically endangered by the International Union for Conservation of Nature [3]. Historically, widely ranging along the Asian coast, contemporary WGW aggregations are known primarily from summer feeding grounds off Sakhalin Island (SI), Russia [4]. WGWs were thought to winter off southern China [4], but current winter reproductive areas and migratory corridors are unknown. Here, we use satellite-monitored tracking data to conduct the first investigation of WGW migratory corridors and breeding areas to better evaluate threats to the population. The tag data reveal extensive migrations to traditional EGW breeding habitats, calling into question the identity of the WGW stock.

2. Material and methods

The International Whaling Commission's WGW Satellite Tagging Steering Committee established tagging protocols followed throughout two expeditions [5,6]: from 1 September to 7 October 2010 and 21 August to 22 September 2011. Only adult males in good body condition [7] were considered 2010 tagging candidates. Prior to a tagging approach, we visually identified whales from unique pigmentation patterns,

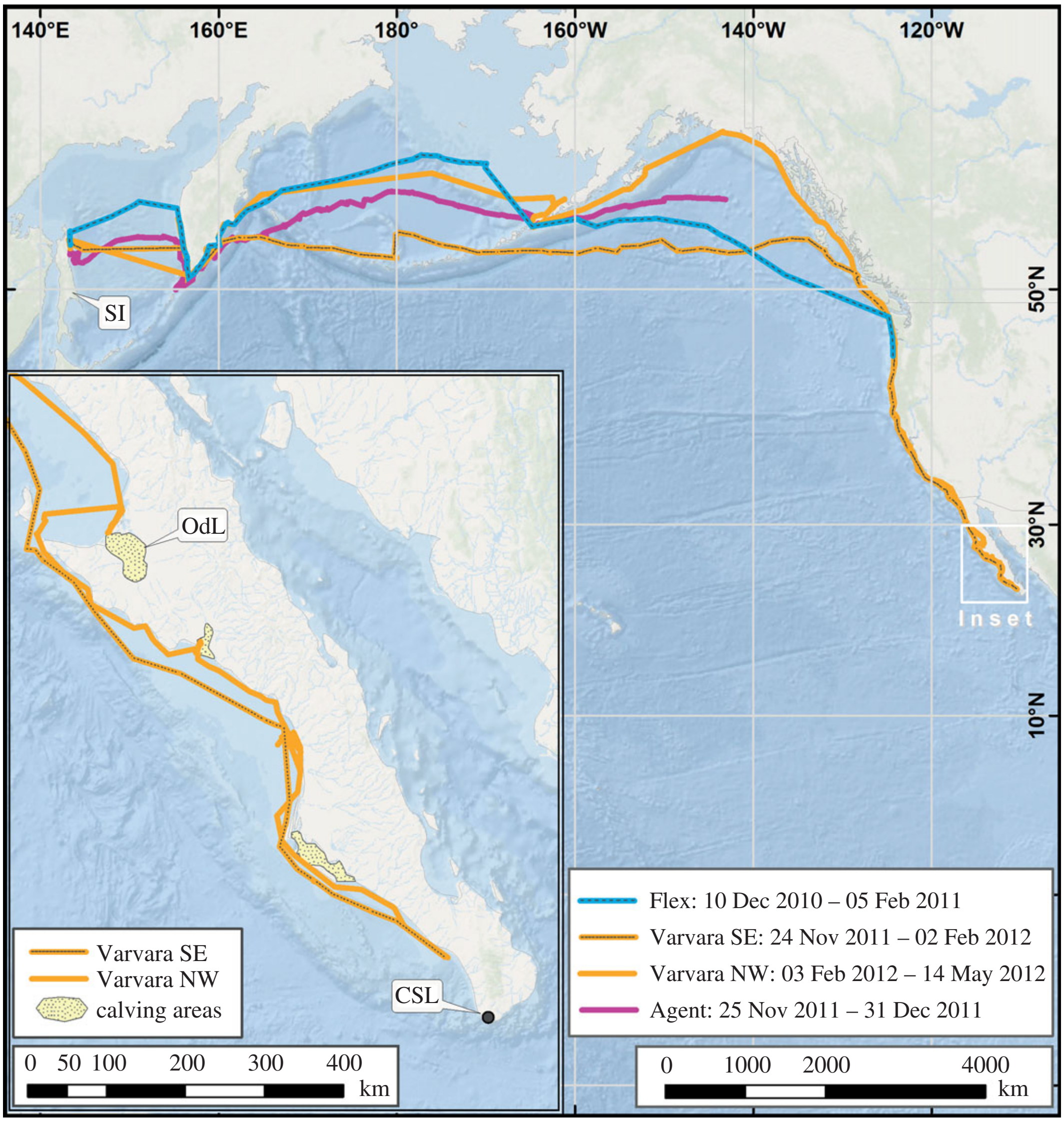

Figure 1. Routes of three western gray whales migrating from Sakhalin Island, Russia, to the eastern North Pacific. The legend depicts departure and arrival/end dates. Varvara visited all three major eastern gray whale reproductive areas off Baja California, Mexico (inset). (Online version in colour.)

using a WGW photo-identification catalogue. Sex is known for almost 80% of catalogued individuals from previous biopsy sampling, and many individuals were photographed as calves allowing age determination. Initially in 2011, only juveniles less than 6 years and females that had calves that year were not candidates. The latter criterion was later amended to allow tagging of females in good body condition that had weaned a calf.

We conducted tagging from a variety of small (less than or equal to 7 m) vessels powered by inboard diesel or four-stroke gas outboard engines, which were launched from the 50 m *Igor Maximov* support ship. We deployed tags from a distance of less than 4 m using a modified air-powered line-thrower [8]. Photos and videos were taken of tag deployments to document whale identity, tag penetration and location.

Tags consisted of a Wildlife Computers Spot-5 Argos transmitter and three Saft A-cell lithium batteries cast in an epoxy-filled stainless steel cylinder. The implantable tags were 28.2 cm long and 2.0 cm in diameter with attachments similar to those used for tagging other large whales [8]. To reduce the likelihood of infections, we partially coated tags with 2.5 g of Gentamycin sulfate, a broad-spectrum antibiotic, in a bio-soluble methacrylate for long-term release of the antibiotic into the tag site. Tags were sealed in gas-permeable bags for 12 h of ethylene-oxide sterilization.

Tags were programmed to transmit during four 1 h periods daily, coinciding with good satellite coverage over a broad range of possible North Pacific migration paths and destinations. Service Argos calculated locations with estimated accuracy based on the timing and number of transmissions received during individual satellite passes [9]. Three of seven location classifications have specific accuracies from less than 150 m (LC 3) to approximately 1 km (LC 1) [10]. We filtered unreasonable data by removing poor quality locations and limiting swim speeds to less than 10 km h^{-1} [8]. Distances travelled and swim speeds were calculated using ArcGIS 10.1 and are minimum estimates calculated from straight lines between consecutive locations.

3. Results

Three of seven tagged adult WGWs off SI during the two expeditions transmitted long enough to document migration away from SI after 68–89 days of near-shore movements: a male (13 year old 'Flex') in 2010 and two females (6 year old 'Agent' and 9 year old 'Varvara') in 2011. Each whale took different outbound routes across the Bering Sea, through the Aleutian Island chain, and across the Gulf of Alaska (figure 1), travelling an average of 6.2 km h^{-1} (table 1).

Tags attached to Flex and Varvara functioned long enough to document the whales entering the EGW southbound migration corridor. The last received location from Flex was 5 February 2011 off Lincoln City, OR, USA, after

travelling at least 7661 km. Flex was re-sighted in good body condition during the 2011 SI tagging expedition. Varvara departed SI on 24 November 2011, 17 days earlier than Flex, and passed Lincoln City on 8 January 2012, during the peak of the EGW southern migration. She travelled 10 880 km south to within 103 km of Cabo San Lucas, Baja California Sur, Mexico (CSL), on 2 February 2012, 69.5 days after departing SI (figure 1). Varvara spent 42 days off Baja California, Mexico including 32 days of generally northward movement, passing all three major EGW reproductive areas [11]. From CSL to the northernmost breeding area at Laguna Ojo de Liebre (OdL), Varvara travelled 1147 km, averaging 2.0 km h^{-1} (figure 1, inset). Her 10 484 km migration from OdL back to SI followed a different route from her eastward trip, crossing the eastern Bering Sea near the southerly face of the retreating ice edge and took 79 days, ending on 14 May 2012. Some slower movement segments were recorded along the north side of the Alaska Peninsula and while crossing the Bering Sea. The overall average speed for her spring migration was 5.5 km h^{-1}. The entire 22 511 km round-trip migration lasted 172 days.

4. Discussion

Varvara's 10 880 km autumn migration constitutes the longest recorded distance travelled during a mammal migration [12]. The linear travel segments over deep water made by tagged whales in this study indicate excellent navigation abilities [13] in sharp contrast with the slower-paced, near-shore and shallow-water migration of EGWs along North America [11]. Varvara's near-shore spring migration route until reaching the Bering Sea was typical of EGWs. However, her more northerly westward route across the Bering Sea indicates she was not obliged to return by the same specific route of her eastward migration, further reinforcing a strong ability to navigate. The occasional slow movement segments observed along the Alaska Peninsula and during the western crossing of the Bering Sea may indicate opportunistic feeding.

New-born gray whale calves follow their mothers during the spring migration to the mother's foraging area, where weaning occurs in late summer [11]. Juvenile and adult WGWs first identified as calves off SI have returned there to feed [4], indicating a very strong allegiance to their mother's migratory destination. Similar natal philopatry has been observed in humpback whale calves, in the North Pacific and elsewhere, returning to their mothers' migratory destinations [14]. Thus, the three migratory tracks documented by this study strongly suggest the tagged whales were born in EGW reproductive areas.

The utilization of feeding areas in the western North Pacific by whales that winter in the eastern North Pacific raises questions about the present status of WGWs. Since these tracking data became available, a preliminary comparison between WGW and EGW photo-ID catalogues discovered 10 WGWs have been photographed near British Columbia and in San Ignacio Lagoon, Baja California, Mexico [15]. Those sightings, combined with two genetic matches, further strengthen the linkage between these two presumed stocks and question whether the present WGWs came from the population previously thought to be extinct or from recovered EGWs with an expanded range [16].

Recent evidence that 'true' WGWs (i.e. whales breeding in Asian waters) are extant includes: four fishing net deaths off the Pacific coast of Japan between 2005 and 2007, including a yearling first observed as a calf off SI [17]; a gray whale stranded in November 2011 off the Fujian Province in southern China [15], adjacent to the region speculated to serve as a reproductive area for WGWs [17]; and a March 2012 live sighting in Mikawa Bay, Japan [15]. EGWs have been sighted well outside their established ranges [18], so it is possible that WGWs are extinct and these western North Pacific sightings represent a wider EGW foraging range, and more variable migratory timing than is presently thought. It is also possible that the SI region is a foraging area where EGWs and a smaller-than-estimated 'true' WGW population co-mingle, with the latter group making a southerly migration along the Asian coast to an as yet undiscovered breeding area or that spatial and temporal concentrations of whales from SI, during their occupancy in the regular winter range of EGWs, allow them to maintain genetic separation from other EGWs. Overall, the tagging and photo-ID data indicate that the population identity of whales off SI needs further evaluation.

Ethics statement. The procedures used in this study were reviewed and approved by the International Whaling Commission's Western Gray Whale Satellite Tagging Steering Committee and the Oregon State University Institutional Animal Care and Use Committee.

Data accessibility. Data for this study are archived at the International Whaling Commission (http://iwc.int/data-availability) and at the Oregon State University Marine Mammal Institute.

Acknowledgements. We are grateful for multiple Russian permits that authorized this research. We thank C. Hayslip, T. Follett, and the scientists and crew aboard the *Igor Maximov* for assistance. We appreciate valuable scientific advice offered by the IWC WGW Satellite Tagging Steering Committee and individual life history data for tagged whales provided by A. Burdin.

Funding statement. Contracting for this research was undertaken by the International Whaling Commission with funds provided by Exxon Neftegas Limited and Sakhalin Energy Investment Company, as well as the Office of Naval Research for data recovery costs and donors to the OSU Marine Mammal Institute.

Author contributions. B.M. participated in the conception, design and coordination of the study, participated in field work and drafted the manuscript. V.I. participated in the conception, design and coordination of the study and reviewed the manuscript. Update Western Gray Whales

The last map on the website was in fact the last one for Varvara's tag, which ended operations on 12 October, 408 days after tagging, which is consistent with the original tag-life estimate. Varvara provided us some truly amazing data and insights that will be written up for peer-reviewed publications. Thanks for your enthusiastic interest and support of this project.

To learn more about the life history of the tagged whales, we asked our colleagues at the Kamchatka Branch of the Pacific Institute of Geography (KBPIG) and at the National Marine Fisheries Service (NMFS), who have been studying gray whales off Sakhalin Island since 1995. Kol, a male, was first sighted off Sakhalin as a calf in 2004, meaning that he is approximately seven and a half years of age. He has been observed off Sakhalin almost every summer since he was a calf. Agent is a six and a half year old female who has been seen frequently off Sakhalin since she was first sighted as a calf in 2005

Varvara, an eight and a half year old female, has been seen intermittently off Sakhalin since she was first sighted as a calf in 2003. Varvara has a reputation for being particularly curious and playful during small boat encounters! Blaze was accompanied by a calf when first identified off Sakhalin in 1995, making her at least 26 years of age. She has been sighted in almost all subsequent years and has been observed with five calves during this period. We are no longer hearing from the tag on Blaze, but it was not well attached and has probably fallen off.

Svetlana leaves an impression on all who encounter her because of her calm demeanor, her enormous size (potentially the biggest of the Sakhalin whales), and a large scar on her back (most likely the result of a previous vessel collision). Svetlana was an adult when first identified in 1997 and has been sighted off Sakhalin in virtually every year since. Svetlana has been observed with four calves over the years, and we know that she is at least 23 years of age, although we suspect she is quite a few years older. Bud, so-called because she is also especially tolerant of the research vessel, has other characteristics in common with Svetlana. Bud is also a reproductive female, was first identified off Sakhalin as an adult in 1997, and has been sighted there in most of the following years. Based on when she was first observed with a calf, we know that Bud is at least 19 years of age, but she may indeed be older. Bud has had at least four calves, including one that she weaned earlier in the 2011 tagging season. Bud’s calf from 2006 was unfortunately fatally entrapped in a set net off Japan in early 2007. To date, Bud represents the only known connection between Sakhalin and the historical western gray whale migratory corridor.

During our tagging efforts this summer, we saw Flex (the whale tagged in 2010) on several occasions. He appeared to be in good body condition and, while scarred, the tag area has healed.

Anyone making reference to these data needs to acknowledge the source of the data by using the following text: "This research was conducted by A.N. Severtsov Institute of Ecology and Evolution of the Russian Academy of Sciences (IEE RAS) and Oregon State University Marine Mammal Institute in collaboration with the U.S. National Marine Fisheries Service, Kronotsky State Nature Biosphere Reserve and the Kamchatka Branch of the Pacific Institute of Geography. The research was contracted through the International Whaling Commission (IWC) and International Union for Conservation of Nature (IUCN) with funding from Exxon Neftegas Ltd. and Sakhalin Energy Investment Company Ltd.

Abstract

The National Marine Fisheries Service (NMFS) conducted a review of the status of the Eastern North Pacific stock of gray whales (*Eschrichtius robustus*). This review culminated in a workshop held by the National Marine Mammal Laboratory (NMML) in Seattle, Washington, on 16-17 March 1999. Based on the continued growth of this population (rising at 2.5% annually; currently at an estimated 26,600 individuals) and the lack of evidence of any imminent threats to the stock, workshop participants recommended the continuation of this stock's classification as non-threatened. They also concluded that abundance monitoring should continue at some level, especially as this stock approaches its carrying capacity, and that, ideally, research should continue on human impacts to critical habitats. This stock's annual migrations along the highly populated coastline of the western United States and their concentration in limited winter and summer areas may make them particularly vulnerable to impacts from commercial or industrial development or local catastrophic events. The Western North Pacific gray whale stock has not recovered and should continue to be listed as endangered.

The workshop and status review conclude the 5-year assessment of the Eastern North Pacific gray whale stock following its removal from the List of Endangered and Threatened Wildlife and Plants on 16 June 1994.

CONTENTS

Appendices

Background

Under the Marine Mammal Protection Act (16 U.S.C. 1361 *et seq.*; the MMPA), the National Marine Fisheries Service (NMFS) has jurisdiction over most marine mammal species[1], including whales. Under section 4(a) of the Endangered Species Act (16 U.S.C. 1531 *et seq.*; the ESA) and 50 CFR part 424 of NMFS' listing regulations, NMFS makes determinations as to whether a marine mammal species should be listed as endangered or threatened, or whether it should be reclassified or removed from the List of Endangered and Threatened Wildlife and Plants (the List). Accordingly, NMFS conducted comprehensive evaluations of the status of the Eastern North Pacific gray whale stock, *Eschrichtius robustus,* (sometimes referred to as the "California stock") in 1984 (Breiwick and Braham 1984). Based upon their review, NMFS concluded that this stock should be listed as threatened instead of endangered (49 FR 44774, 9 November 1984); however, no further action was taken at that time. Another review was completed and made available to the general public on 27 June 1991 (56 FR 29471). The 1991 review showed the best available abundance estimate, in 1987/88, was 21,296 (CV = 6.05%; 95% CI = 18,900 to 24,000) whales and the average annual rate of increase was 3.29% (SE = 0.44%) (Buckland et al. 1993). Back-calculations, dynamic response, and Bayesian estimations indicated that this stock was probably approaching current carrying capacity (Reilly 1992). Therefore, NMFS determined that the Eastern North Pacific stock no longer met the standards for classification as an endangered "species." Although individual and cumulative impacts might have the potential to adversely affect these whales, it was determined that this stock was neither in danger of extinction throughout all or a significant portion of its range (i.e., not endangered), nor was it likely to again become endangered within the foreseeable future (i.e., not threatened). Therefore, on 22 November 1991 (56 FR 58869), NMFS proposed that this stock be removed from the List. Of note, changes to the listing of this stock had no bearing on the status of the Western North Pacific gray whale stock (sometimes referred to as the "Korean stock"), which has not recovered and is still considered endangered throughout its range (USFWS 1997). After an extensive public comment period (22 November 1991 to 6 March 1992), NMFS published a final notice of determination that the Eastern North Pacific stock should be removed from the List (58 FR 3121, 7 January 1993). The population abundance and trends in the population's growth rate were deemed sufficient to allow this stock to be removed from the List without first being down-listed to threatened status.

As a result of NMFS' determination, the U.S. Fish and Wildlife Service (USFWS) removed the Eastern North Pacific stock of gray whales from the List under the ESA on 16 June 1994 (59 FR 31094) with the amendment of 50 CFR 17.11(h). To correspond with that ruling, NMFS also removed this stock from the List under its jurisdiction (50 CFR part 222) through an amendment of 50 CFR 222.23(a).

As required under section 4(g) of the ESA, NMFS drafted the "5-year Plan for Research and Monitoring of the Eastern North Pacific Population of Gray Whales"

---

[1] The U.S. Fish and Wildlife Service (USFWS) has jurisdiction over polar bears, sea otters, manatees, dugongs, and walrus.

(NMFS 1993) to monitor the status of the stock for a period of at least 5 years following the delisting. This plan (NMFS 1993:25) states that a "Task Group will conduct a comprehensive 'status review' of the gray whale . . . Included in that report will be a recommendation on whether to 1) continue the monitoring program for an additional 5-year period; 2) terminate the monitoring program; or 3) consider changing the status of the gray whale under the ESA." The draft plan, dated October 1993, was not finalized by the NMFS Office of Protected Resources; however, it has provided the framework and guidelines for research, monitoring, and management over the past 5 years. The plan was prepared by 11 NMFS scientists (the Gray Whale Monitoring Task Group), including Howard Braham (Chair), Jeffrey Breiwick, Robert Brownell, Jr., Marilyn Dahlheim, Douglas DeMaster (Vice-Chair), Kenneth Hollingshead, Jeffrey Laake, Stephen Reilly, John Stein, Steven Swartz, and Grant Thompson.

On 16-17 March 1999, 3 months prior to the conclusion of the 5-year period following the delisting of the Eastern North Pacific gray whale stock, a workshop was convened by NMFS at the Alaska Fisheries Science Center's National Marine Mammal Laboratory (NMML) in Seattle. Most of the original Task Group participated in this workshop, and other participants were invited as well, depending on their expertise and contributions that could help in the review process (see the participant list, Appendix A). The workshop provided an opportunity for interactions among researchers conducting studies pertinent to the evaluation of the status of gray whales. Agenda and abstract materials were circulated prior to and following the workshop to provide additional time for detailed reviews. An expanded agenda, with summaries of critical information, is included in the following report under "Outline of Available Information." Most of this material is explained further in the attached abstracts (Appendix B). Research documents from the past 5 years that pertain to this subject are in the literature section, including the literature cited in the Status Review.

Information included in the Outline of Available Information is inclusive of all pertinent studies and available data collected up to and including 16 June 1999, the 5-year anniversary of the removal of the Eastern North Pacific stock of gray whales from the List.

This Status Review document will be forwarded to the NMFS Assistant Administrator for Fisheries for approval and release to the public. The NMFS Office of Protected Resources will publish a Federal Register notice to announce the availability of this document and invite public comment.

Workshop objectives

The central objective of the status review and workshop held 16-17 March 1999 was to evaluate available information pertinent to the health of the Eastern North Pacific stock of gray whales. Questions to be answered through this process were:

1. Was it appropriate to delist this stock 5 years ago?
2. Should this stock continue to be considered non-endangered and non-threatened?
3. Should the monitoring process continue for another 5-year period?

Factors to be considered in determining the status of gray whales

The ESA specifies regulatory elements that were used to determine the status of the Eastern North Pacific stock of gray whales both in the delisting process in 1993-94 (see above) and in the review of scientific materials available during the 5 years that followed delisting (i.e., this report). Listing, reclassifying, or removing a species from the List is based on review of five factors, of which only one need apply for a "species" to be listed as either endangered or threatened (ESA: 16 U.S.C. 1533(a)(1); NMFS: 50 CFR 424):

1. Present or threatened destruction, modification, or curtailment of its habitat or range.
2. Overutilization for commercial, recreational, scientific, or educational purposes.
3. Disease or predation.
4. Inadequacy of existing regulatory mechanisms.
5. Other natural or manmade factors affecting its continued existence.

The workshop participants used these five factors as a guide to determine whether or not the current status of the Eastern North Pacific gray whale stock should be changed from non-threatened. The following information is a collection of research pertinent to this decision. The outline was adapted from the list of research needs in the 5-year monitoring plan (NMFS 1993:52).

Outline of Available Information

1) Abundance, distribution, population trend, and status

1.1) Abundance

1.11) **1993/94 abundance:** Systematic counts of southbound migrating gray whales were conducted 10 December 1993 to 18 February 1994 at Granite Canyon, California (Laake et al. 1994), the census site used most years since 1975 by NMML. In total, 1,864 pods (3,411 whales) were recorded during 447 hours of good or better watch conditions at the primary observation site. The abundance estimate was 23,109 (CV = 5.42%; 95% CI = 20,800 to 25,700).

1.12) **1995/96 abundance:** Systematic counts of gray whales were conducted from 13 December 1995 to 23 February 1996 at Granite Canyon (Hobbs et al. in press). As during previous surveys, census methods included double-counting to assess observer performance as well as aerial surveys and high-powered binoculars to document that a negligible fraction of migrating whales passed beyond the sighting range of the observers. There were 2,151 pods (3,928 whales) counted during 472.7 hours of standard watch effort. Data analysis procedures were modified to account for differential sightability by pod size. Population size was estimated to be 22,263 whales (CV = 9.25%; 95% log-normal CI = 18,700 to 26,500).

1.13) **1997/98 abundance:** Systematic counts of gray whales were conducted from 13 December 1997 to 24 February 1998 at Granite Canyon and Point Lobos, California (Hobbs and Rugh 1999). Counting methods, similar to previous surveys, included double-counting to assess observer performance and high-powered binoculars to document that a negligible fraction of migrating whales passed beyond the sighting range of the observers. In total, 2,318 pods (3,643 whales) were counted during 435.3 hours of standard watch effort. Data analysis procedures were identical to those used for the 1995/96 census. The population was estimated to be 26,635 whales (CV = 10.06%; 95% log-normal CI = 21,878 to 32,427).

1.14) **Counting methodology:** Systematic counts of gray whales have been conducted by NMML during 3 of the past 5 seasons (1993/94, 1995/96, 1997/98) (Hobbs and Rugh 1999). These surveys covered the duration of the southbound migration past the Granite Canyon research station. In addition to the standard primary watch, a second, independent watch was conducted once or twice daily. Offshore distribution of sightings was documented by comparing the paired counts on the standard watch; by searches through paired, fix-mounted 25 X binoculars; and by aerial surveys. In January 1993 and January 1994, pod-size estimation experiments involved an airplane circling pods of whales as several observers independently estimated pod sizes (Withrow in press). Tests of the counting system, but not full-season counts, were conducted in January 1995 and January 1997 (Rugh[2]). Analytical methods are described in Breiwick and Hobbs (1996).

1.15) **Night travel rates:** In studies conducted by Perryman et al. (1999a) in January 1994, 1995, and 1996, there was no significant diel variation in gray whale swimming speed. Prior to 15 January each year (the median migration date), diurnal and nocturnal rates (average number of whales/hour) were not significantly different; after 15 January, the nocturnal rate was significantly higher (28%, SE = 11.6%) than the diurnal rate.

1.16) **Database management:** Census data have been collected on gray whales during their southbound migration since 1952 (Shelden[3]). Currently the "raw" count data are not readily available to the scientific community or the general public. Therefore, researchers at NMML are in the process of creating a single, uniform, and easily accessible database. Before this can occur, the following tasks must be completed: 1) convert all computerized databases (Yankee Point/Granite Canyon/Point Lobos study sites used from 1967/68 to1997/98) into a common format, and place all data into one master database; 2) find and incorporate data from Point Loma (1952-78) into the master database; and 3) store the master database on CD-ROM for distribution to the public. It is anticipated that this product will be available by September 2000, pending support from the NMFS Office of Protected Species.

[3] Pers. comm. Kim Shelden, National Marine Mammal Lab, AFSC, NMFS,7600 Sand Point Way NE, Seattle, WA 98115-0070.

1.2) **Distribution**

1.21) **Migration**

1.211) **Relative to the census station**

1.2111) **Shore-based observations:** In January 1995 and 1996, using fixed-mounted 25X binoculars, paired independent searches for gray whales resulted in detection probabilities of 0.97 for pod sizes greater than 1 and 0.87 for single whales (5% of sampled population) within the critical sighting range of 1-3 nautical miles (nmi) (1.8-5.6 km) of shore (Rugh et al. in press).

1.2112) **Aerial observations:** Shelden and Laake (in press) compared the distribution of whales within 3 nmi (5.6 km) north and south of Granite Canyon during six aerial surveys (conducted concurrently with shore-based surveys in 1979, 1980, 1988, 1993, 1994, and 1996). They found that whale distributions within the typical viewing range of shore-based observers (3 nmi from shore) differed by year, but the shifts in the distribution were minor (< 0.3 nmi; < 0.5 km). Inshore (< 2.25 nmi; < 4.17 km) and offshore (> 2.25 nmi) distribution of gray whale pods did not differ significantly between survey years. A mean of 4.76% (SE = 0.85%) of the whale pods were observed beyond 2.25 nmi, and only 1.28% (SE = 0.07%) were observed beyond 3 nmi.

1.212) **Timing in 1998/99**

1.2121) **Oregon:** Alternate half-hour counts were made during the morning hours from 5 December 1998 through mid-February 1999 from the Yaquina Head Lighthouse (49 m above sea level) near Newport, Oregon (Mate and Poff 1999). The first whale was sighted on 23 December, and the peak passage occurred on 7 January. By comparison with previous data from the same site (1978-81), the migration started 3 weeks later than normal, and the migration peaked 6 days later than the latest date reported previously. Whales did not tend to come nearshore to the degree experienced in previous years. In this study, 60% of the sightings were greater than 5 nmi (> 9 km) offshore and 20% were less than 3 nmi (< 5.6 km).

1.2122) **Washington - aerial:** Shelden et al. (1999a, 1999b) conducted six (4 complete and 2 partial) surveys in November and December 1998 and January 1999. Four pods (6 whales) were observed on offshore transect lines from 5.5 to 47 km offshore, and two pods (2 whales) were observed on coastal tracklines from Cape Flattery to Carroll Island, Washington. The authors compared their results to surveys conducted off Granite Canyon, California, and suggested several factors that may have influenced the likelihood of detecting gray whales off the northern Washington coast: timing of the peak of the migration, lulls in the migration, width of the migration corridor, and limitations in the field of view from the aircraft. Of these four factors, corridor width appeared to be the most likely contributor to reduced observer detection rates.

1.2123) **Washington - shore-based:** Gray whales were seen on three occasions (2, 4, and 13 December) during a survey conducted from the tower of the Tatoosh Island lighthouse, on the northwesternmost tip of Washington State, between 30 November and 16 December 1998 (Jones 1999). The maximum possible sighting distance was estimated at 25 km, but gray whales were only seen at a range of 0.6-5.9 km from shore. It is possible that whales passed offshore, out of the observer's sighting range, or that this time period represented the very early stages of the southbound gray whale migration past Washington.

1.2124) **California to Alaska:** According to Rugh et al. (1999a, 1999b), the median sighting date of southbound gray whales prior to 1980 was 8 January (ranging from 5 to14 January) at the Granite Canyon research station. However, since 1980 there has been a 1-week delay in the peak of the migration such that the median date is now closer to 15 January (ranging from 12 to 19 January). Using a travel rate of 144 km/day (Swartz et al. 1987) between shore stations, the expected peak dates in 1998/99 should have been 5 January for Tatoosh Island; 8 January for Yaquina Head; 15 January for Granite Canyon; and 18 January at Point Vicente, near Los Angeles, California. Although no observations were made at Granite Canyon in 1998/99, sightings collected at Yaquina Head (Mate and Poff 1999) and Point Vicente (Schulman-Janiger 1999a) indicate that the southbound migration was within 1 or 2 days of the expected date.

1.213) **Travel rates:** Gray whales migrate at a rate of approximately 144 km/day (SD = 31 km/day), based on radio tags placed on whales near the Granite Canyon research station (Swartz et al. 1987). This travel speed was similar to rates calculated from a comparison of timings of peaks in sightings as whales migrated south past several shore stations ($\bar{x}$ = 139 km/day; SD = 18 km/day) (Rugh et al. 1999a, 1999b).

1.214) **Relative to Arctic and subarctic conditions:** Rugh et al. (1999a, 1999b) determined that gray whale migratory timing is remarkably regular: the 20 peaks observed at Granite Canyon during the southbound migration from 1967/68 to 1997/98 varied less than 4 days from the overall median dates. Regularity of this sort is likely driven by photoperiod (that is, shortening day lengths), not by weather. Arctic and subarctic temperatures and ice conditions are far from being so regular. Inter-year variations of a few days in migratory dates may be explained in part by variations in the median location of whales in the Bering or Chukchi Seas just prior to the onset of the migration. The farther north the whales are in autumn, the shorter the photoperiod will be, which might accelerate the onset of their southbound migration.

1.22) **Summering areas**

1.221) **Arctic and subarctic:** During aerial surveys in the Alaskan Chukchi and Beaufort Seas in 1982-91 (Moore and DeMaster 1997), gray whales were associated with virtually the same habitat throughout the summer (40 m depth and ≤ 1% ice cover) and the autumn (38 m depth and ≤ 7% ice cover), unlike bowhead and beluga whales. Moore and DeMaster (1997) believe that shallow coastal and offshore-shoal areas provide habitat rich in gray whale prey, and there is little reason for whales to abandon this habitat prior to winter onset. The association of gray whales with discrete offshore shoals in the northern Chukchi Sea may indicate that these are important feeding areas for the expanding population.

1.222) **Washington:** From 1984 to 1997, 168 individual gray whales were photo-identified (as seasonal resident whales from spring through fall) in coastal areas of Washington State (Calambokidis and Quan 1999, Gosho et al. 1999a, 1999b). Gray whales showed some localized site fidelity but also moved widely within and between years. Expanded research in 1998 (Calambokidis and Quan 1999) revealed that seasonal resident gray whales in Washington also used coastal areas from northern California to southeast Alaska from spring to fall. This large feeding range may account for inconsistent year-to-year resightings. Whales in northern Puget Sound showed strong site fidelity for part of the season and then moved to unknown areas. Use of southern Puget Sound was variable, mortality was high, and whales were rarely seen more than once.

1.23) **Wintering areas:** According to Urbán et al. (1997, 1998a, 1998b), the annual maximum count of all whales in San Ignacio Lagoon during the winters of 1978-85 averaged 348.7 (SE = 35.2) adults, of which 238.2 (SE = 36.7) were single whales and 110.5 (SE = 27.6) were cow-calf pairs. From 1996 to 1998, there was an average of 230 (SE = 18.4) adults in the lagoon, of which 140 (SE = 33.5) were single whales and 90 (SE = 37) were cow-calf pairs. During photo-identification studies in the lagoon in 1996-98, 752 whales were identified, including 411 single whales, 332 cow-calf pairs, and 9 whales which could not be classified. Of these, 120 whales were resighted: 14 single whales and 106 cow-calf pairs. Cow-calf pairs stayed in the lagoon an average of 19.1 days (± 4.8 95% CI) in 1996, 19.6 days (± 3.5 95% CI) in 1997, and 20.6 days (± 4.1 95% CI) in 1998, while single whales used the lagoons an average of 2.6 days (± 0.9 95% CI) in 1996, 6.2 days (± 3.2 95% CI) in 1997, and 5.6 days (± 2 95% CI) in 1998. During surveys in 1996 and 1998 (Urbán et al. 1998b), most whales were observed heading west off the coast of Bahía Ballenas, Baja California Sur, Mexico. Single whales were observed farther offshore than the cow-calf pairs. The number of single whales recorded in 1996 and 1998 was higher than the recorded number of cow-calf pairs. Similar traveling patterns and group composition were reported by Sánchez Pacheco and Valdés Aragón (1997) in 1997.

1.3) **Population trend:** Between 1967/68 and 1995/96, the Eastern North Pacific gray whale population increased 2.5% per annum (SE = 0.3%), and the estimated asymptote from a logistic model was 26,046 (SE = 6,281) with the inflection point in 1971 (SE = 6.5) (Buckland and Breiwick in press). Using a generalized linear model to fit abundance estimates from 1967/68 to 1997/98, the *ROI* (rate of increase) was 2.52% per annum (SE = 0.27%); using a logistic model, *K* (carrying capacity) was estimated to equal 37,364 (SE = 24,854), which is larger by 11,000 than a similar estimate based on the 1967/68 to1995/96 data; and *RY* (replacement yield) equaled 612 (Breiwick 1999). Density-dependent slowing of the population growth rate was supported by use of a Bayesian statistical method to compare the fit of the data to density-dependent versus density-independent models. Point estimates of the equilibrium population size ranged from 24,000 to 32,000, depending on the model (Wade and DeMaster 1996). Using a Bayesian statistical method to assess the stock with 1966/67 to1995/96 data, point estimates of carrying capacity ranged from 24,640 to 31,840; the median depletion (population size as a fraction of carrying capacity) was 0.75, with a lower 2.5th percentile of 0.36; the probability that the population is still below one-half of the carrying capacity was 0.21, and the probability that it is still below its maximum sustainable yield level was 0.28 (Wade in press).

1.4) **Population status**

1.41) **Criteria for ESA listing status:** Using 19 years of abundance estimates for the Eastern North Pacific gray whale, Gerber et al. (in press) sampled subsets of the original survey data to identify the minimum number of years of data required to consistently recommend removing the population from the ESA List of Endangered and Threatened Wildlife. These subsets of data were then analyzed using their proposed classification criteria. It was found that a quantitative decision to delist was unambiguously supported by 11 or more years of data, but precariously uncertain with fewer than 10 years of data.

2) **Calf production and pregnancy rate**

2.1) **Southbound migration at Granite Canyon/Yankee Point and Point Loma:** Calf sightings (number of calves/total whales) recorded by NMFS observers during the gray whale southbound migrations were summarized by Shelden et al. (in press) for 1952-95 and by Shelden and Rugh (1999) for 1995-98. Percentages of calves ranged from 0.0 to 0.2% from 1952-74, 0.1-0.9% from 1984-95, and 0.3-1.5% from 1995-98. The apparent increase in the percentage of calf sightings may be related to a trend towards successively later migrations over the 43-year observation period, or it may be due to an increase in spatial and temporal distribution of calving as the population has increased. The distribution of cows with calves relative to shore was similar to earlier years where the majority of sightings occurred inshore of the main migration corridor (1.4-2.8 km) during both shore-based and aerial surveys. Aerial surveys (between 1979 and 1994) indicated that shore-based observers missed 62% of the calves within their viewing area

(0-2.6 km from shore), suggesting that calves are under-represented in the data (Shelden et al. in press).

2.2) **Southbound migration at Point Vicente:** Schulman-Janiger (1999b), of the American Cetacean Society, Los Angeles Chapter (ACS/LA), reported that percentages of calves in the southbound migrations from 1983/84 to 1989/90 ranged from 0.5% to 2.5%, averaging 1.7%. From 1990/91 to 1992/93, these percentages increased to 3.0-3.9%, averaging 3.5%. The calf percentages from 1993/94 to 1998/99 ranged from 2.0% to 8.6%, averaging 4.6%. However, the calf count in the 1998/99 migration (n = 15; 2.2%) was one of the lowest in the past nine seasons. The highest calf count (n = 106; 8.6%) was in the 1997/98 season.

2.3) **Northbound migration at Point Vicente:** Schulman-Janiger (1999b) reported that percentages of newborn calves sighted in the ACS/LA surveys of the northbound migrations from 1983/84 to 1991/92 ranged from 0.9% to 8.3%, averaging 3.4%. From 1992/93 to 1997/98, these percentages generally increased, ranging from 4.3% to 13.8% and averaging 9.6%. Some of the highest percentages, ranging from 9.4% to 13.8% (averaging 11.2%), occurred in recent years (1995/96 to1997/98). These were substantially higher than previously published figures for California waters. The highest calf count (n = 222, 13.8%) occurred in the 1996/97 season and was more than double the count of any of the preceding nine seasons. However, the percentage of calves in the 1998/99 northbound migration was only 2.5% (n = 34), well below percentages seen in recent years.

2.4) **Northbound migration at Piedras Blancas:** Perryman et al. (1999b) conducted shore-based surveys at Piedras Blancas in central California to estimate the number of calves in the northbound migration. There were 1,000 calves (SE = 88.85) in 1994; 601 calves (SE = 69.56) in 1995; 1,141 calves (SE = 72.23) in 1996; 1,439 calves (SE = 78.62) in 1997; a preliminary estimate of 1,316 calves (SE = 77.56) in 1998; and a preliminary estimate (Perryman[4]) of 471 calves (SE = 77) in 1999. Calf production indices (calf estimate/total population estimate) were 4.5%, 2.6%, 5.1%, 6.5%, 5.9%, and 1.8% for the years 1994-99, respectively .

2.5) **Photogrammetric studies:** According to Perryman and Lynn (1999), the southbound migration is led by large whales, many of them pregnant females; juvenile whales usually arrive late in the migration. Based on the proportion of pregnant and recent postpartum females, 15 January was estimated to be the median birth date for the Eastern North Pacific stock of gray whales. The estimated length at 1 year was 8.6 m. Results indicated that relatively small changes in condition or fatness of gray whales are detectable in measurements from photographs.

---

3) **Habitat use**

3.1) **Climate trends:** Changes in the extent and concentration of sea ice in the Arctic Ocean over the past 20-30 years, coincident with warming trends, may alter the seasonal distributions, geographic ranges, patterns of migration, nutritional status, reproductive success, and ultimately the abundance and stock structure of some species (Tynan and DeMaster 1997a). Effects of climate warming on Eastern North Pacific gray whales are unknown, but studies of benthic-pelagic coupling in the Arctic and subarctic (e.g., Grebmeier and Barry 1991) suggest depression of production in surface waters that may lead to reduced availability of gray whale prey in primary feeding areas offshore of Alaska.

3.2) **Food resources:** According to Highsmith and Coyle (1992), gray whales rely on rich benthic amphipod populations in the Bering and Chukchi Seas to renew fat resources needed to sustain them during their winter migration to and from Baja California Sur. Gray whale feeding areas offshore of northern Alaska are characterized by low species diversity, high biomass, and the highest secondary production rates reported for any extensive benthic community. Stoker (in press) studied one of the high-use areas, the central Chirikov Basin between St. Lawrence Island and the Bering Strait, and found that gray whales disturb at least 6% of the benthos each summer and consume more than 10% of the yearly amphipod production. There are indications that this resource is being stressed and that the gray whale population may be expanding its summer range in search of alternative feeding grounds. Specifically, Highsmith and Coyle (1992) showed that the abundance and biomass of the amphipod community decreased during the 3-year period from 1986 to 1988, resulting in a 30% decline in production. They noted that high-latitude amphipod populations are characterized by low fecundity and long generation times, and that large, long-lived individuals are responsible for the majority of amphipod secondary production. Therefore, a substantial reduction in the density of large individuals in the population will result in a significant, long-term decrease in production.

4) **Potential anthropogenic concerns**

4.1) **Contaminants:** Tilbury et al. (1999) studied contaminants in gray whales. During migrations, prolonged fasting may alter the disposition of toxic chemicals within the whales' bodies. Gray whales feeding in coastal waters may be at risk from exposure to toxic chemicals in some regions. The higher concentrations of polychlorinated biphenyls (PCBs) found in stranded animals compared to harvested animals may be due to the retention of organochlorines in blubber during fasting rather than to increased exposure to these contaminants. The elevated concentrations of certain trace elements (e.g., cadmium) found in some tissues, such as kidneys, of stranded animals and the high levels of aluminum found in the stomach contents and tissues of harvested whales, compared to other marine mammal species, is consistent with the ingestion of sediment by gray whales.

4.2) **Oil spills:** Moore and Clarke (in press) reported that gray whales were seen swimming through surface oil from the *Exxon Valdez* oil spill along the Alaskan coast. Also, gray whales showed only partial avoidance to natural oil seeps off the California coast. Laboratory tests suggest that gray whale baleen, and possibly skin, may be resistant to damage by oil, but spilled oil or oil dispersant in a primary feeding area could negatively affect gray whales by contaminating benthic prey.

4.3) **Noise:** Moore and Clarke (in press) summarized studies of short-term behavioral responses to underwater noise associated with aircraft, ships, and seismic explorations. These studies indicate a 0.5 probability that whales will respond to continuous broadband noise when sound levels exceed *ca.* 120dB, and to intermittent noise when levels exceed *ca.* 170dB, usually by changing their swimming course to avoid the source. They also reported that preliminary results from studies to determine gray whale responses to a low-frequency active (LFA) anthropogenic source indicate that whales avoided exposure to transmissions in the 100-500 Hz frequency band at levels of 170-178 dB by deviating from their swimming path. Moore and Clarke (in press) noted that gray whales 'startled' at the sudden onset of noise during playback studies but demonstrated a flexibility in swimming and calling behavior that may allow them to circumvent increased noise levels. Conversely, some whales swim toward small skiffs deployed from whale watching boats in breeding lagoons, seemingly attracted by the noise of idling outboard engines. Gray whales sometimes change course and alter their swimming speed and respiratory patterns when followed by whale watching boats. Dahlheim (1984, 1988) found that gray whales respond to variation in underwater noise by changing the structure and timing of their calls. Ambient noise (both natural and man-made) has a profound affect on the behavior of this coastal species, causing them to modify their calls to optimize signal transmission and reception. Jones et al. (in press) described the significant decline in the number of whales using San Ignacio Lagoon during acoustic playback research conducted in the winter of 1984, and the re-occupation of this lagoon the following winter, although the numbers seen in 1985 were lower than observed during the 1978-82 period. The noise playback experiments documented alterations in vocal behavior and a significant decline in the number of whales occupying the lagoon during continuous playback (24-hour periods) of industrial noise (Dahlheim 1988). This experiment demonstrated the sensitivity of gray whales to noise disturbance within the lagoon.

4.4) **Entanglement in fishing gear:** From 1990 through 1998, 47 gray whales were reported entangled in fishing gear off the coasts of Alaska, Washington, Oregon, and California. Of these animals, 13 appeared to have survived; the remaining 34 were either mortalities or their status was unknown (Hill 1999a). A whale mortality, due to entanglement in a net pen, was reported in British Columbia in 1999 (Lochbaum[5]).

4.5) **Salt extraction in Mexico's lagoons:** Exportadora de Sal, sometimes referred to as ESSA, has operated a salt extraction facility at the town of Guerrero Negro, midway along the Pacific Coast of Baja California Sur, since 1954, and it is planning to expand its operation to San Ignacio Lagoon (Mate 1995). In 1994, ESSA entered into negotiations with the Mexican environmental authorities to expand its salt extraction and marketing activities within the buffer zone of the El Vizcaíno Biosphere Reserve. Specifically, they propose development of a 52,150 ha salt production facility on the shore of San Ignacio Lagoon (Dedina and Young 1995a). In 1995, due to insufficiencies in the Statement of Environmental Impact (MIA, acronym in Spanish), the Mexican authorities denied the permit for the San Ignacio Lagoon expansion and established a Scientific Committee, made up of seven specialists of different nationalities, to specify the terms of reference necessary for a new MIA. This task was completed in July 1996; however, to date, no proposal based on the new terms of reference has been received (SEMARNAP 1997).

4.6) **Commercial developments in Bahía Magdalena:** The growth of gray whale tourism in the North Zone of Bahía Magdalena has led to a proposed Japanese owned and financed tourist resort development at Bahía Magdalena (Dedina and Young 1995a). Although this represents a potential threat to the whales and their habitat, at this time, there are no plans to proceed with this development (Rojas Bracho[6]).

4.7) **Whale watching**

4.71) **Regulations in Baja California Sur, Mexico:** Urbán Ramírez[7] reported that whale watching is allowed in every lagoon in Baja California Sur except in the southern part of Bahía Magdalena (also see Sánchez Pacheco 1997a). Since 1997, government whale watching regulations (modified annually) have existed for commercial operators. There are currently four specific whale watching areas in the lagoons where the numbers of boats and methods of approach are regulated. There are no minimum approach distances, but whales cannot be chased.

4.72) **Whale disturbance in Ojo de Liebre and San Ignacio Lagoons:** A change in a whale's direction of movement is considered an indicator of disturbance. Sánchez Pacheco (1997b) defined a procedure to estimate the Maximum Simultaneous Number (NMS, acronym in Spanish) of vessels that can watch whales in an area without disturbing more than 50% of them. The procedure was applied in Ojo de Liebre Lagoon and San Ignacio Lagoon during 1995. Vessels followed selected whales, while observers recorded whale reactions and the distance between the vessel and disturbed whales.

[7] Pers. comm. Jorge Urbán Ramírez, Programa de Investigacion de Mamiferos Marinos, Dept. de Biologia Marina, Universidad Autonoma de Baja California Sur, Ap. Post. 12-B, La Paz, B.C.S., 23081 México.

The NMS was 6 vessels in each of two areas in Ojo de Liebre Lagoon and 13 vessels in San Ignacio Lagoon.

4.73) **Whale disturbance and regulations in Bahía Magdalena:** A shore-based study was conducted in the northern part of Bahía Magdalena, Estero A. Lopez Mateo, to observe the effect of whale watching boats on whale behavior (Pérez-Cortés Moreno[8]). In this narrow and shallow area of the lagoon, single-day visits predominate and enforcement is difficult. Regulations permit a maximum of 22 boats in the area at one time; boats must have a permit and fly a flag when whale watching; and only two boats can be close to a whale at one time. Preliminary results indicated that whales did not interact with the boats in 65.3% of the sightings; no impacts were recorded in 28.4% of the sightings; and behavior changes were recorded in only 6.3% of the sightings. Not all of these changes were negative as there were some "friendly" whales that approached boats. Although there did not appear to be any negative impacts on the whales, increased enforcement was recommended since there was an "observer effect" on the boat operators (i.e., they were more likely to obey regulations if under observation).

4.74) **Whale watching off California:** Schulman-Janiger[9] described whale watching guidelines and activities off the coast of California. The guidelines specify a minimum approach of 100 yards (100 m) and recommend that vessels approach whales from the rear and avoid separating cow-calf pairs. However, there is very little enforcement, and it is hard to prove harassment. Whale watching is a major seasonal industry off California. For example, a total of 44,125 people in 1996 and 41,879 people in 1997 participated in the Cabrillo Whalewatch Program trip cruises alone (on 6 vessels) off Los Angeles, California . During the mid-1980s, abundant nearshore gray whale sightings prompted many operators to start to guarantee whale sightings, which led to increased pressure to locate whales. During 1989-91, the number of nearshore gray whale sightings decreased, and commercial vessels began to cooperate to locate whales. Several vessel operators combined assets to charter a spotting plane, and another vessel hired staff to spot whales from the ACS/LA survey site. A significant problem is the number of private boats that follow commercial boats. Off Los Angeles, there can be 8-12 boats following one whale. Jet-skis are also a significant problem; they harass whales and can separate cows from calves close to shore.

4.75) **Regulation suggestions in California:** Recommendations for improved regulations (Schulman-Janiger[9]) include: 1) issue permit numbers to whale watching vessels and require them to fly flags while following a whale; 2) make ship traffic aware of whales in the area; 3) set speed limits for vessels moving in and out of harbors; 4) do not extend the current whale-watching season

(26 December-31 March) to target cow-calf pairs; 5) do not guarantee sightings; and 6) schedule boat races to avoid concentrations of whales, especially cow-calf pairs, in the area.

4.8) **Strandings:** From 1990 to 1998, there were 250 gray whale strandings (excluding the stranded whales in which the cause of death was due to entanglement) reported along the coasts of Alaska, Washington, Oregon, and California (Hill 1999b). In 1999 (as of 16 June), there were 24 gray whale strandings reported in Alaska (Sternfeld[10]); 6 in British Columbia--not including one death due to entanglement (Lochbaum[5]); 21 in Washington (11 on the coast; 10 within inland waters) (Norberg[11]); 1 in Oregon (Norberg[11]); and 32 on the California coast (Cordaro[12]). Pérez-Cortés Moreno (1999) reported that from 1975 to 16 June 1999, there were 518 strandings in Mexico (also see Sánchez Pacheco 1998). Thorough surveys were conducted in Mexico in the early 1980s and in 1998 and 1999, while relatively high numbers of strandings were recorded only in 1980 (53 whales), 1982 (46), 1991 (45), and 1999 (114). Although the number recorded in 1999 was high relative to other years, this was in part due to increased survey effort. These strandings occurred in many locations between December 1998 and June 1999 and were not related to a single stranding event. Of 89 stranded whales examined, 72% were adults, and of these, 78% were females.

4.9) **Ship strikes:** From 1990 to 1998, seven vessel strikes of gray whales were reported off the coasts of Alaska, Washington, Oregon, and California (Hill 1999c). Three of these animals appeared to have survived, while the other four were either mortalities or their status was unknown. Additional mortalities probably go unreported if the whales do not strand or are not thoroughly necropsied.

5) **Aboriginal harvest**: The current International Whaling Commission (IWC) quota (for 1998-2002) allows for a harvest of 140 gray whales per year for local consumption by aborigines (IWC 1998a).

5.1) **Russian:** From 1970 to 1998, an average of 139 gray whales were taken annually along the coasts of the Chukotka Peninsula (Quan 1999, Brownell[13]). The Russian Federation has agreed to take no more than 135 whales annually from 1998 to 2002 (IWC 1998a).

[13] Pers. comm., Robert Brownell, Jr., Southwest Fisheries Science Center, NMFS, P.O. Box 271, La Jolla, CA 92038-0271.

5.2) **Alaskan:** No gray whales have been allocated by the IWC to Alaskan Native subsistence hunters since 1991 (Quan 1999). Two incidental takes of gray whales by an Alaskan Native occurred in 1995 (Brownell[13], Quan 1999).

5.3) **Makah:** The Makah Indian Tribe received a 5-year quota from the IWC in 1997 to harvest 20 gray whales for ceremonial and subsistence purposes. The Tribe may harvest up to five gray whales per year from 1998 through 2002 (IWC 1998a, Gearin 1999). Makah whalers struck and killed one gray whale on 17 May 1999 (Gosho[14]).

6) **Review of potential research projects:** As a part of the conclusions of the workshop, it was recommended that the Eastern North Pacific stock of gray whales be monitored for another 5-year period. This would occur between June 1999 and June 2004. Monitoring could provide information relevant to the regular reviews conducted by NMFS (e.g., Hill and DeMaster 1998) and the IWC (e.g., IWC 1998b). The high visibility of this stock along the west coast of North America has made it very popular, so there is considerable public awareness and concern for the gray whales' status. This stock's annual migrations along highly populated coastlines and their concentration in limited winter and summer areas may make them particularly vulnerable to impacts from commercial or industrial development or local catastrophic events. Also, the ease and efficiency of monitoring this stock during its migration past shore stations has provided scientists a rare opportunity to document a large whale species recovering from near extinction. Never before has there been as good an opportunity to study life history parameters of a cetacean population approaching its carrying capacity–a study which will be very beneficial to research on other, less accessible whale stocks. The following list includes potential projects that will help in this monitoring and further improve our understanding of the status of this whale stock. Inherent in this research is the encouragement to keep open lines of communication among scientists studying gray whales, which includes researchers in Mexico, the United States, Canada, and Russia.

6.1) **Abundance and trends in abundance**

6.11) **Granite Canyon, California:** NMML frequently conducts full-season counts of gray whales during the southbound migration past this shore station in central California (Shelden et al. in press). This has proven to be an optimal site both logistically (easy access in an area with a relatively mild climate) and biologically (where most of the gray whale population passes close to shore each year). The census conducted at Granite Canyon has provided a long-term, consistent monitoring of stock abundance and trends (since 1968). Although this stock is not considered to be at risk, the continuation of the seasonal counts will provide an ideal opportunity to study a large cetacean population as it approaches carrying capacity. The Granite Canyon census is considered to be a low risk investment as it is a system that has been well tested. Further testing is needed to improve corrections for pod-size estimates,

---

[14] Pers. comm. Merrill Gosho, National Marine Mammal Lab, AFSC, NMFS, 7600 Sand Point Way NE, Seattle, WA 98115-0070.

continue studies of observer performance, and increase the accuracy of statistical variances within the observation data.

6.12) **Point Vicente, California:** Every year, ACS/LA volunteers conduct full-season counts of both the southbound and northbound migrations past Point Vicente, near Los Angeles (Schulman-Janiger 1999a) . These counts have been collected consistently since 1984 and are beneficial to time-series analyses; however, only a portion of the population passes this site during the southbound and northbound migrations.

6.13) **Yaquina Head, Oregon:** A volunteer from Oregon State University conducted counts of gray whales at Yaquina Head, near Newport, Oregon, in the 1998/99 season (Mate and Poff 1999). This site was also used for counts of the southbound and northbound migrations in 1978-81 (Herzing and Mate 1984).

6.14) **Other sites:** NMFS has no plans for systematic counts at locations other than Granite Canyon since this has proven to be the best site for shore-based counts.

6.141) **Cape Sarichef, Alaska:** Cape Sarichef, on the west edge of Unimak Island, is an ideal location for studying the gray whale migration in and out of the Bering Sea. This site was used for gray whale counts during several southbound and northbound migrations in the 1970s (e.g., Rugh 1984). However, the U.S. Coast Guard no longer maintains a facility there, making it logistically impractical to conduct research.

6.142) **Narrow Cape, Kodiak Island, Alaska:** Narrow Cape, on the south side of Kodiak Island, is an accessible site with a good view of the migratory corridor in the area, but gray whales also migrate on the north side of Kodiak Island, so the portion of the population passing Narrow Cape each year is unknown. No full-season counts have been conducted from this site.

6.15) **Stock assessment:** NMFS conducts an assessment of the Eastern North Pacific stock of gray whales at least every 3 years (Hill and DeMaster 1998); the stock assessment is currently being updated. The IWC conducts comprehensive assessments of stocks before harvest quotas are set (IWC 1998b); the next gray whale assessment will be in 2003.

6.16) **Stock identification and discreteness:** Genetic analysis may provide information on the degree of genetic variety within the Eastern North Pacific gray whale stock as well as determine differences between this stock and the Western North Pacific (Korean) stock (e.g., Rosel and Kocher 1997). Genetic discreteness of summering populations may be a factor in management decisions (Darling et al. 1998), specifically with regard to the whales in northwestern Washington where Makah Indians are whaling.

6.2) **Population health and viability**

6.21) **Calf counts**

6.211) **Granite Canyon, California:** The whale counts conducted by NMML at Granite Canyon during the southbound migration include counts of calves (Shelden et al. in press).

6.212) **Piedras Blancas, California:** During the past several years, the NMFS Southwest Fisheries Science Center (SWFSC) has conducted shore-based counts of gray whale calves during the northbound migration (Perryman et al. 1999b). Sighting rates at Piedras Blancas are compared to abundance estimates made by NMML during the southbound migration.

6.213) **Point Vicente, California:** The ACS/LA chapter includes calf counts in their ongoing effort at Point Vicente. The results show the percentage of calves seen during both the southbound and northbound migrations (Schulman-Janiger 1999b).

6.214) **Baja California Sur:** Counts of calves will continue to be a part of the studies of gray whales in Baja California Sur (e.g., Urbán et al. 1997).

6.22) **Condition index:** Photogrammetric studies conducted by the SWFSC help provide data on number of pregnant whales, proportion of sightings with calves, and lengths and other dimensions of whales. Dimension data can indicate animal health as a function of fat reserves (Perryman and Lynn 1999).

6.23) **Biological sampling**

6.231) **Harvest:** Data from harvested whales can help establish pregnancy rates and indicate health of individuals (e.g., Reilly 1992, Blokhin in press c).

6.232) **Natural mortality:** Samples from stranded whales may provide information on biological parameters, including reproductive condition, age, length, contaminant loads, stock discreteness, types of parasites or diseases, and cause of death (e.g., Heyning and Dahlheim in press).

6.3) **Distribution and habitat use**

6.31) **Baja California Sur:** Proposed studies include photo-identification of individual whales, radio-telemetry, and satellite-tagging. Results will provide information on persistence and consistency of use of certain lagoons. There was an intense study in 1980-85 that involved several of the lagoons (e.g., Jones and Swartz 1984). A multi-dimensional study over another 5-year period would provide a valuable comparison to the previous research.

6.32) **Washington State:** Photo-identification studies conducted by Cascadia Research Collective and the NMML (e.g., Calambokidis and Quan 1999, Gosho et al. 1999a, 1999b) provide information on how often individual whales are found in areas around northwestern Washington. This research will help answer questions about the "resident" vs. "transient" whales in the area where Makah Indians hunt whales.

6.33) **Migration and foraging**

6.331) **Satellite tagging:** Satellite tagging of gray whales would provide information on the timing and location of whales during their northbound migration and where they spend time feeding.

6.332) **Distribution information:** Distribution data may be collected from a variety of marine mammal surveys, such as the NMML cetacean surveys across southern Alaska, observations on fisheries research cruises, records collected in the Platforms of Opportunity Program, etc.

6.333) **Migratory timing:** Migratory timing can be documented through shore-based observations at sites used in the past, such as Point Vicente, Granite Canyon, and Yaquina Head (Rugh et al. 1999a, 1999b).

6.34) **Summer distribution:** Aerial and/or vessel surveys may provide information on current gray whale use of historic feeding grounds in the Bering and Chukchi Seas. Oceanographic sampling could document potential changes in prey production and availability (e.g., Grebmeier and Barry 1991).

6.4) **Anthropogenic concerns**

6.41) **Contaminant loads:** Contaminant loads are documented by the NMFS Northwest Fisheries Science Center (NWFSC) from samples collected from strandings and biopsies (Tilbury et al. 1999).

6.42) **Oil spills and post-spill monitoring:** There is a need for an oil-spill response protocol to minimize the effects of oil spills on gray whales. To develop this protocol, experimental designs are needed to minimize impacts of oil spills and better understand the risks to gray whales relative to different locations and intensities of oil spills.

6.43) **Noise:** Peter Tyack (Woods Hole Oceanographic Institute) and Chris Clark (Cornell University) have recently conducted and will probably continue to conduct acoustic studies relative to the response of large cetaceans, including gray whales, to Low Frequency Active (LFA) underwater transmissions (Tyack and Clark 1998).

6.44) **Fishery interactions:** The degree of impact of commercial and recreational fisheries on gray whales may be assessed through examinations of stranded whales, permit reports, and ships' log books. In particular, more information is needed from Mexico and Canada.

6.45) **Commercial development in critical habitats**

6.451) **Salt extraction in Baja California Sur:** A large salt evaporation facility is proposed for San Ignacio Lagoon (SEMARNAP 1997). If this facility is developed, the impact on whales using this lagoon should be studied. A comparison could be made between potential impacts of proposed salt work developments in Baja California Sur and the observed impacts of northwestern Australian salt works on humpback whales.

6.452) **Oil and gas exploration and extraction:** Oil and gas exploration and extraction have the potential of impacting whales along much of the migratory route, including feeding areas in the Bering and Chukchi Seas.

6.453) **Coastal development:** Coastal development, and the concomitant increase in human activities offshore, along much of the western shores of Mexico, the United States, and Canada has the potential of adversely impacting gray whales along their migration route (Moore and Clarke in press).

6.46) **Whale watching**

6.461) **Regulations:** A monitoring system should be established for operators of whale watching vessels; for example, through permit reports and/or log books. The IWC has established a subcommittee to provide guidelines for whale watching (IWC 1997d).

6.462) **Studies:** Studies should be conducted to evaluate the impact of whale watching operations. Whales and boats could be tracked using theodolites based on strategic shore-based sites. In Bahía Magdalena and San Ignacio Lagoon there are ongoing studies of whale watching operations (Pérez-Cortés Moreno[8], Sánchez Pacheco 1997b)

6.463) **Photographs:** Whale watching operations can be a source of photographs that may be used to identify individual whales. This could be beneficial in determining the amount of time individual whales stay in an area relative to the number of boats.

6.47) **Strandings:** Currently there are stranding networks in the United States and Mexico. On the U.S. West Coast, stranding information is collected by the NMFS Alaska Regional Office in Alaska, Northwest Regional Office in Washington and Oregon, and Southwest Regional Office in California. Besides aerial and vessel surveys of the lagoons in Mexico (Pérez-Cortés Moreno 1999), there is an ongoing research project in Scammon's Lagoon (Pérez-Cortés Moreno[8]).

6.48) **Ship strikes:** The number of strikes can be partially recorded through adequate documentation of marks on stranded whales and through ship logs (e.g., Hill 1999c, Heyning and Dahlheim in press).

6.5) **Research priorities:** Workshop participants were asked to select the five research projects that they would consider to be of the highest priority in evaluating the status of the Eastern North Pacific stock of gray whales. Preference was given to (in order of priority):

1) survey of the southbound migration at Granite Canyon (Section 6.11);
2) studies in the lagoons (Section 6.214, 6.31, 6.451, 6.453, 6.462, and 6.47);
3) photogrammetry/condition index (Section 6.22, 6.31, and 6.32);
4) calf counts (Section 6.21); and
5) Bering and Chukchi Sea surveys of foraging habitat/regime shifts (Section 6.34).

Summary

The workshop convened by NMFS at NMML in Seattle, Washington, on 16-17 March 1999, culminated the review of the status of the Eastern North Pacific stock of gray whales. This review was based on research conducted during the 5-year period following the delisting of this stock and includes information collected through 16 June 1999. The workshop followed guidelines outlined in the NMFS 5-year Plan to conduct the status review and recommend whether to: 1) continue the monitoring program for an additional 5-year period; 2) terminate the monitoring program; or 3) consider changing the status of the gray whale under the ESA. The 28 invited participants determined that this stock was neither in danger of extinction, nor was it likely to become endangered within the foreseeable future, according to the determining factors listed in section 4(a)(1) of the ESA. Therefore, there was no apparent reason to reverse the previous decision to remove this stock from the List.

Canada's Committee on the Status of Endangered Wildlife in Canada lists the "Northeast Pacific population" of gray whale as "not at risk." This is the lowest category for animals in their classification system, which also includes vulnerable, threatened, endangered, extirpated, or extinct.

The status of the Eastern North Pacific stock does not in any way alter the status of the still-endangered Western North Pacific ("Korean") stock of gray whales.

There was a consensus among the workshop participants that the Eastern North Pacific stock of gray whales should be monitored for an additional 5-year period (1999-2004), especially as this stock may be approaching its carrying capacity. Monitoring should include a continuation of surveys at Granite Canyon during the southbound migration; collaborative research with Mexican scientists on phenology of gray whales and the use of the lagoons in Baja California Sur; photogrammetry as a study of whale condition; calf counts; and an examination of the affect of environmental parameters, especially climate warming, on the whales' use of foraging areas.

Although the Eastern North Pacific stock of gray whales no longer receives protection under the ESA, it continues to be protected under the MMPA. As required by the MMPA, NMFS conducts an assessment of this stock every 3 years, or when new information becomes available. The last assessment occurred in 1997 (Hill and DeMaster 1998); it is currently being updated. Subsistence take is managed under quotas set by the IWC. Comprehensive assessments of gray whales are conducted by the IWC before quotas are set; the last assessment occurred in 1997 (IWC 1998b); the next will be in 2003 (IWC 1999a). There is no allowable commercial take of any gray whales, and the Convention on the International Trade in Endangered Species (CITES) regulates the transportation of animal parts. Furthermore, if there is evidence of a significant negative decline and research indicates that such a change would be warranted, this stock can be proposed to be listed again as threatened or endangered under the ESA.

This status review concludes the 5-year assessment of the Eastern North Pacific stock of gray whales (required by section 4(g)(1) of the ESA) that commenced on 16 June 1994 (59 FR 31094) when this stock was removed from the List.

Acknowledgments

Funding for travel to the workshop was provided by the NMFS Office of Protected Resources. Doug DeMaster was the chair for the workshop. Scientists making presentations at the workshop included: Héctor Pérez-Cortés Moreno, Lorenzo Rojas Bracho, and Jorge Urbán Ramírez from Mexico; Alisa Schulman-Janiger, from the American Cetacean Society/LA Chapter; John Calambokidis from Cascadia Research Collective; Jen Quan from the University of Washington; Bruce Mate from Oregon State University; Bob Brownell, Meghan Donahue, and Wayne Perryman from the NMFS Southwest Fisheries Science Center; John Stein and Gina Ylitalo from the NMFS Northwest Fisheries Science Center; and Jeff Breiwick, Marilyn Dahlheim, Doug DeMaster, Pat Gearin, Merrill Gosho, Scott Hill, Rod Hobbs, Sue Moore, Dave Rugh, and Kim Shelden from the NMFS Alaska Fisheries Science Center (National Marine Mammal Laboratory). Rod Hobbs provided the initial outline for the potential research projects. Helpful guidance at the workshop was provided by Greg Silber from the NMFS Office of Protected Resources, Steve Swartz from the NMFS Southeast Fisheries Science

Center, and Judy Zeh from the University of Washington. Greg Donovan, Helen Sharp, and staff of the International Whaling Commission provided abstracts of manuscripts from the IWC Journal of Cetacean Research and Management Special Issue 2 (in press) on gray whales. We are grateful to Ken Hollingshead and Greg Silber for their careful review of the Background section. Gary Duker and James Lee, of the AFSC Publications Unit, provided formatting edits. This document was improved by review comments from Héctor Pérez-Cortés Moreno, Lorenzo Rojas Bracho, Jorge Urbán Ramírez, José Sánchez Pacheco, Alisa Schulman-Janiger, Kim Shelden, Rod Hobbs, Tom Loughlin, and Steve Swartz.

Literature

The following list includes publications and unpublished documents dealing with gray whale research that has been conducted since 1993, following the circulation of the NMFS 5-year Plan for Research and Monitoring of the Eastern North Pacific Population of Gray Whales. Also included is any literature cited in the current status review and attached abstracts (indicated with an asterisk).

Laake, J.L., D.J. Rugh, J.A. Lerczak, and S.T. Buckland. 1994. Preliminary estimates of population size of gray whales from the 1992/93 and 1993/94 shore-based surveys. Unpubl doc. SC/46/AS7 submitted to Sci. Comm. of Int. Whal. Commn. 13 p.

The California stock of gray whales (*Eschrichtius robustus*) has been recently proposed for removal from the U.S. list of endangered and threatened species. As part of the delisting regulation under the U.S. Endangered Species Act, the National Marine Fisheries Service has begun a monitoring effort that has included shore-based surveys conducted 10 December 1992 to 7 February 1993 and 10 December 1993 to 18 February 1994, during the whales' southbound migration past Carmel, California. Survey methods were the same as those used in previous seasons. Paired, independent counts were made whenever possible but not during every watch as occurred in 1987/88. In total, 1,180 pods (2,112 whales) were recorded during 343 hours of watch from the main (south) observation site when visibility was classified as excellent to good in 1992/93, and 1,864 pods (3,411 whales) were recorded during 447 hours in 1993/94. The survey data were analyzed using methods consistent with those used in the 1987/88 data analysis. The population estimate from the 1992/93 survey is 17,674 (CV = 5.87%, 95% confidence interval, 15,800 - 19,800), which is significantly lower than the 1993/94 estimate of 23,109 (CV = 5.42%, 95% confidence interval, 20,800 - 25,700) (z = -3.36, P = 0.0004). Possible reasons for the difference are: 1) changes in the number of whales migrating as far south as Carmel; 2) poor sighting conditions in 1992/93, particularly during the peak of the migration; 3) missing sources of variation. The 1993/94 estimate is not significantly different than the 1987/88 estimate of 20,869 (CV = 4.37%) (z = 1.46, P = 0.072).

Agenda Section 1.12

ABUNDANCE OF GRAY WHALES IN THE 1995/96 SOUTHBOUND MIGRATION IN THE EASTERN NORTH PACIFIC

R.C. Hobbs, D.J. Rugh, J.M.Waite, J.M. Breiwick and D.P. DeMaster

National Marine Mammal Laboratory
Alaska Fisheries Science Center, NMFS, NOAA
7600 Sand Point Way NE, Bin C15700
Seattle, WA 98115-0070, USA

Hobbs, R.C., D.J. Rugh, J.M. Waite, J.M. Breiwick, and D.P. DeMaster. In press. Abundance of gray whales in the 1996/96 southbound migration in the eastern North Pacific. J. Cetacean Res. Manage. Special Issue 2.

Systematic counts of gray whales (*Eschrichtius robustus*) were conducted from 13 December 1995 to 23 February 1996 at Granite Canyon, California. This study is the second of three during the 5-year period following the removal of gray whales from the U.S. government list of endangered and threatened wildlife. The counts were made at the same research station used most years since 1975 by the National Marine Mammal Laboratory to observe the southbound migration of the eastern North Pacific stock. Counting methods were kept similar to those used in previous surveys and included double counting to assess observer performance. In addition, aerial surveys and high-powered binoculars provided documentation that a negligible fraction of migrating whales passed beyond the sighting range of the counting observers. A total of 2,151 pods (3,928 whales) was counted during 472.7 hours of standard watch effort with a visibility recorded as fair to excellent. Data analysis procedures were substantially the same as in previous years with a modification to account for differential sightability by pod size. Population size is estimated to be 22,263 whales (CV = 9.25%; 95% log-normal CI = 18,700 to 26,500). This estimate is similar to the previous estimate of 23,109 (CV = 5.42%; 95% CI = 20,800 to 25,700) from the 1993/94 survey.

1.14

THE ABUNDANCE OF GRAY WHALES IN THE 1997/98 SOUTHBOUND MIGRATION IN THE EASTERN NORTH PACIFIC

Roderick C. Hobbs and David J. Rugh

National Marine Mammal Laboratory
Alaska Fisheries Science Center, NMFS, NOAA
7600 Sand Point Way NE, Bin C15700
Seattle, WA 98115-0070, USA

Hobbs, R.C., and D.J. Rugh. 1999. The abundance of gray whales in the 1997/98 southbound migration in the eastern North Pacific. Unpubl. doc. SC/51/AS10 submitted to Sci. Comm. of Int. Whal. Commn. 18 p.

Systematic counts of gray whales (*Eschrichtius robustus*) were conducted from 13 December 1997 to 24 February 1998 at Granite Canyon and Point Lobos, California. This study is the third of three during the 5-year period following the removal of gray whales from the U.S. government list of endangered and threatened wildlife. The counts were made at the same research station used most years since 1975 by the National Marine Mammal Laboratory to observe the southbound migration of the eastern North Pacific stock of gray whales. Counting methods were kept similar to those used in previous surveys and included double counting to assess the performance of observers. In addition, high-powered binoculars provided documentation that a negligible fraction of migrating whales passed beyond the sighting range of the counting observers. In total, 2,318 pods (3,643 whales) were counted during 435.3 hours of standard watch effort when visibility was recorded as fair to excellent. Data analysis procedures were substantially the same as those used in previous years and identical to those used for the 1995/96 census. The population is estimated to be 26,635 whales (CV = 10.06%; 95% log-normal confidence interval = 21,878 to 32,427). This estimate is similar to the previous estimates of 23,109 (CV = 5.42%; 95% confidence interval = 20,800 to 25,700) from the 1993/94 survey and 22,263 whales (CV = 9.25%; 95% log-normal confidence interval = 18,700 to 26,500) from the 1995/96 survey.

Agenda Section 1.14

PRELIMINARY DOCUMENTATION OF GRAY WHALE ABUNDANCE ESTIMATION PROCEDURES

J.M. Breiwick and R.C. Hobbs

National Marine Mammal Laboratory
Alaska Fisheries Science Center, NMFS, NOAA
7600 Sand Point Way NE, Bin C15700
Seattle, WA 98115-0070, USA

Breiwick, J.M., and R.C. Hobbs. 1996. Preliminary documentation of gray whale abundance estimation procedures. Unpubl. doc. SC/48/AS2 submitted to Sci. Comm. of Int. Whal. Commn. 5 p.

The National Marine Mammal Laboratory (NMML) produces abundance estimates of the Eastern North Pacific stock of gray whales based on counts made from Granite Canyon, near Carmel, California. These abundance estimates are based on the number of pods observed and the average recorded pod size obtained directly from the field data. These numbers are corrected for 1) number of pods passing outside of count periods; 2) rate of night travel; 3) pods missed within the viewing range of observers while on watch; and 4) mean pod size. In conjunction with recent counts, aerial surveys have been flown to compare the offshore distribution of gray whale sightings with the distribution based on shore counts. Results since 1988 have indicated, however, that a correction factor for whales passing beyond the viewing range of shore-based observers is not necessary. Aerial observations of pod size have been used in comparison with shore-based pod size estimates to compute a correction factor for pod size bias. This document summarizes the analytical procedures used during the past decade.

Perryman, W.L., M.A. Donahue, J.L. Laake, and T.E. Martin. 1999a. Diel variation in migration rates of eastern Pacific gray whales measured with thermal imaging sensors. Mar. Mammal Sci. 15(2):426-45.

We recorded the blows of southbound gray whales from central California in January 1994, 1995, and 1996 using thermal imaging sensors. For our sampling purposes, we defined day (0730-1630) and night (1630-0730) to coincide with the on/off effort periods of the visual surveys being conducted concurrently. We pooled data across the three years of sampling and tested for diel variation in respiration interval, pod size, offshore distance, migration rate, and swimming speed by comparing paired day/night means for samples collected within the same 24-hour period. We performed these tests using data from the entire migration period and then repeated the tests for samples collected prior to and after the approximate median migration date (January 15th). Over the entire migration period we observed significantly larger daytime pod sizes ($\bar{x}_{day} = 1.75 \pm 0.280$ km, noted here and throughout with one standard deviation, $\bar{x}_{night} = 1.63 \pm 0.232$km) and offshore distances ($\bar{x}_{day} = 2.30 \pm 0.328$ km, $\bar{x}_{night} = 2.03 \pm 0.356$ km), but found no significant diel variation in respiration interval. For the entire migration period, the nocturnal migration rate (average number of whales passing per hour) was significantly higher ($t = -2.65$, $\bar{x} = 20$, $p = 0.02$). During the early migration period, we detected no significant diel variation in pod size or respiration interval, but daytime offshore distances were significantly larger ($\bar{x}_{day} = 2.28 \pm 0.273$ km, $\bar{x}_{night} = 1.96 \pm 0.318$ km). Diurnal and nocturnal migration rates prior to January 15th were not significantly different. During the late migration period, there was no significant diel variation in respiration interval, pod size, or distance offshore, but the nocturnal migration rate was significantly higher (28%, SE = 11.6%) than the diurnal rate. We found no significant diel variation in swimming speed in any comparison. We propose later migrants socialize more during the day, which effectively slows their diurnal rate of migration even though they maintain equal speeds day and night when swimming.

Rugh, D.J., J.A. Lerczak, R.C. Hobbs, J.M. Waite, and J.L. Laake. In press. Evaluation of high-powered binoculars to detect inter-year changes in the offshore distribution of gray whales. J. Cetacean Res. Manage. Special Issue 2.

Paired, independent searches for gray whales (*Eschrichtius robustus*) were conducted through fix-mounted, 25-power binoculars during January 1995 and 1996 at Granite Canyon, California. This study was a test of an efficient method for documenting inter-year changes in the offshore component of the gray whale migration. The research site has been used most years since 1975 by the National Marine Mammal Laboratory to make gray whale counts for abundance estimates. Matching sightings between these paired observation efforts showed a very high agreement between observers (detection probability 0.97) for whale groups consisting of more than one animal within 1 to 3 nmi of shore, and a fairly high agreement (0.87) for animals that appeared to be traveling alone (5% of the sampled population) within 1 to 3 nmi of shore. Therefore, sighting probability remained high out to 3 nmi, a distance which includes most (98.7%) of the whale migration. For the critical sighting range of 1 to 3 nmi, the method we applied here, using paired, fix-mounted binoculars, is considered a feasible, cost-effective technique for detecting inter-year differences in the offshore tail of the distribution of gray whales.

Agenda Section 1.2112

COMPARISON OF THE OFFSHORE DISTRIBUTION OF SOUTHBOUND MIGRATING GRAY WHALES FROM AERIAL SURVEY DATA COLLECTED OFF GRANITE CANYON, CALIFORNIA, 1979-96

National Marine Mammal Laboratory
Alaska Fisheries Science Center, NMFS, NOAA
7600 Sand Point Way NE, Bin C15700
Seattle, WA 98115-0070, USA

Shelden, K.E.W., and J.L. Laake. In press. Comparison of the offshore distribution of southbound migrating gray whales from aerial survey data collected off Granite Canyon, California, 1979-96. J. Cetacean Res. Manage. Special Issue 2.

Aerial surveys provide an assessment of the offshore distribution of gray whales and an estimate of the proportion of whales that migrate beyond the visual range of shore-based observers. Six surveys were conducted concurrent with shore-based surveys during 1979, 1980, 1988, 1993, 1994 and 1996. Annual differences were tested for in the distribution of whales within an area 3 nmi north and south of Granite Canyon, and it was found that the distributions within 3 nmi of the shore differed by year but the shifts in the distribution were minor (<0.3 nmi). The inshore (<2.25 nmi) and offshore (>2.25 nmi) distribution of gray whale pods did not differ significantly between survey years. An average of 4.76% (SE = 0.85%) of the whale pods were observed beyond 2.25 nmi and only 1.28% (SE = 0.07%) were observed beyond 3 nmi.

THE SOUTHBOUND MIGRATION OF GRAY WHALES
WINTER 1998/99

Bruce R. Mate and Amy Poff

Oregon State University, Hatfield Marine Science Center
Newport, OR 97365, USA

Mate, B.R., and A. Poff. 1999. The southbound migration of gray whales, winter 1998/99. Unpubl. doc. submitted to the Workshop to Review the Status of the Eastern North Pacific Stock of Gray Whales, 16-17 March 1999, Seattle, WA.

Alternate half-hour counts were made during the morning hours from 5 December through mid-February from the Yaquina Head Lighthouse (162 feet above sea level). Observations were made on all fair-weather days (< Beaufort 4).

The first whale was sighted on 23 December and the peak passage of whales per hour occurred 7 January. By comparison with previous data from the same site (1978/81: Herzing and Mate 1984), the migration started 3 weeks later than normal and the migratory population peaked 6 days later than the latest date.

Aerial surveys in early December showed a number of animals along the coast but not moving consistently in southerly directions. Surveys closer to Christmas about 10 miles offshore showed more animals beyond 5 miles than inside 5 miles. This was an unusual distribution from efforts in previous years when most of the population was within 3 miles of the coast. Despite periods of good weather, whales did not tend to come nearshore to the degree experienced in previous years. In this study, 60% of the animals were 5 miles or farther offshore and 20% of the animals were within 3 miles of shore judging from lighthouse observations.

Shelden, K.E.W., J.L. Laake, P.J. Gearin, D.J. Rugh, and J.M. Waite. 1999a. Field report on the winter distribution of gray whales in Washington waters, 1998/99. Unpubl. doc. submitted to the Workshop to Review the Status of the Eastern North Pacific Stock of Gray Whales, 16-17 March 1999, Seattle, WA.

The winter distribution of gray whales along the Washington coast has been difficult to characterize primarily because of low survey effort (due to poor surveying conditions). Aerial surveys were conducted during the months of November and December 1998 and January 1999 between Cape Flattery and Carroll Island, Washington. Flights included a coastal trackline extending from Cape Flattery (48°23' N, 124°44' W) to Carroll Island (48°00' N, 124°43' W) and 8 east-west oriented transect lines spaced at 7.4 km intervals, extending 55.6 km offshore. Survey flights were scheduled at 10-day intervals with modifications to the schedule occurring when weather conditions were not optimal. Four complete surveys and two partial surveys were flown between November 1998 and January 1999 for a total of 19.5 on-effort hours and 40 transect lines. Four gray whale pods (6 individuals) and two gray whale pods (2 individuals) were observed on offshore transect lines and coastal tracklines, respectively. Distances off the Washington coast for pods observed on transect ranged from 5.5 km to 47 km. One sighting of an extremely rotund whale on 22 December suggests that pregnant animals continued to pass the Washington coast late in December. No calves were seen. Other marine mammal sightings included aggregations of humpback whales and Pacific white-sided dolphins feeding in the survey area in November and early December. Based on this study and other reports, it appears that gray whales are widely dispersed across the outer continental shelf of Washington State during both migratory and non-migratory periods. Sightings indicate that some may migrate close to shore while others may be nearly 50 km offshore. Gray whales were also observed within Washington State's inside waters during the southbound migration period. Because gray whales utilize the inside waters and outer coast throughout the year, determining when a "resident" becomes a "migrant" has been based on migratory timing. Although migratory timing cannot be confirmed by the aerial survey results reported here because too few whales were seen during the flights, it does appear that the peak of the southbound migration passes through the area in early to mid-January.

Agenda Section 1.2123

GRAY WHALE OBSERVATIONS FROM TATOOSH ISLAND, WASHINGTON, DECEMBER 1998

Bete Jones

National Marine Mammal Laboratory
Alaska Fisheries Science Center, NMFS, NOAA
7600 Sand Point Way NE, Bin C15700
Seattle, WA 98115-0070, USA

Jones, B. 1999. Unpubl. doc. submitted to the Workshop to Review the Status of the Eastern North Pacific Stock of Gray Whales, 16-17 March 1999, Seattle, WA.

Gray whales (*Eschrichtius robustus*) were surveyed from the tower of the Tatoosh Island lighthouse from 30 November - 16 December 1998. The purpose of the study was to determine the onset of the southbound migration of gray whales past Cape Flattery, the most northwestern point of Washington State. Observations were conducted primarily without the use of optical aids. 7 X 50 Fujinon binoculars, equipped with reticles and a magnetic compass, were used to document sighting location. Gray whales were seen on three occasions (2, 4, and 13 December) during 49.3 hours of observation effort over a total of 12 days. The average daily observation effort for this time was 4.1 hours. The maximum possible sighting distance was estimated at 25 km. Gray whales were seen at a range of 0.6 - 5.9 km from shore. Although few migrating gray whales were observed during this period, it is possible that whales passed offshore, out of the observer's sighting range. It is also possible that this time period (30 November - 16 December) represented the very early stages of the southbound gray whale migration past Washington, thus few whales were in the vicinity. Aerial and vessel surveys conducted by the National Marine Mammal Laboratory in November and December 1998, and January 1999 support the latter hypothesis.

Rugh, D.J., K.E.W. Shelden, and A. Schulman-Janiger. 1999a. Timing of the southbound migration of gray whales in 1998/99. Unpubl. doc. submitted to the Workshop to Review the Status of the Eastern North Pacific Stock of Gray Whales, 16-17 March 1999, Seattle, WA.

The southbound migration of gray whales has been documented most seasons since 1967 from Granite Canyon, a shore-based observation station in central California. Prior to 1980, median dates of sightings ranged from 5-14 January, with an overall median date of 8 January. Since 1980, there has been a 1-week delay in the peak, such that the median date is now closer to 15 January (ranging 12-19 January). Allowing for this delay, and using a travel rate of 144 km/day between shore stations, expected peak dates in 1998/99 should have been 11 December for Cape Sarichef, at the tip of the Alaska Peninsula/Unimak Island; 18 December for Narrow Cape near Kodiak, Alaska; 5 January for Tatoosh Island, the northwesternmost tip of Washington State; 8 January for Yaquina Head, near Newport, Oregon; 15 January for Granite Canyon, central California; and 18 January at Point Vicente, near Los Angeles, California. Although no observations were made at Granite Canyon in 1998/99, sightings collected at Yaquina Head and Point Vicente indicate that the southbound migration was within 3 days of the expected date. Inter-year variations of a few days in migratory dates may be explained in part by variations in the median location of whales in the Bering or Chukchi Seas just prior to the onset of the migration. The further north the whales are in late October, the shorter the days will be (i.e., a perceived reduction in photoperiod), which seems to be the primary cue to initiating the southbound migration.

Agenda Section 1.221

CETACEAN HABITATS IN THE ALASKAN ARCTIC

Sue E. Moore[1] and Douglas P. DeMaster[2]

[1]Science Applications International Corporation
3990 Old Town Avenue, Suite 105A
San Diego, CA 92110-2931, USA

[2]National Marine Mammal Laboratory

Seattle, WA 98115-0070, USA

Moore, S.E., and D.P. DeMaster. 1997. Cetacean habitats in the Alaskan arctic. J. Northwest Atl. Fish. Sci. 22:55-69.

Marine mammals can be used as indicators of environmental productivity because they must feed efficiently and therefore aggregate where prey is plentiful. Three species of cetaceans, bowhead whales (*Balaena mysticetus*), gray whales (*Eschrichtius robustus*), and white whales (*Delphinapterus leucas*) migrate to the Alaskan arctic each year to feed. These species have distinctly different feeding modes and forage at dissimilar trophic levels. Bowhead whales filter zooplankton from the water column, gray whales siphon infaunal crustaceans from the benthos and white whales catch a variety of nekton including crustaceans, cephalopods and fishes.

Line transect aerial surveys were conducted over the Alaskan Chukchi and Beaufort Seas each late summer and autumn 1982-91. The resulting database, consisting of 634 flights, was post-stratified by survey type and sea state (Beaufort $\leq$ 04) to provide a database of cetacean sightings made along random transects during good survey conditions. Sightings made during connect and search legs of the survey, and in rough seas were excluded. Post-stratification resulted in a cumulative (1982-91) database of 276,754 transect-km of survey effort during which there were 554 bowhead, 608 gray and 831 white whale sightings.

Habitat partitioning and variability in habitat use among cetaceans in offshore areas of northern Alaska is poorly defined. Available data suggest that cetacean distribution and abundance patterns can be quantified on the basis of water depth and surface ice cover, and that these indices can be linked to large-scale oceanographic processes. In summer, mean depth and percent surface ice cover were significantly different ($p < 0.001$) among bowhead (900 m, 52%; $n = 79$), gray (40 m, 1%; $n = 497$) and white whales (1,314 m, 60%; $n = 146$). All pairs were significantly different ($p < 0.003$), except for bowhead-white whale ice cover ($p < 0.13$). Similarly in autumn, mean depth and percent ice cover were significantly different ($p < 0.001$) among bowhead (109 m, 22%; $n = 475$), gray

(38 m, 7%; $n = 111$) and white whales (652 m, 52%; $n = 685$); all pairs were significantly different ($p < 0.001$). In addition, mean depth and percent ice cover were significantly different ($p < 0.001$) between summer and autumn for bowhead and white whale sightings. Currents are bathymetrically driven, and ice cover influenced by currents and wind, in the Chukchi and Beaufort Seas. The association of cetaceans with specific bathymetric and ice cover regimes provides a foundation for further investigation of inter-specific habitat selection, zones of productivity and insight to the role of cetaceans in Alaskan arctic ecology.

Agenda Section 1.222

PHOTOGRAPHIC IDENTIFICATION RESEARCH ON SEASONAL RESIDENT WHALES IN WASHINGTON STATE

John Calambokidis and Jennifer Quan

Cascadia Research
218½ W 4th Ave.
Olympia, WA 98501, USA

Calambokidis, J., and J. Quan. 1999. Photographic identification research on seasonal resident whales in Washington State. Unpubl. doc. submitted to the Workshop to Review the Status of the Eastern North Pacific Stock of Gray Whales, 16-17 March 1999, Seattle, WA.

Photographic identification of gray whales in Washington State has been conducted by Cascadia Research since 1984. This has been part of an ongoing research effort to study the abundance, movements, residence times, and return rate of seasonal resident gray whales that spend the spring, summer, and fall feeding in these areas. Starting in 1992, surveys were more frequent and encompassed a broader region. Since 1996, this effort has also included identifications from the National Marine Mammal Laboratory from systematic surveys along the northern Washington Coast and western Strait of Juan de Fuca.

Through 1997, more than 600 identifications of whales have been made, representing 168 unique individuals. In 1996 and 1997, 47 and 37 different gray whales were identified primarily on the northern coast of Washington State and near the western entrance to the Strait of Juan de Fuca (both the Washington and Vancouver Island sides). Movements among these three regions were very common and most animals were seen multiple times (up to 11) over periods of up to 163 days. Of whales identified in northwest Washington in 1996 and 1997, 64%-83% had been identified in a previous year. Gray whales identified near Grays Harbor in the spring were less likely to have been seen multiple times (52%) or a previous year (26%). Comparison of photographic catalogs with researchers working in British Columbia revealed that many of the whales that feed along the Washington coast through the summer range along the British Columbia coast to areas north of Vancouver Island. Gray whale occurrence in Puget Sound has been more variable from year to year.

Analysis is currently underway of the 1998 sample which is the largest and most comprehensive to date. Effort by Cascadia Research included surveys and identifications off California, Oregon, several regions of Washington State (including Puget Sound), southern British Columbia, and southeast Alaska. Photographs of animals in specific regions within this range were also obtained by collaborating researchers with NMML, West Coast Whale Research Foundation, Humboldt State University, University of Victoria, University of British Columbia, Department of Fisheries and Oceans, Vancouver Aquarium, Juan de Fuca Express, and Coastal Ecosystems Research Foundation. These represent close to 500 records of over 150 different individuals. Preliminary results of this analysis has provided new information on the status and movements of these seasonal resident whales.

Overall conclusions include:

1. Seasonal resident gray whales utilize coastal areas from northern California to southeast Alaska from spring to fall with some interchange of animals among most of these areas.
2. Gray whales show some localized site fidelity to certain areas but also move widely within and between years. Gray whales seen in northern Puget Sound show a strong site fidelity to this area but only for part of the season and then move to other unknown areas (not currently sampled).
3. Utilization of some areas, such as southern Puget Sound, are highly variable year to year and whales seen in this area have a high mortality rate and are rarely seen in more than one year.
4. The total number of seasonal resident animals is not known (in the hundreds), nor is how they are recruited to this group, or the degree to which they need to be managed as a separate unit.

Gosho, M.E., P.J. Gearin, J. Calambokidis, K.M. Hughes, L. Cooke, L. Lehman, and V.E. Cooke. 1999a. The summer and fall distribution of gray whales in Washington waters. Unpubl. doc. submitted to the Workshop to Review the Status of the Eastern North Pacific Stock of Gray Whales, 16-17 March 1999, Seattle, WA.

The National Marine Mammal Laboratory has been studying gray whale distribution and identification since 1996 in the Strait of Juan de Fuca, off the northern Washington coast, and off the southwest coast of Vancouver Island. Each year the animals were concentrated in different locations. In 1996, the largest concentration of gray whales occurred off Portage Head and Makah Bay on the northern Washington coast. In 1997, the majority occurred in the westernmost Strait of Juan de Fuca from Bullman Beach to Mushroom Rock. In 1998, most of the gray whales were sighted off the southwest coast of Vancouver Island. Photographs of gray whales allowed the identification of 18 individual animals in 1996 and 28 animals in 1997. Photo-identification and co-operation with other researchers showed that gray whales moved freely between areas in the Strait of Juan de Fuca, off the Washington coast, and off the southwest coast of Vancouver Island.

GRAY WHALE STUDIES AT LAGUNA SAN IGNACIO, B.C.S., MÉXICO, WINTER 1996

Jorge Urbán R., Alejandro Gómez-Gallardo U., Victor Flores de Sahagún,
Jessica Cifuentes L., Stephan Ludwig, and Miguel Palmeros R.

Departamento de Biología Marina, Universidad Autónoma de Baja California Sur
Ap. Post. 19-B, La Paz, B.C.S., 23081 México

Urbán R., J., A. Gómez-Gallardo U., V. Flores de Sahagún, J. Cifuentes L., S. Ludwig, and M. Palmeros R. 1997. Gray whale studies at Laguna San Ignacio, B.C.S., México, winter 1996. Rep. Int. Whal. Commn. 47:625-633.

Laguna San Ignacio, located on the west coast of the Baja California Peninsula, is one of the four main calving-breeding lagoons of the eastern Pacific gray whale (*Eschrichtius robustus*). Uncertainty exists concerning the potential effects of both whale watching and the development of a proposed salt project on gray whales and the lagoon ecosystem. This note documents the current use of Laguna San Ignacio by gray whales for comparison with previous studies and, as far as possible, to provide a baseline to detect and analyse changes in the whales' use of this lagoon. Twenty boat censuses were carried out from 17 January to 27 March 1996. The maximum combined count was 207 (115 single whales and 92 cow-calf pairs). The peak numbers of both single whales and cow-calf pairs were at the same time in early March when almost 40% fewer whales were observed in 1996 than the 1978-82 average. Density estimates at the maximum combined count were: 8.6 whales/km^2 in the lower zone, 3.8 whales/km^2 in the middle zone and 1.3 whales/km^2 in the upper zone. Of the 329 identified whales, 164 were singles, 141 cow-calf pairs and 24 undetermined; 51 whales were seen more than once (43 cow-calf pairs and 8 singles). Different residency intervals were documented: cow-calf pairs stayed in the lagoon 18.3 ± 4.8 (95% C.I.) days and single whales 2.6 ± 1 (95% C.I.) days. Four systematic aerial surveys were carried out at Bahía Ballenas between 1 February and 4 March. The maximum count in this bay was on 28 February with 127 adult whales (119 single whales and 8 cow-calf pairs). These observations must be continued for a period of years to establish a new basis for comparison with previous research results. Further photographic and tagging studies may help in developing turnover rates, which will allow the number of whales using the lagoon to be calculated, based on visual surveys.

Agenda Section 1.23

A NOTE ON THE 1997 GRAY WHALE STUDIES AT LAGUNA SAN IGNACIO, B.C.S., MÉXICO

Jorge Urbán R., Alejandro Gómez-Gallardo U., and Miguel Palmeros R.

Departamento de Biología Marina, Universidad Autónoma de Baja California Sur
Ap. Post. 19-B, La Paz, B.C.S., 23081 México

Urbán R., J., A. Gómez-Gallardo U., and M. Palmeros R. 1998a. A note on the 1997 gray whale studies at Laguna San Ignacio, B.C.S., México. Rep. Int. Whal. Commn. 48:513-516.

This note includes the results of our second year of gray whale studies at Laguna San Ignacio, B.C.S., México. Uncertainty exists concerning the potential effects of both whalewatching and the development of the proposed salt project on gray whales and the lagoon ecosystem. The purpose of this report is to document the current use of Laguna San Ignacio by the gray whales for comparison with previous studies. Eleven complete censuses of the lagoon were done by boat to determine whale abundance and distribution from 11 February to 29 March 1997. The maximum combined count was 253 (127 single whales and 126 cow-calf pairs) during the last week of February. Six dead calves (four males and two females) were found inside the lagoon. The upper zone of the lagoon was the most important for cow-calf pairs and the lower zone for single whales. There were 22% more whales than in the 1996 winter season, but this is still 36% lower than the highest count in 1985. Different residency intervals were documented: cow-calf pairs stayed in the lagoon 19.6 ± 3.5 days (95% C.I.), and the single whales 6.2 ± 3.2 days (95% C.I.). Nine whales photo-identified in 1996 were also photographed during the 1997 winter season.

Sánchez Pacheco, J.A., and J.L. Valdés Aragón. 1997. Transito de ballena gris (*Eschrichtius robustus*) en Bahía Ballenas, Baja California Sur, México. [The transit of the gray whale (*Eschrichtius robustus*) in Bahía Ballenas, Baja California Sur, Mexico.] Boletín Pesquero CRIP-La Paz 7:26-33.

Results are presented on observations of the transit of gray whales at different distances from the coast in Bahía Ballenas, Baja California Sur, during the 1996 and 1997 seasons. Whales that moved northwards prevailed (96%). There were fewer single whales in 1997 than in 1996; the reverse situation occurred in whales with calves. Single whales transited further from the coast (75.4% ≥2 km) than whales with calves (82.32% within 3 km). The number of single whales estimated to migrate north from the observation point was 2,888 and 2,195 for 1996 and 1997, respectively. There were 418 cow/calf pairs seen in 1996 and 621 in 1997.

Buckland, S.T., and J.M. Breiwick. In press. Estimated trends in abundance of eastern Pacific gray whales from shore counts, 1967/68 to 1995/96. J. Cetacean Res. Manage. Special Issue 2.

Estimates of abundance of eastern Pacific gray whales are obtained from counts made during their southbound migration past a shore-based station near Monterey, California. Assuming an exponential rate of increase, the population is estimated to have increased at 2.5% per annum (SE = 0.3%) between 1967/68 and 1995/96. However, there is some indication that the population growth is slowing, so that an asymptotic growth curve may be more appropriate. The estimated asymptote from a logistic model is 26,046 (SE = 6,281) and the inflection point is approximately in 1971 (SE = 6.5). The onset of the migration, when 10% of the whales have passed the station, has occurred increasingly later through this sample period, by approximately one day every 2 years. Median dates show a similar trend of roughly one day every 3 years. However, there is no significant change in the date at which 90% of whales have passed the station.

GRAY WHALE ABUNDANCE ESTIMATES, 1967/68 - 1997/98: *ROI*, *RY*, AND *K*

J.M. Breiwick

National Marine Mammal Laboratory
Alaska Fisheries Science Center, NMFS, NOAA
7600 Sand Point Way NE, Bin C15700
Seattle, WA 98115-0070, USA

Breiwick, J.M. 1999. Gray whale abundance estimates, 1967/68 - 1997/98: *ROI*, *RY* and *K*. Unpubl. doc. submitted to the Workshop to Review the Status of the Eastern North Pacific Stock of Gray Whales, 16-17 March 1999, Seattle, WA.

Gray whale abundance estimates for the period 1967/68 to 1997/98 were fit using a generalized linear model (Poisson error, logarithmic link), giving a rate of increase of 2.52% per annum (SE = 0.27%). In addition, a (continuous) logistic model fit to the data gave a *K* (carrying capacity) of 37,364 (SE = 24,854), larger by 11,000 than a similar estimate based on the 1967/68 - 1995/96 data. Both estimates have very large CVs associated with them. A discrete logistic model was also used to estimate R_{max} and *K*. A replacement yield (*RY*) of 612 was calculated based on the rate of increase estimate, average catches and the abundance estimates. A Monte Carlo procedure was used to calculate a 95% confidence interval for *RY*.

Wade. P.R., and D.P. DeMaster. 1996. A Bayesian analysis of eastern Pacific gray whale population dynamics. Unpubl. doc. SC/48/AS3 submitted to Sci. Comm. of Int. Whal. Commn. 21 p.

A Bayesian statistical method was used to investigate the population dynamics of eastern Pacific gray whales. Apparent stability in the three most recent abundance estimates may be due to a density-dependent slowing of the population growth rate. This hypothesis was tested by comparing how well density-dependent population models fit the data relative to density-independent population models. Additionally, a second hypothesis was tested, which was whether using a parameter representing additional variance in the abundance estimates provided a better fit to the data than not including it. In total, the fit of eight different models were compared through the use of the Bayes factor. Density-dependent models were decisively supported by the data over density-independent models when the additional variance term was not used. However, the use of the additional variance term was also decisively supported by the comparisons. When the additional variance term was included, the data still favored the density-dependent models, but only marginally. Point estimates of the equilibrium population size ranged from 24,000 to 32,000 depending upon which model was used, but values as high as 70,000 still had some probability.

Agenda Section 1.3

A BAYESIAN STOCK ASSESSMENT OF THE EASTERN PACIFIC GRAY WHALE USING ABUNDANCE AND HARVEST DATA FROM 1967 TO 1996

Paul R. Wade

Office of Protected Resources, National Marine Fisheries Service, NOAA
c/o National Marine Mammal Laboratory
Alaska Fisheries Science Center, NMFS, NOAA
7600 Sand Point Way NE, Bin C15700
Seattle, WA 98115-0070, USA

Wade. P.R. In press. A Bayesian stock assessment of the eastern Pacific gray whale using abundance and harvest data from 1967 to 1996. J. Cetacean Res. Manage. Special Issue 2.

Abundance and harvest data since 1966/67 were used to assess the eastern Pacific stock of gray whales. A Bayesian statistical method was used to estimate probability distributions for the parameters of both a simple and an age and sex structured population dynamics model, as well as output quantities of interest. Model comparisons using the Bayes Factor provided conclusive evidence that an additional parameter should be used to account for unexplained variation in the abundance time series. Incorporating the additional variance parameter decreased the precision of the estimates of the other parameters. Point estimates of carrying capacity ranged from 24,640 to 31,840 for the different models, but the posterior distributions from the selected models were very broad and excluded few values. The current depletion level (population size as a fraction of carrying capacity) was estimated to be about 0.75, with a lower 2.5th percentile of 0.36. The probability that the population was still below one-half of its carrying capacity was estimated to be 0.21, with a corresponding probability of 0.28 that the population was still below its maximum sustainable yield level. Quantities from which catch limits could potentially be calculated were estimated, including current replacement yield, maximum sustainable yield and the quantity Q_1 (described in Wade and Givens 1997).

Gerber, L.R., D.P. DeMaster, and P.M. Kareiva. In press. Gray whales illustrate the value of monitoring data in implementing the Endangered Species Act. Conserv. Biol.

Many scientists lament the absence of data for endangered species and argue that more funds should be spent acquiring basic information regarding population trends. Using nineteen years of abundance estimates for the eastern North Pacific gray whale *(Eschrichtius robustus)*, we sampled subsets of the original survey data to identify the number of years of data required to remove the population from the Endangered Species Act's (ESA) List of Endangered and Threatened Wildlife. For any given duration of monitoring, we selected all possible combinations of consecutive counts. To incorporate variability in growth rates we extracted a maximum likelihood estimator of growth rate and confidence interval about that growth rate on the assumption that the population changes can be approximated by a simple diffusion process with drift. We then applied a new approach to determine ESA status for each subset of survey data and found that a quantitative decision to delist is unambiguously supported by eleven years of data, but precariously uncertain with fewer than ten years of data. The data needed to produce an unequivocal decision to delist gray whales cost the National Marine Fisheries Service an estimated $660,000, a surprisingly modest expense given the fact that delisting can greatly simplify regulatory constraints. This example highlights the value of population monitoring in administering the ESA, and provides a compelling example of the utility of such information in identifying both imperiled species and recovered species. The economic value of such data should be clear: they provide the foundation for delisting, which could ultimately save much more money than the collection of the data would ever cost.

Agenda Section 2.1

GRAY WHALE CALF SIGHTINGS COLLECTED DURING SOUTHBOUND MIGRATIONS, 1952-95

Kim E.W. Shelden, David J. Rugh, and Sally A. Boeve[1]

National Marine Mammal Laboratory
Alaska Fisheries Science Center, NMFS, NOAA
7600 Sand Point Way NE, Bin C15700
Seattle, WA 98115-0070, USA

Shelden, K.E.W., D.J. Rugh, and S.A. Boeve. In press. Gray whale calf sightings collected during southbound migrations, 1952-95. J. Cetacean Res. Manage. Special Issue 2.

For the past 43 years, scientists at the National Marine Mammal Laboratory and preceding organizations, have collected information on sightings of gray whale calves during the whales' annual migration between Alaska and Mexico. The data document the timing and location of calving during the southbound migration along the California coast. Calf-sighting data were collected by observers conducting abundance surveys of gray whales from shore-based sites at Point Loma, near San Diego, in 1952-69 and 1975-78; Yankee Point, Carmel, in 1967-74; and Granite Canyon, Carmel, during most years between 1974 and 1995. Although some reporting methods have changed over the years, all records indicate that observers searched for and recorded calves. In addition to shore-based surveys, aerial surveys were conducted in five seasons between 1979 and 1994. Results indicate that shore-based observers missed 62% of the calves within their viewing area (0-2.6 km from shore), suggesting that calves are significantly under-represented in the shore-based data record. For many of the early census years (1952-74), the percentage of calves sighted (number of calves/total whales) was within the range 0.0-0.2%. In 1975 the percentage of calves sighted at Point Loma increased substantially (to 0.7%) but it did not show up at the Carmel shore stations, 570 km north of Point Loma, until 1984. The highest calf count (n = 36; 0.8%) occurred during 1993/94 at Granite Canyon, when migration dates were later than for any other year. The apparent increase in calf sightings may be related to a trend towards successively later migrations over the 43 year observation period, or to an increase in spatial and temporal distribution of calving as the population has increased. As the population reaches carrying capacity, food resources may be more limited, resulting in pregnant females departing from the feeding grounds later and with reduced fat reserves. As a result, parturition may be occurring prior to reaching the preferred calving grounds at Baja California, Mexico.

Agenda Section 2.1

GRAY WHALE CALF SIGHTINGS DURING SOUTHBOUND MIGRATIONS, 1995-98

Kim E.W. Shelden and David J. Rugh

National Marine Mammal Laboratory
Alaska Fisheries Science Center, NMFS, NOAA
7600 Sand Point Way NE, Bin C15700
Seattle, WA 98115-0070, USA

Shelden, K.E.W., and D.J. Rugh. 1999. Gray whale calf sightings during southbound migrations, 1995-98. Unpubl. doc. submitted to the Workshop to Review the Status of the Eastern North Pacific Stock of Gray Whales, 16-17 March 1999, Seattle, WA.

As an addendum to Shelden et al. (in press), this report provides data on sightings of gray whale calves that were collected during aerial surveys conducted in January 1996 and shore-based surveys conducted during the winters of 1995/96, January 1997, and 1997/98 near the shore station at Granite Canyon, California. The proportions of calves to adults observed from 1995 to 1998 (0.003 - 0.015) were similar to those recorded from 1984 to 1995 (0.001 - 0.009). The highest number of sightings occurred during the 1997/98 season with 61 calves reported. The proportion of calves visible from the air in 1996 (0.0308) was much higher than the proportion observed in 1988 (0.0024) but fell between the proportions observed in 1993 and 1994 (0.0238 and 0.0440). The distribution of cows with calves relative to shore was similar to earlier years where the majority of sightings occurred inshore of the main migration corridor (1.4 - 2.8 km) during both shore-based and aerial surveys. The median distance for shore-based sightings was 0.79 km compared to 1.34 km from the air during the 1995/96 season. Although calves appeared to be closer to shore in 1995/96 when comparing shore-based observations from earlier years (1.1 km from pooled data 1987-95); median distances during aerial surveys were not different (1.3 km from pooled data 1988, 1993 and 1994). Shelden et al. (in press) noted that it was rare that more than one independent observer at a time recognized the presence of a calf. During the 1995/96 season, 12 calves were identified during paired-independent observations of which only 3 were also seen by the second observer. In January 1997, only 1 of 7 sightings were matched between observers, and during the 1997/98 season only 5 matches occurred among 40 sightings.

SOUTHBOUND AND NORTHBOUND GRAY WHALE CALF SIGHTINGS OFF LOS ANGELES, 1984-99

Alisa Schulman-Janiger

American Cetacean Society, Los Angeles Chapter
2716 South Denison Avenue, San Pedro, CA 90731, USA

Schulman-Janiger, A. 1999b. Southbound and northbound gray whale calf sightings off Los Angeles, 1984-99. Unpubl. doc. submitted to the Workshop to Review the Status of the Eastern North Pacific Stock of Gray Whales, 16-17 March 1999, Seattle, WA.

For the past 16 seasons, trained volunteers have conducted the shore-based full-season Gray Whale Census and Behavior Project, sponsored by the Los Angeles Chapter of the American Cetacean Society (ACS/LA), at or near Point Vicente (near Los Angeles, California). Gray whales and other cetaceans are counted from shore, 10-12 hours per day, 7 days a week, for 5 to 6 months. Southbound counts have ranged from 301 to 1,301 per year, including 3 to 106 newborn calves. The percentage of southbound calves sighted (number of calves/total southbound whales) during the first 7 years of our study (1983/84 to 1989/90) ranged from 0.5% to 2.5%, averaging 1.7%. During the next three seasons (1990/91 to 1992/93) these percentages increased to 3.0-3.9%, averaging 3.5%. The calf percentages from 1993/94 to 1998/99 ranged from 2.0% to 8.6%, averaging 4.6%. However, the calf count in the 1998/99 migration (n = 15; 2.2%) was one of the lowest in the past nine seasons. The highest calf count (n = 106; 8.6%) was in the 1997/98 season. These calf percentages are considerably higher than those published for other censuses. As their numbers increase, more gray whales may delay departures from northern feeding grounds (especially in seasons that include warmer arctic waters and late ice formation); more females may give birth off southern California rather than in Mexican calving lagoons, possibly subjecting calves to higher mortality rates. Gray whales with newborns appear to favor a more protected coastal (rather than offshore) migratory corridor, thus raising nearshore percentages of southbound calves. The relatively high (and apparently increasing) percentage of southbound gray whale calves documented here indicate that births off southern California are more common than previously thought.

The northbound migration of cow/calf pairs peaks between 6 April and 27 April, generally during the last half of April; this peak occurs 4-8 (averaging 6) weeks after the earlier migration peak that primarily consists of whales with no calves. Northbound counts have ranged from 793 to 3,412 per year, including 11 to 222 newborn calves. The percentage of newborn calves sighted (number of calves/total number of northbound whales) during the first nine seasons of our study (1983/84 to1991/92) ranged from 0.9% to 8.3%, averaging 3.4%. During three seasons (1987/88, 1989/90, and 1990/91) the percentage of northbound calves observed was actually lower than the percentage of southbound calves observed earlier in those migrations; this occurred during a period of generally lower whale counts. During the next six seasons (1992/93 to 1997/98) this percentage generally increased: it ranged from 4.3% to13.8%, averaging 9.6%. Some of the highest percentages, ranging from 9.4% to 13.8% (averaging 11.2%), have occurred in recent years (1995/96 to1997/98). These were substantially higher than previously published figures for California waters. The highest calf count (n = 222, 13.8%) occurred in the 1996/97 season and was more than double the count of any of the preceding nine seasons. However, the percentage of calves in the 1998/99 northbound migration was only 2.5% (n = 34), well below percentages seen in recent years. Factors that may be contributing to this increase in northbound calf percentages include: shore-based observers are detecting a higher percentage of calves; there may be some shortening of gray whale calving intervals; and, more calves may be surviving the first few months of life. These annual counts, complementing those conducted from other areas, could help indicate whether gray whale calf production is decreasing, stabilizing, or increasing.

Agenda Section 2.4

ANNUAL CALF PRODUCTION FOR THE CALIFORNIA STOCK OF GRAY WHALES 1994-98
[Preliminary Analysis]

Wayne L. Perryman, Meghan A. Donahue, Stephen B. Reilly, and Peter C. Perkins

Southwest Fisheries Science Center, NMFS, NOAA
P.O. Box 271, La Jolla, CA 92038, USA

Perryman, W.L., M.A. Donahue, S.B. Reilly, and P.C. Perkins. 1999b. Annual calf production for the California stock of gray whales 1994-98 [Preliminary analysis]. Unpubl. doc. submitted to the Workshop to Review the Status of the Eastern North Pacific Stock of Gray Whales, 16-17 March 1999, Seattle, WA.

We conducted shore-based sighting surveys to estimate the number of northbound migrating gray whale calves passing Piedras Blancas, California, for four consecutive years (1994-98). In addition, we conducted aerial surveys to determine offshore distribution of the migration in 1994 and 1995, measured day/night migration rates with thermal sensors in 1994-96, and maintained concurrent replicate watches near the peak of each migration to estimate the proportion of the northbound cow-calf pairs missed by the census team. During good weather conditions, we counted 325, 194, 408, 501, and 440 calves during 1994-98 respectively. Correcting these counts for periods not on watch, calves passing far offshore (1994 only), and for calves missed by the census team produced final estimates of 1,000 calves (SE = 88.85) for 1994; 601 calves (SE = 69.56) for 1995; 1,141 calves (SE = 72.23) for 1996; 1,439 calves (SE = 78.62) for 1997; and a preliminary estimate of 1,316 calves (SE = 77.56) for 1998. Calf production indices (calf estimate/total population estimate) are 4.5%, 2.6%, 5.1%, 6.5%, and 5.9% for the years 1994-98, respectively.

Agenda Section 2.5

RESULTS OF PHOTOGRAMMETRIC WHALING FOR GRAY WHALES ALONG THE CENTRAL AND SOUTHERN CALIFORNIA COAST BETWEEN 1994 AND 1998

Wayne L. Perryman and Morgan S. Lynn

Southwest Fisheries Science Center, NMFS, NOAA
P.O. Box 271
La Jolla, CA 92038, USA

Perryman, W.L., and M.S. Lynn. 1999. Results of photogrammetric whaling for gray whales along the central and southern California coast between 1994 and 1998. Unpubl. doc. submitted to the Workshop to Review the Status of the Eastern North Pacific Stock of Gray Whales, 16-17 March 1999, Seattle, WA.

More than 25 years after the last gray whale was taken along the California coast under a special permit issued by the IWC to study the biology and ecology of this population, we began an aerial photogrammetric sampling effort with the goal of revisiting some of the results derived from the examination of specimens. Analysis of length, maximum width, and fluke width data for southbound gray whales indicate that the migration is led by large whales, many of them ?pregnant females," and that juvenile whales are most common late in the migration. Calves photographed around the California Channel Islands averaged 4.60 m in length. Based on the proportion of ?pregnant" and recent postpartum females, we estimate 15 January to be the median birth date for eastern Pacific gray whales. Northbound calves photographed in late May averaged 7.10 m in length which is inconsistent with the accepted growth curve for young gray whales. We estimate length at 1 year to be 8.6 m and propose a new growth curve. There was a significant positive linear relationship between the length of a cow and her associated northbound calf. Lengths of cows with calves were shorter on average than adult females examined by Rice and Wolman (1971: 12.3 m versus 12.7 m), which may reflect gunner selection for large whales, stretching of specimens during processing, or bias in the photographic sample. Based on the relationship between log length and log width, northbound whales were significantly thinner than those photographed southbound. This difference was most pronounced between ?pregnant females" and northbound cows with calves. Our results indicate that relatively small changes in condition or fatness of gray whales are detectable in measurements from photographs.

Seattle, WA 98115-0070, USA

Tynan, C.T., and D.P. DeMaster. 1997a. Observations and predictions of arctic climatic change: potential effects on marine mammals. Arctic 50(4):308-322.

Recent analyses have revealed trends over the past 20-30 years of decreasing sea ice extent in the Arctic Ocean coincident with warming trends. Such trends may be indicative of the polar amplification of warming predicted for the next several decades in response to increasing atmospheric CO_2. We have summarized these predictions and nonuniform patterns of arctic climate change in order to address their potential effects on marine mammals. Since recent trends in sea ice extent are nonuniform, the direct and indirect effects on marine mammals are expected to vary geographically. Changes in the extent and concentration of sea ice may alter the seasonal distributions, geographic ranges, patterns of migration, nutritional status, reproductive success, and ultimately the abundance and stock structure of some species. Ice-associated seals, which rely on suitable ice substrate for resting, pupping, and molting, may be especially vulnerable to such changes. As recent decreases in ice coverage have been more extensive in the Siberian Arctic (60°E-180°E) than in the Beaufort Sea and western sectors, we speculate that marine mammal populations in the Siberian Arctic may be among the first to experience climate-induced geographic shifts or altered reproductive capacity due to persistent changes in ice extent. Alteration in the extent and productivity of ice-edge systems may affect the density and distribution of important ice-associated prey of marine mammals, such as arctic cod *Boreogadus saida* and sympagic ("with ice") amphipods. Present climate models, however, are insufficient to predict regional ice dynamics, winds, mesoscale features, and mechanisms of nutrient resupply, which must be known to predict productivity and trophic response. Therefore, it is critical that mesoscale process-oriented studies identify the biophysical coupling required to maintain suitable prey availability and ice-associated habitat for marine mammals on regional arctic scales. Only

an integrated ecosystems approach can address the complexity of factors determining productivity and cascading trophic dynamics in a warmer Arctic. This approach, integrated with monitoring of key indicator species (e.g., bowhead whale, ringed seal, and beluga), should be a high priority.

Agenda Section 3.1

THE INFLUENCE OF OCEANOGRAPHIC PROCESSES ON PELAGIC-BENTHIC COUPLING IN POLAR REGIONS: A BENTHIC PERSPECTIVE

Jacqueline M. Grebmeier[1] and James P. Barry[2]

[1]Graduate Program in Ecology
The University of Tennessee
Knoxville, TN 37996, USA

[2]Scripps Institution of Oceanography
University of California - San Diego
La Jolla, CA 92093, USA

Grebmeier, J.M., and J.P. Barry. 1991. The influence of oceanographic processes on pelagic-benthic coupling in polar regions: a benthic perspective. J. Mar. Syst. 2:495-518.

Benthic community abundance and biomass in polar marine systems is directly influenced by food supply from the overlying water column. Variability in hydrographic regimes, ice coverage, light, water column temperature and pelagic food web structure limit the amount of organic carbon reaching the benthos. Data from the high Arctic and Antarctic indicate that a large percentage of surface-produced organic matter is consumed by both macro- and micro-zooplankton as well as recycled in the water column via the microbial loop. This results in food-limited regimes for the underlying benthos. The few exceptions are nearshore continental shelf systems, such as in the Bering and Chukchi Seas in the western Arctic and portions of the Canadian Archipelago and Barents Sea in the eastern Arctic, where high benthic abundance and biomass occurs due to a tight coupling between water column primary production and benthic secondary production. A major difference between the Antarctic and Arctic is that the nearshore deep Antarctic is characterized by relatively high benthic abundance and biomass despite low water column production, suggesting that stability, low disturbance levels and cold temperatures enable benthic organisms to grow larger than in the Arctic. Both physical and biological disturbance levels are high in the marginal seas of the Arctic and may directly influence benthic productivity. The relationship between primary production and sedimentation of organic material to the benthos is nonlinear due to its dependence on the role of the pelagic food web. Therefore, in this review we will only discuss the pelagic system with respect to how it impacts the net food supply reaching the benthos. A major objective of this review paper is to demonstrate the influence of oceanographic processes on pelagic-benthic coupling in polar regions from a "bottom-up" perspective, using benthic studies from various regions in both the Arctic and Antarctic. Similarities and differences in oceanographic processes, benthic abundance and biomass, and benthic carbon cycling within these polar marine systems are discussed and areas for further research identified.

Agenda Section 3.2

PRODUCTIVITY OF ARCTIC AMPHIPODS RELATIVE TO GRAY WHALE ENERGY REQUIREMENTS

Raymond C. Highsmith and Kenneth O. Coyle

Institute of Marine Science, School of Fisheries and Ocean Sciences
University of Alaska Fairbanks
Fairbanks, AK 99775-1080, USA

Highsmith, R.G., and K.M. Coyle. 1992. Productivity of arctic amphipods relative to gray whale energy requirements. Mar. Ecol. Prog. Ser. 83:141-150.

Amphipod crustaceans dominate the benthic community in vast areas of the northern Bering Sea; they are the major prey of the California gray whale *Eschrichtius robustus*. The protected whale population is growing steadily and may be approaching the carrying capacity of the amphipod community, one of the most productive benthic communities in the world. The abundance and biomass of the amphipod community decreased during the 3-year period 1986 to 1988, resulting in a 30% decline in production. High-latitude amphipod populations are characterized by low fecundity and long generation times. Large, long-lived individuals are responsible for the majority of amphipod secondary production. A substantial reduction in the density of large individuals in the population will result in a significant, long-term decrease in production.

Agenda Section 3.2

DISTRIBUTION AND CARRYING CAPACITY OF GRAY WHALE FOOD RESOURCES IN THE NORTHERN BERING AND CHUKCHI SEAS

Sam W. Stoker

Beringian Resources, Inc.

Stoker, S.W. In press. Distribution and carrying capacity of gray whale food resources in the northern Bering and Chukchi seas. J. Cetacean Res. Manage. Special Issue 2.

During their summer residency in the Bering and Chukchi Seas, gray whales rely on the rich benthic amphipod populations of the region to renew fat resources needed to sustain them during their winter migration to and from the breeding lagoons of Mexico. Surveys of gray whale population distribution on these northern grounds indicate that concentrations of feeding whales return annually to certain locations, and that these locations coincide, in most cases, with high density and high productivity amphipod communities.

The annual impact of gray whales feeding within these preferred areas is probably considerable. Studies of one of the high-use areas, the central Chirikov Basin between St. Lawrence Island and the Bering Strait, indicate that gray whales disturb at least 6% of the benthos each summer and consume more than 10% of the yearly amphipod production. Whether or not this rate of consumption is within sustainable bounds is unclear since it is impossible, at this time, to assess additional demands imposed upon amphipod populations by other predators such as epibenthic invertebrates and demersal fishes. There are indications, however, that this resource is being stressed and that the gray whale population is expanding its summer range in search of alternative feeding grounds.

Tilbury, K.L., J.E. Stein, C.A. Krone, G.M. Ylitalo, R.L. Brownell, Jr., M. Gosho, A. Blokhin, J.L. Bolton, and D.W. Ernest. 1999. Chemical contaminants in gray whales (*Eschrichtius robustus*) from off their western Bering Sea arctic feeding grounds and the California and Washington coasts. Unpubl. doc. submitted to the Workshop to Review the Status of the Eastern North Pacific Stock of Gray Whales, 16-17 March 1999, Seattle, WA.

The gray whale (*Eschrichtius robustus*) is a coastal migratory baleen whale (Mysticete) with a benthic feeding strategy and a long period of fasting during its southbound migration and residence in the breeding grounds. The prolonged fasting may alter the disposition of toxic chemicals within the animal. Additionally, gray whales have been observed feeding in coastal waters, which may present a risk of exposure to toxic chemicals in some regions. We measured the concentrations of organochlorines (OCs) and trace elements in tissues and stomach contents collected from juvenile gray whales that were taken off their Arctic feeding grounds in the western Bering Sea during a Russian subsistence harvest. Blubber biopsy samples that were taken from gray whales off the California and Washington coasts were also analyzed for OCs; previously we measured these contaminants in tissues and stomach contents of gray whales that stranded along the U.S. west coast and Alaska. There were no differences in the concentrations (based on wet weight of tissue) of contaminants between female and male subsistence animals. The lipid content [48 (5)%] of blubber for animals from the Arctic feeding grounds was higher than that in the biopsy samples [9.4 (0.8)%] from free-ranging, apparently healthy whales. Concentrations on a lipid basis of the sum of polychlorinated

biphenyls (∑PCBs) in the juvenile stranded whales and the juvenile subsistence whales were significantly different [19,000 (14,000) and 680 (67) ng/g lipid, respectively]. The mean concentration of the ∑PCBs for the biopsy samples was 2,000 (280) ng/g lipid weight. We hypothesize that the higher concentration of ∑PCBs in the stranded animals may be due to the retention of OCs in blubber during fasting rather than to increased exposure to these contaminants. The concentrations of certain trace elements (e.g., cadmium) is some tissues, such as kidney, were also elevated in the stranded animals. Moreover, aluminum in stomach contents and tissues of the subsistence whales was high compared to other marine mammal species, which is consistent with the ingestion of sediment during feeding.

Agenda Section 4.2

POTENTIAL IMPACT OF OFFSHORE HUMAN ACTIVITIES ON GRAY WHALES

Sue E. Moore[1] and Janet T. Clarke

SAIC, Maritime Services Division
3990 Old Town Avenue, Suite 105A
San Diego, CA 92110-2931, USA

Moore, S.E., and J.T. Clarke. In press. Potential impact of offshore human activities on gray whales. J. Cetacean Res. Manage. Special Issue 2.

Gray whale (*Eschrichtius robustus*) reactions to offshore human activities have been relatively well studied compared to those of other mysticetes. Studies of short-term behavioural responses to underwater noise associated with aircraft, ships and seismic explorations indicate a 0.5 probability that whales will respond to continuous broadband noise when sound levels exceed *ca.* 120dB[2] and to intermittent noise when levels exceed *ca.* 170dB, usually by changing their swimming course to avoid the source. Gray whales 'startled' at the sudden onset of noise during playback studies, but demonstrated a flexibility in swimming and calling behaviour that may allow them to circumvent increased noise levels. Whales may be 'harassed' by noise from large commercial vessels, especially in shipping lanes or near busy ports. Gray whales sometimes change course and alter their swimming speed and respiratory patterns when followed by whalewatching boats. Conversely, some whales swim toward small skiffs deployed from whalewatching boats in breeding lagoons, seemingly attracted by the noise of idling outboard engines. Reported gray whale reactions to aircraft are varied and seem related to ongoing whale behaviour and aircraft altitude. Whale response to research involving tagging and biopsy sampling appears to be short term. Gray whales were seen swimming through surface oil from the *Exxon Valdez* oil spill along the Alaskan coast and showed only partial avoidance to natural oil seeps off the California coast. Laboratory tests suggest that gray whale baleen, and possibly skin, may be resistant to damage by oil, but spilled oil or oil dispersant in a primary feeding area could negatively affect gray whales by contaminating benthic prey. Gray whales are sometimes injured or killed in collisions with vessels or entanglement in fishing gear. Concern about the cumulative long-term impact of offshore human activities is particularly acute in the Southern California Bight, where many activities are often concurrent.

BIO-ACOUSTICS OF THE GRAY WHALE (*ESCHRICHTIUS ROBUSTUS*)

Marilyn E. Dahlheim[1]

The University of British Columbia
Canada

Dahlheim, M.E. 1988. Bio-acoustics of the gray whale (*Eschrichtius robustus*). Ph.D. Thesis, University of British Columbia. xiii+266 p.+appendices.

Gray whales (*Eschrichtius robustus*), while engaged in underwater signalling, circumvent noise in the acoustical channel by the structure and timing of their calls. Data yielding this conclusion were collected during an acoustical study on gray whales and their habitats (1981-84). Sonographic analyses of tape recordings were used to quantify the acoustical repertoire, the ambient noise characteristics of the area, and the relationship between the animals' calls and the environment. The acoustical responses of whales to artificially increased levels of noise were documented during playback experimentation in Mexico. Nine sound parameters were inspected and compared between control and experimental conditions: calling rates, call types, frequency range of signals (Hz), emphasized frequencies (Hz), received levels of sounds (dB re 1 μPa), call duration (sec), percentage of calls exhibiting frequency modulation, number of pulses per series, and repetition rates of signals. The observed surface behavior of gray whales in response to noise (i.e., dive durations, movements and abundance) was also investigated. Analyses yielded: a description of gray whale call types; a characterization of the acoustical habitats occupied by this species, including a list of sources contributing to the ambient noise and a profile of the propagation characteristics of the study area; a determination of the relationship between whale calls and their habitats; and the acoustical capabilities and strategies of whales in response to noise. The plasticity observed in the overall behavior of this whale is of adaptive significance when considering the dynamic nature of noise in the environment. Typically, the multiple strategies employed by the whales when faced with various noise situations enable them to minimize the detrimental effect that noise has on their underwater signalling. Gray whale responses varied with the sound source and may also differ relative to the geographical range and/or general behavior of the animal. It is concluded that ambient noise (both natural and man-made) has a profound effect on the behavior of this coastal species and that acoustical calling is modified to optimize signal transmission and reception.

A REPORT TO THE MARINE MAMMAL COMMISSION ON PROPOSED SALT PRODUCTION FACILITIES AT SAN IGNACIO LAGOON BAJA CALIFORNIA

Bruce R. Mate
Oregon State University, Hatfield Marine Science Center
Newport, OR 97365, USA

Mate, B.R. 1995. A report to the Marine Mammal Commission on proposed salt production facilities at San Ignacio Lagoon, Baja California. Unpubl. report to U.S. Marine Mammal Commission, Washington, D.C. 13 p.

Exportadora de Sal, sometimes referred to as ESSA, has been a business partnership between Mitsubishi, Japan (49%), and Mexico (51%) since 1954. It operates a salt production facility at the town of Guerrero Negro, midway along the Pacific Coast of Baja California. It is the world's largest solar evaporative operation and produces 6.5 million metric tons of salt per year from the adjacent Laguna Ojo de Liebre. ESSA is planning to expand its operation to San Ignacio Lagoon.

Laguna Ojo de Liebre and San Ignacio Lagoon are both in the Vizcaíno Desert Biosphere Reserve, Mexico's largest refuge administered by Secretaria de Desarrollo Social (SEDESOL), the Secretariat of Social Development. An Environmental Impact Assessment was completed in July 1994 and was reviewed by SEDESOL. The application was either denied or withdrawn in March 1995.

This report summarizes the activities of the current operation and the proposed activity based on interviews with company officials in January 1995 and a review of the Environmental Impact Assessment.

Agenda Section 4.5

CONSERVATION AND DEVELOPMENT IN THE GRAY WHALE LAGOONS OF BAJA CALIFORNIA SUR, MEXICO

Serge Dedina and Emily Young
Department of Geography and Regional Development
University of Arizona
Harvill Building, Box #2
Tucson, AZ 85721, USA

Dedina, S., and E. Young. 1995a. Conservation and development in the gray whale lagoons of Baja California Sur, Mexico. Final report to U.S. Marine Mammal Commission, Washington, D.C. NTIS PB96-113154. iii+56 p.

In this report we identify ongoing and possible future development and related activities that could have a negative impact on two of the three main calving/breeding habitats for the eastern North Pacific gray whale (*Eschrichtius robustus*) population in Baja California Sur, namely Laguna San Ignacio and Bahía Magdalena. We also identify steps that are being or could be taken to assess and to prevent or minimize activities that may have adverse effects. We provide: 1) a brief summary of the natural history, exploitation, protection, and current status of the gray whale population in Mexico; 2) a description of the physical and human geography of the study area; 3) a history of environmental conservation efforts in the study area; 4) an overview of the environmental management structure in the study area and the environmental impact review process in Mexico; 5) descriptions of past, existing, and planned development and commercial activities in the study area; and 6) descriptions of impediments to effective assessment and control of activities with potentially adverse impacts and possible means to strengthen current gray whale conservation.

This study is based on field research undertaken in Laguna San Ignacio and Bahía Magdalena. We also conducted background research and interviews in San Diego, California, La Paz, Baja California Sur, and Mexico City. The research included: 1) open-ended and semi-structured interviews with local residents, government officials and others with knowledge of the area and matters of interest or concern to this study; 2) participant observation of local residents' activities; 3) a review of archival sources on the history of the study area and gray whale conservation; and 4) a review of newspaper coverage of issues related to gray whale conservation in Baja California Sur. This enabled us to compare actual use and management of gray whale habitats with: how government officials think these areas are and should be used and managed; and how different user groups in the study area view regulations of their activities for gray whale habitat management.

Laguna San Ignacio is the only primary gray whale breeding/calving area in Mexico that remains superficially unaltered. In contrast, portions of Bahía Magdalena have been changed by industrial and mining activities, as well as part of the Vizcaíno Biosphere Reserve. Bahía Magdalena remains unprotected.

Three federal agencies are responsible for on-site protection of gray whales and regulation of human activities in Laguna San Ignacio and Bahía Magdalena. These are the National Institute of Ecology (INE), the Federal Attorney General's Office for Environmental Protection (PROFEPA), and the Secretariat of Fisheries (Pesca).

The greatest potential threats to the whales and their habitat are from: 1) the proposed development of a 52,150 ha salt production facility on the shore of Laguna San Ignacio; 2) a proposed tourist resort development at Bahía Magdalena; and 3) the growth of gray whale tourism in the North Zone of Bahía Magdalena. Strict review and monitoring of development and whale-tourism by INE, PROFEPA, and Pesca under existing environmental impact assessment regulations, and the review of project plans and tourism activities by non-governmental organizations, research institutions, and scientists familiar with gray whale habitat, could help to minimize potentially adverse impacts.

Agenda Section 4.5

SAN IGNACIO SALTWORKS:
SALT AND WHALES IN BAJA CALIFORNIA

Secretaria de Medio Ambiente, Recursos Naturales y Pesca (SEMARNAP)
Periférico Sur 4209
Fracc. Jardines en la Montaña, 14210
Tialpan, D.F., México

SEMARNAP (Secretaria de Medio Ambiente, Recursos Naturales y Pesca). 1997. San Ignacio saltworks: Salt and whales in Baja California. 25 p.

The desert-like central region of the Baja California peninsula has characteristics that are unique in the world. One notable facet of its rich wildlife is that some of its coastal waters are winter sanctuaries where the gray whale reproduces. A significant area of this region was declared a Biosphere Reserve in 1988 (El Vizcaíno, the largest in the country: more than two and a half million hectares).

In 1994, a company (Exportadora de Sal, S.A. de C.V.) entered into negotiations with the environmental authorities to considerably expand its salt extraction and marketing activities within the Reserve's buffer zone. In 1995, owing to insufficiencies in the Statement of Environmental Impact (MIA, acronym in Spanish), the authorities denied the corresponding permit. In view of the company's wish to reopen negotiations for the project, and in order to address the unusual complexity of the analysis, the authorities established a Scientific Committee made up of seven distinguished specialists of different nationalities. This Scientific Committee was entrusted with specifying the terms of reference necessary for a new MIA (July 1996). Mexico's environmental authorities also pledged to submit to the consideration of the Committee any new MIA that might be presented, and to respect its opinion in any decision taken. The establishment of such a significant Scientific Committee and its public performance in assessing environmental impact is without precedent in this country, and possibly in Latin America.

To date, no proposal based on the rigorous terms of reference agreed upon has yet been received.

Irrespective of the economic importance of the project, the Government of Mexico will not authorize any proposal that runs counter to current regulations and that could jeopardize conservation of the region's natural resources, and in particular, its biological richness, which is the heritage of all Mexicans.

A.P. #65 Guerrero Negro, Baja California Sur, C.P. 23940 México

Sánchez Pacheco, J.A. 1997a. Descripción y desarrollo de las actividades turísticas de observación de ballena gris en las lagunas de la reserva de la Biosfera "El Vizcaíno" y Bahía Magdalena, Baja California Sur, México, temporadas 1996 y 1997. [Description and development of tourist gray whale watching activities in the lagoons of the biosphere reserve "El Vizcaíno" and Magdalena Bay, Baja California Sur, Mexico, during the 1996 and 1997 seasons.] Boletín Pesquero CRIP-La Paz 7:8-18.

A description is given of the development and monitoring of gray whale watching in the lagoons of the biosphere reserve "El Vizcaíno" and Magdalena Bay in 1996 and 1997. Described are the operations of the tourist industry in each lagoon, the observation time, the number of vessels involved, and an analysis of the demand for services. The above is discussed in light of the rules that regulate whale watching activities in Mexico. The 4 lagoons were visited by 23,971 tourists to whale watch in 1996 and 28,484 in 1997. This activity was estimated to generate a total of $321,590 in 1996 and $453,300 in 1997 for whale watching trips alone. An estimation of the economic activity generated included all services and expenses incurred by tourists at their whale watching destination and while traveling.

DETERMINACION DE LA CAPACIDAD DE CARGA EN TERMINOS DEL NÚMERO MÁXIMO SIMULTÁNEO DE EMBARCACIONES EN LAGUNA OJO DE LIEBRE Y LAGUNA SAN IGNACIO AREAS DE OBSERVACIÓN DE BALLENA GRIS EN BAJA CALIFORNIA SUR, MÉXICO

José Angel Sánchez Pacheco[1]

Reserva de la Biosfera "El Vizcaíno"
Instituto Nacional de Ecología SEMARNAP
A.P. #65 Guerrero Negro, Baja California Sur, C.P. 23940 México

Sánchez Pacheco, J.A. 1997b. Determinacion de la capacidad de carga en terminos del número máximo simultáneo de embarcaciones en Laguna Ojo de Liebre y Laguna San Ignacio areas de observación de ballena gris en Baja California Sur, México. [Determination of the carrying capacity in terms of maximum simultaneous number of vessels in the Ojo de Liebre Lagoon and San Ignacio Lagoon gray whale observation areas in Baja California Sur, Mexico.] Boletín Pesquero CRIP-La Paz 7:19-25

The change in the direction of movement of whales is considered an indicator of disturbance. A procedure was defined to estimate the Maximum Simultaneous Number (NMS, acronym in Spanish) of vessels that can watch whales in an area without disturbing more than 50% of them. In this procedure, vessels followed selected whales, while observers recorded whale reactions and the distance between the vessel and disturbed whales. The procedure was applied in Ojo de Liebre Lagoon and San Ignacio Lagoon during 1995. The NMS was 6 vessels in each of two areas in Ojo de Liebre Lagoon and 13 vessels in San Ignacio Lagoon.

Agenda Section 4.8

GRAY WHALE MORTALITY AT OJO DE LIEBRE AND GUERRERO NEGRO LAGOONS, BAJA CALIFORNIA SUR, MEXICO: 1984-1995

José Angel Sánchez Pacheco[1]

Reserva de la Biosfera "El Vizcaíno"
Instituto Nacional de Ecología SEMARNAP
A.P. #65 Guerrero Negro, Baja California Sur, C.P. 23940 México

Sánchez Pacheco, J.A. 1998. Gray whale mortality at Ojo de Liebre and Guerrero Negro lagoons, Baja California Sur, Mexico: 1984-1995. Mar. Mammal Sci. 14(1):149-155.

During a study of gray whale strandings at Ojo de Liebre and Guerrero Negro lagoons, conducted from 1984 to 1995, a total of 191 whales was found. Length was determined for 176 whales, sex was determined for 146, and time of death was estimated for 117. Common stranding locations within and adjacent to the lagoons were identified. Most (77%) of the calf mortality occurred between 15 January and 15 February. Stranded whales were divided into three size/age classes based on the frequency distributions of their lengths: calves (3.4 to 6.5 m, $\bar{x} = 4.63$), yearlings (6.6 to 9.5 m, $\bar{x} = 8.13$), and 2 years and older (9.6 to 14.2 m, $\bar{x} = 11.94$). During 1990-1992, an extraordinary number of whales 2 years and older stranded in the study area, with a maximum of 37 in 1991. Differences in the average lengths between female and male neonates and yearlings were not statistically different, but females were longer than males at two years and older. It was possible to determine causes of death in only a few cases.

Quan, J. 1999. Records of harvested gray whales. Unpubl. doc. submitted to the Workshop to Review the Status of the Eastern North Pacific Stock of Gray Whales, 16-17 March 1999, Seattle, WA.

Level of aboriginal harvest: In 1997 the International Whaling Commission set an aboriginal subsistence quota. A total of 620 gray whales, not to exceed 140 annually, may be taken over the years 1998-2002.

5.1) **Russian take:** Over the years 1998-2002 the Russian Federation has agreed to take no more than 135 whales annually. From 1970 to 1998 an average of 139 gray whales were taken annually (Table 1).

5.2) **Alaskan take**: Currently there are no allocations for a gray whale harvest by Alaskan Natives and none have been in place since 1991. An incidental take of two gray whales by Alaskan Natives occurred in 1995 (Table 1).

Table 1 (Continuation of Agenda Sections 5.1 and 5.2). Numbers of Eastern North Pacific gray whales harvested (including whales that were lost) between1970 and 1998. Parenthetic numbers in the USSR/Russia column indicate alternate counts from other sources.

Year	USSR/Russia		USA	Totals
1970	146[1,2,3]		5[4]	151

MAKAH WHALING

Patrick Gearin

National Marine Mammal Laboratory
Alaska Fisheries Science Center, NMFS, NOAA
7600 Sand Point Way NE, Bin C15700
Seattle, WA 98115-0070, USA

Gearin, P. 1999. Makah whaling. Unpubl. doc. submitted to the Workshop to Review the Status of the Eastern North Pacific Stock of Gray Whales, 16-17 March 1999, Seattle, WA.

The Makah Indian Tribe received a five-year quota from the International Whaling Commission (IWC) in 1997 to harvest 20 gray whales for ceremonial and subsistence purposes. The Tribe may harvest up to five gray whales per year from 1998 through 2002 with no more than 33 strikes. The IWC approved a combined 5-year quota of 620 gray whales for aboriginal subsistence whaling by U.S. and Russian aboriginals based on the aboriginal needs statement from each country. The U.S. government requested the quota on behalf of the Makah Tribe in acknowledgment of the Makah's explicit treaty right to whaling (Treaty of Neah Bay, 1855). The NMFS-Northwest Regional Office will monitor the hunt and work with the tribe to ensure that the hunt is conducted within IWC guidelines. In accordance with an agreement between NOAA and the Makah Tribe, the Makah whalers will limit their hunting to the Pacific Ocean areas to the west of the entrance of the Strait of Juan de Fuca. The Makah hunt has no commercial aspects; the meat will be used only for local consumption and will not be sold. The Makah Tribe will use traditional methods of harvest including use of a cedar canoe and hand-thrown harpoon. However, to ensure humaneness of the hunt, the tribe will use a .50-caliber rifle to dispatch the whale. Makah whalers struck and killed one gray whale on 17 May 1999 (Gosho[14]).

RECENT TECHNICAL MEMORANDUMS

Copies of this and other NOAA Technical Memorandums are available from the National Technical Information Service, 5285 Port Royal Road, Springfield, VA 22167 (web site: *www.ntis.gov)*. Paper and microfiche copies vary in price.

Abstract

Eastern and western North Pacific gray whales should be managed separately because their ranges do not currently overlap, genetic analyses indicate that the two stocks are significantly different from each other, and the evidence that the former has made a recovery while the latter has not indicates no meaningful dispersal between the two. Data are lacking regarding stock structure within western North Pacific gray whales. Eastern North Pacific gray whales breed promiscuously and mix in their winter assembly areas (i.e., during migration and along coastal waters and within the lagoons of Baja California) making population structure within the nuclear genome highly unlikely. Because selection occurs primarily on the nuclear genome it is unlikely that there is structuring among this population that could result in evolutionary differences. However, there are data from photographic identification studies on some of the feeding grounds indicating site fidelity, but these data exist for only a small proportion of the gray whales' range. Therefore, current data cannot exclude either hypothesis that there are or are not separate feeding stocks that would require separate management within eastern North Pacific gray whales.

CONTENTS

1. INTRODUCTION

To develop a systematic process for defining stocks of large whales within the management regime of the International Whaling Commission (IWC), the Stock Identity Working Group (SIWG) of the Scientific Committee is examining case studies for individual whale species. These case studies should reveal how the different life history strategies of species affect population structure, as well as how they reveal the utility of various types of data for evaluating stock identity and structure within populations. Therefore, the current review provides a section by section overview of the life-history strategy and ecology of gray whales as a context for discussion of the species stock structure. In this review we use 'population' to refer to units where virtually no gene flow (less than one disperser) would be expected within a generation (approximately 20 years). Such a unit is sometimes called an evolutionarily significant unit (ESU) because gene flow is sufficiently low to allow meaningful differences to develop. 'Stock' refers to a unit with a level of gene flow greater than an ESU but still small enough to be demographically important for management. For purposes of clarity, we suppose this level to be less than one percent dispersal between units per year. See the introduction of the review of bowhead (*Balaena mysticetus*) stock identification paper (DeMaster *et al*, 2000) for further discussion of this terminology.

2. BACKGROUND

Within historic Holocene time, there were two allopatric populations of gray whales, one with a circum-North Atlantic distribution and the other with a circum-North Pacific distribution. During inter-glacial periods over the last 3 million years, the Arctic Basin formed a corridor between the North Pacific and North Atlantic and was possibly a dispersal route followed by the gray whale. In current times, gray whales are extinct in the North Atlantic (Mead and Mitchell 1984), but in the North Pacific this species exhibits a highly migratory behavior with distinct corridors down either side of the North Pacific Basin. The Quaternary (Pleistocene to Recent) distribution of gray whales was undoubtedly influenced by cyclical changes in sea level during four massive glacial advances and retreats (Gilmore 1978). Lowering of sea level of up to 100 m correlated with glacial cooling eliminated some continental shelf areas presumably utilized by gray whales, while sea level rises during warming periods are suggested to have increased continental shelf space (Berta and Sumich 1999). During periods of Pleistocene glacial maxima, the polar ice pack and emergent Bering Isthmus which replaced the Bering Sea would have excluded gray whales entirely from the Arctic Basin and undoubtedly pushed their summer distribution farther south than at present. The more recent 'little ice age' investigated by Overpeck, *et al.* (1997) suggests that Arctic-wide cooling and widespread glaciation within the last 400 years may have affected the distributions of populations. Such an ice driven southerly shift in the distribution of species could have facilitated the mixing of eastern and western gray whales in the North Pacific during these ice ages as described for bowhead whales (Dyke *et al.* 1996).

The Atlantic population is now extinct (Mead and Mitchell 1984). Of the two extant populations, the western North Pacific or Korean-Okhotsk population remains critically depleted while the eastern North Pacific or California-Chukchi population has recovered to what may be its pre-exploitation size after it was harvested to depletion by the 1850s. The species was afforded protection from commercial whaling in 1946 by the International Convention for the Regulation of Whaling. Currently, the IWC sets an annual quota allowing gray whales to be harvested from the eastern North Pacific population for aboriginal subsistence use. In spite of the persistent subsistence harvest, the eastern North Pacific population has recovered to an estimated 26,635 animals in 1997/98 (CV=10.06%; Hobbs and Rugh 1999), and is increasing at a rate of 2.5% per year (SE=0.3%; Buckland and Breiwick, In press) (*See Section 4.2 Distribution, Abundance, and Current Status*).

Management authorities currently regard both the eastern and western North Pacific populations as separate 'stocks' for management purposes. Research on the current status of the small western population has only recently begun (Weller *et al.* 1999). Therefore, nearly all of what is known about the biology and natural history of the gray whale results from research conducted on the eastern North Pacific population.

3. WESTERN NORTH PACIFIC POPULATION

3.1 History of Exploitation

The western North Pacific population was probably never as numerous as the eastern North Pacific population. It was intensively hunted during the past three centuries. Pre-exploitation numbers are unknown. By the time commercial whaling ceased in the 1960s, this population was reduced to only a fraction of its original size and was thought by some to be extinct (Bowen 1974).

Intensive whaling pressure from the Japanese hand-harpoon fishery was underway by the 16th century, and Japanese net whaling continued to take gray whales during the 17th to 19th centuries (Omura, 1984). Groups of Koryak natives lived in the northeastern Okhotsk Sea and hunted whales, perhaps even into the early 1900s (Krupnick 1984). European and American whalers operating in the western North Pacific and Okhotsk Sea took gray whales between the late 1840s and early 1900s. Russian steam whalers took gray whales in the coastal waters of the Far East at the end of the 1800s. Japanese and Korean whalers continued to hunt gray whales until as recently as 1966 (Brownell and Chun 1977). Kato and Kasuya (1993) reviewed the catch history of western gray whales by Japanese and Korean modern whaling during the 1900s and revealed a period of peak annual catch of 100-200 whales occurred in the 1910s. This was followed by a rapid decline of the catch in the 1920s and 1930s, dropping to 10-20 whales per year for over 40 years until the hunt ended in the 1960s. It is estimated that a minimum of between 1,800 and 2,000 gray whales were taken during the whaling period between 1891 and 1966 (Kato and Kasuya 1993). They concluded that this last phase of continuing small scale exploitation could have been a major factor in suppressing the recovery of this population.

3.2 Distribution

Historic sighting data and whaling records suggest that summer feeding grounds were in the Okhotsk Sea and that the whales migrated to presently unknown wintering areas suspected to be along the coast of Guangdong Province and around the nearby Hainan Island in southern China (Henderson 1990). The western population formerly occupied the northern Sea of Okhotsk in the summer, as far north as Penzhinskaya Bay, and south to Akademii and Sakhalinskiy Gulfs on the west and the Kikhchik River on the east (Yablokov and Bogoslovskaya 1984). Southbound whales migrated along the coast of eastern Asia from Tatarskiy Strait to South Korea to wintering areas. Records of gray whale sightings, strandings and catches from 1933 to 1996 suggest that western gray whales frequent the coastal waters of China during the winter months as far south as Gwangxi and Gwangdong provinces and around Hainan Island (Zhu and Yue 1998) . The southernmost record of a western gray whale was from the east coast of Hainan Island (Rice 1998). The long-held belief that the western Pacific gray whales spent the winter along the south coast of Korea was based on unsupported conjecture (Rice, 1998).

Formerly, another migration corridor ran along the east coast of Japan to postulated calving grounds in the Seto Inland Sea. Prior to the 20th century, gray whales migrated to the coastal waters of Japan: one group to the southern coast of Hokkaido and Honshu and another group to the west coast of Kyushu (Omura 1984). The former migrated along the east coast of Japan from the north and entered the Seto Inland Sea, a supposed calving ground. The latter group is believed to migrate along the east coast of Korea and then to southwest Honshu and northwest Kyushu. It is plausible that these groups represented two stocks within the western population each with distinctive migration routes and wintering grounds. Recent sightings of gray whales along the east coast of Japan (National Geographic 1993) suggest that these two groups may still exist but in very reduced numbers.

Soviet scientists reported sightings of gray whales in the Okhotsk Sea along the shallow-water shelf of northeastern Sakhalin Island near Piltun Lagoon. A joint American-Russian-Japanese research project began in 1995 to determine the status of the western population and to identify a means to mitigate ongoing threats to its survival. The seasonal site fidelity and annual return of previously identified whales to this area, including mothers with calves, suggest these animals may represent a discrete sub-population that consistently utilizes the northeastern Sakhalin Island feeding ground (Weller *et al.*1999).

The western North Pacific gray whale population is generally thought to be independent from the eastern North Pacific population because there is a distinct gap in distribution along the eastern shore of the Kamchatka Peninsula, between the Okhotsk and Bering Seas, at least as far east as the Commander Islands (IWC 1993; Fig. 1). Strandings of gray whales reported from the Commander Islands are believed to be from the eastern population, while gray whales reported along the western Kamchatka coast are believed to be from the western population.

3.3 Current Status

The western North Pacific gray whale population was considered to be extinct or nearly so during the 20th century but is known to survive today as a remnant population. Catch records for 67 gray whales taken from the Korean coast between 1948 and 1966 (Brownell and Chun 1977) indicated the continuing existence of this population. Four gray whales observed in the western Okhotsk Sea in 1967, the sighting of a female gray whale with a calf in Korean waters in 1968, and three gray whales observed feeding off the eastern coast of Japan in 1993 (National Geographic magazine 1993) confirmed these whales were not extinct. Today the western North Pacific gray whale population is considered one of the most endangered large-whale populations in the world. While pre-exploitation abundance is unknown, catch histories suggest that this population once numbered at least in the few thousands of animals (*See Section 3.2 History of Exploitation*). Current abundance has yet to be reliably estimated owing to a lack of data. The portion of the population that summers off northeastern Sakhalin Island is thought to be about 100 animals, based on initial results of photo-identification studies conducted 1994-98 which identified 69 individuals (Weller *et al.*1999).

3.4 Morphology and Morphometrics

Few studies have been done to compare the morphology and morphometrics of eastern and western North Pacific gray whales. Zimushko (1972 in Yablokov and Bogoslovskaya 1984) compared data collected by Andrews (1914) on the external morphology of these two populations and believed that differences may indicate the existence of two distinctive populations or 'sub-species'. Andrews (1914) examined fifty or more gray whales harvested at the Toyo Hogei Kaisha whaling station in Ulsan, South Korea. He made detailed descriptions of gray whale morphology and collected two complete skeletons. Zimushko (1972) reported that the distance from the tip of the rostrum to the base of the pectoral flippers, from the tip of the rostrum to the eye, the maximum width of the pectoral flipper, and the length of the baleen plates were statistically greater in the western gray whales, and that western gray whales had fewer baleen plates and fewer throat grooves. Unfortunately, the details of these analyses have not been published. A re-examination of these data may help determine whether these differences are sufficient to reliably assign skeletal remains to the eastern or western populations.

3.5 Other Data

Recent genetic analyses comparing western and eastern North Pacific gray whales indicates that the two populations are significantly different from each other (LeDuc *et al.* 2000), and along with additional information on morphology, parasites, etc. have the potential to resolve the relationship of the western North Pacific population to the larger eastern North Pacific population (*See Section 5.2 Genetics*). Analysis of chemical signatures (*e.g.*, heavy metals and organochlorines) as ecological tracers could potentially distinguish differences between western and eastern gray whales. Other animals that use inland Asian waters (*e.g.*, the North Pacific minke whales of the J-stock) have highly distinctive chemical signatures, which distinguish them from other animals within the same species (Nakata *et al.* 1999; Fujise, *et al.* 1999). Such information could be used to detect dispersers and new individuals that enter the population from other areas. Mark-recapture through photographic identification should be effective at determining the plausibility that the western population is 'closed' because of its small size and resultant high probability for re-sightings of individuals (Weller *et al* 1999). The high annual re-sighting rate of individuals in this population suggests that any new individuals will likely be detected if eastern North Pacific gray whales are dispersing into the western population.

The strongest evidence that the eastern and western gray whale populations are segregated is the lack of recovery of the western population through a period in which the eastern population has rebounded remarkably well. If there was dispersal of individuals from east to west, the western population would have been re-populated by now. If the eastern population is approaching carrying capacity, then some individuals might expand their range in search of new feeding grounds. The apparent small population abundance of the western population suggests that emigration from the eastern population is not occurring at any meaningful level. Considering the existing data, it is generally agreed that the western population of gray whales represent a geographically isolated population, and should be treated as a distinctive stock for management purposes.

4. EASTERN NORTH PACIFIC POPULATION

The eastern North Pacific or California-Chukchi gray whale population has made a remarkable recovery from depletion caused by commercial whalers. This population has become one of the best studied groups of baleen whales. Most whales in this population make an extensive migration each year between their primary summer feeding grounds in the Bering and Chukchi seas and their winter assembly areas in the near-shore waters of Southern California, the coastal waters, bays and lagoons of Baja California, and to some extent the lower Gulf of California (Fig. 1). Most of what is known about gray whale biology, life history, ecology and behavior results from research conducted on this population. Because of their predictable migrations along the west coast of the U.S., these whales have been easy to find and access, making them relatively convenient to study.

4.1 History of Exploitation

Eskimos hunted gray whales near the shores of the northern Bering and Chukchi Seas for thousands of years. Natives of the Chukotka Peninsula selected young gray whales that were killed by using toggle-headed harpoons attached to seal and walrus skin floats (Krupnick 1984). Up until 1928 several Indian tribes between the Aleutian Islands and California hunted gray whales as a part of their cultural and religious traditions. They hunted from boats made of skin or wood and used hand-held harpoons, often with poison enhanced tips. Stranded whales were also utilized by some of these tribes. These included the Alutes, Koniag, Chugash, Tlingit, Haida, Tsimshian, Nootka, Makah, Ozette, Quileute, Klallam and the Chumash (O'Leary 1984).

In northeastern Asia, aboriginal whaling diminished early in the mid-nineteenth century. This resulted from a decline in the aboriginal populations as well as from changes in cultural traditions following contact with westerners, particularly Yankee whalers. Commercial shore whaling took gray whales along the coast of the Californias from the mid 1850s to the early 1900s (Sayers 1984). Scammon (1874) defined shore whaling as the pursuit of a whale from a boat launched from the shore. When the whale was captured, it was towed back to shore where it was flensed and its oil and other by-products were processed for market. The first station was established on Monterey Bay in 1854, and over the next 45 years 15 stations were operated at various times from Crescent City, to Punta Eugenia, Baja California. The industry was profitable for approximately 40 years, but by the turn of the century, whales had become scarce along the coast, and shore whaling became obsolete.

From 1845 to about 1900, American whalers hunted gray whales on their winter grounds in Baja California as well as along their coastal migration routes and on their summer grounds in the subarctic (Scammon 1874; Henderson 1984). After whalers discovered the wintering areas in lagoons along the Pacific Coast of Baja California, they took whales by the hundreds outside the entrances and within the lagoon interiors (Henderson 1984). The gray whale earned the names of 'devil fish' and 'hard head' from their habit of attacking whaling skiffs when harpooned. Skiffs were frequently overturned and stoved in, and human lives were lost. Thus, the whalers preferred hunting gray whales from shallow waters along the edges of the lagoon channels where they were relatively safe from attacks by injured whales, particularly after harpooning calves in order to capture the accompanying adult. Because females congregate within the lagoon interiors in winter to rear their calves, these catches comprised mostly females and their calves. This whaling strategy drastically reduced the reproductive capacity of the population. By the turn of the century, whaling for gray whales was no longer commercially viable. Henderson (1984) estimates that between 1845 and 1874 approximately 11,300 gray whales were harvested throughout the eastern North Pacific, including approximately 3,200 from the lagoons and bays of Baja California. Estimates of likely population sizes in 1846 range from 12,000 to 15,000 animals (Reilly 1992) which was reduced to 4,000 to 5,000 or fewer animals by 1900 (Butterworth *et al.* 1990) (*See Section 4.3, Abundance and Current Status*). Clearly, nineteenth century whaling from ships and shore stations resulted in dangerous decline in the eastern North Pacific population.

Modern whaling for eastern North Pacific gray whales began around 1914 and was pursued by the United States, Japan, Norway and the Soviet Union (Reeves 1984). Modern whaling refers to the catching of whales through the use of deck-mounted cannons, explosive grenades, direct fastening to the whales and diesel, gas or steam-powered boats and ships (Mitchell and Reeves 1983). From 1914-46, an estimated 940 gray whales were taken by factory ships and/or fleet whalers working from the North Pacific to Baja California in all seasons (Reeves 1984). The catch of gray whales off the Chukotka Peninsula increased in the 1930s after commercial over-harvesting caused the decline of the bowhead whale (Yablokov and Bogoslovskaya 1984). From 1933-46, the Soviet whaling fleet took 623 gray whales in the

Bering and Chukchi seas (Sleptsov 1955 in Blokhin 1997b). In 1940, the Japanese factory ship *Tonan Maru* took 58 gray whales in the North Pacific. After 1937, Norway and the United States protected gray whales from commercial whaling, and after 1938 Canada protected them from commercial whaling.

Commercial whaling for gray whales was banned by the International Convention for the Regulation of Whaling in 1946. That agreement included the provision for the natives of Chukotka and Koryak to harvest gray whales for subsistence use, a provision that continues under IWC management. From 1948-54, Chukchi hunters took 182 whales, and from 1956-68, the catches increased to more than 100 animals annually (Zimushko and Ivashin 1980). Between 1959-69, 316 gray whales were killed under Special Permits off central California during the fall southward and spring northward migrations. This take was for scientific investigations to establish the status of the population (Rice and Wolman 1971). From 1969-98, Chukotka natives harvested an average of 140 gray whales annually. In 1997 the IWC set an aboriginal subsistence quota of 620 gray whales for 1998-2002, not to exceed 140 whales annually (IWC 1998): the Russian Federation is allowed to take up to 135 gray whales annually, and the United States is allowed to harvest up to 5 gray whales annually (IWC 1998).

Donovan (1991) noted that a management unit is defined such that specific management goals are met (*e.g.*, commercial or aboriginal subsistence harvests do not lead to local depletions or extirpation). It would be useful to know if harvests of gray whales occurred at specific times or seasons and at locations containing genetically distinct sub-groups of the eastern North Pacific population of gray whales. Preferential harvests from such sub-groups could have the potential to extirpate or deplete them and/or result in abandonment of portions of the populations' range as proposed for some species of whales (Clapham and Pasboll 1999, Clapham and Hatch 2000).

There is evidence that gray whales segregate by age and sex on their northern feeding grounds, as reflected in the Russian harvests. Gray whales begin to arrive along the Chukotka coast in May and June (depending on annual ice conditions) and remain until late-October or early-November (Blokhin 1998). Gray whales are harvested in this area from late-June to early-November in most years (Blokhin 1997a, 1997b). Analysis of the summer catches of gray whales from 1969-81 indicated that 69.8% were female and 30.2% were male, and that females and young whales were distributed in the shallow coastal waters while larger adult animals were found further offshore in waters up to 50-60 m deep (Yablokov and Bogoslovskaya 1984). Bogoslovskaya (1982) concluded that the majority of the newly weaned whales congregated in nearshore, shallow waters and lagoons along the coast.

In the last decade selective harvesting in the nearshore areas is indicated by the increase in the number of immature animals in the catches when 'traditional' small-scale nearshore whaling methods replaced the use of state-supported whaling ships capable of taking animals of any size further from shore and from a wider geographic area (Blokhin 1995). If the Chukotka natives consistently harvest whales near their villages, and if there exist genetically distinct sub-groups that return to these areas each summer, the continuation of harvests could result in local depletions and extirpations of unique sub-groups. Alternatively, if gray whales move seasonally through the harvest areas as they search for productive feeding sites and do not show site fidelity, harvests probably do not focus on any genetically distinct portion of the population. Although some data are available on assemblages of young gray whales that segregate in areas along the coast of Vancouver, B.C. (Darling *et al.* 1998), data on the habits of individual gray whales in the northern feeding areas are lacking. Examination of harvest records (especially locations of takes), genetic analyses of the harvested animals and photographic identification research could be used to address the issue of population structure and fidelity on the northern feeding grounds.

Similarly, if there were unique stocks or groups of whales using the lagoons of Baja California, the intense whaling conducted there over a century ago would have eliminated them. However, all of the primary lagoons where historical removals occurred continue to be utilized by gray whales today. Removals did not result in the abandonment of these lagoons and presumably did not result in the extirpation of any distinct sub-groups of the population (*See Section 4.3 Migration Timing and Segregation*). Previous reports of San Diego Bay being utilized by gray whales in the winter have never been substantiated.

4.2 Distribution

While most of the eastern North Pacific gray whale population summers on feeding grounds in the northern Bering and southern Chukchi Seas (Moore and Ljungblad 1984), gray whales in this population are distributed from California to the Arctic during the summer months. In the Beaufort Sea, gray whales have been seen as far east as 130°W in August (Rugh and Fraker 1981). In the East Siberian Sea, gray whales are found as far west as 174° E in late September (Reilly 1984, Berzin 1984). In fall the population migrates south along the coast to its winter range off the coast of Southern California, the west coast and lagoons of Baja California, and to a limited extent into the Gulf of California and the mainland coast of Mexico (Fig. 1) (Gilmore 1960, Swartz 1986).

Observations of gray whales in summer months in locations well south of their northern summer feeding areas are not recent occurrences, and have been documented during periods of low and high population abundance (Gilmore 1960 and 1976, Pike 1962, Rice 1963, Hattler and Darling 1974, Patten and Samaras 1977, Darling 1984, Nerini 1984, Mallonee 1991, Avery and Hawkinson 1992, Clapham *et al.* 1997, Calambokidis and Quan 1999, Sanchez-Pacheco *et al. In Press*). Often these animals are observed feeding in various locations along the migration route. Such occurrences may not be solely the result of range expansion in an increasing population, but may reflect the gray whales' predilection to forage widely for suitable prey species. A number of identifiable individual gray whales, termed 'summer residents,' have been observed to return each summer to the same areas in various locations from Southeast Alaska to Vancouver Island, Canada, and the states of Washington, Oregon and California (Hattler and Darling 1974, Darling *et al.* 1998, Darling 1984, Calambokidis and Quan 1999, Gosho *et al.* 1999) (*See Section 4.5, Feeding and Prey Species*).

ABSTRACT

1. In response to conservation and management concerns about gray whale *Eschrichtius robustus* population and stock structure, we provide an overview of the life history and ecology of gray whales as a context for discussion of population and stock structure within the species. Historically eastern and western North Pacific gray whales were managed separately because: (i) their ranges do not overlap; (ii) genetic analyses indicate that the two populations are significantly different; and (iii) eastern gray whales have increased in abundance over the past century while western gray whales have not.

2. Here, we review gray whale migration timing and segregation, feeding and prey species, and reproduction and reproductive behaviour. For the eastern and western gray whale, we review their distribution, history of exploitation, abundance and current status, although most of what is known is founded on the better studied eastern gray whale and only implied for the lesser known western gray whale. Methods to investigate population and stock identity are reviewed including genetics, morphology, chemical signatures, carbon isotopes, parasites, photographic identification and trends in abundance.

3. While the evidence indicates that there is at least some degree of mixing within each of the gray whale populations, no stocks or sub-stocks can be defined. Population structure is not evident in nuclear data, and because selection occurs primarily on the nuclear genome, it is unlikely that there is structuring within each population that could result in evolutionary differences. For western gray whales, there are insufficient data to assess the plausibility of stock structure within the population, owing to its extremely depleted state. Research on eastern gray whales has focused mostly on documenting changes in abundance, feeding biology and behaviour, and suggests separate breeding groups to be unlikely. Both males and females are promiscuous breeders lending little opportunity for the nuclear genome to be anything other than well mixed as is suggested by the high haplotypic diversity of the eastern population.

4. The available data strongly indicate that western gray whales represent a population geographically isolated from eastern gray whales and therefore that the western and eastern populations should be treated as separate management units.

INTRODUCTION

Conservation of large whales has been an international concern ever since widespread commercial hunts severely depleted whale stocks, in many cases continuing to take whales until many species were too scarce to be an economic resource (see review in Reeves, 2002). The International Whaling Commission (IWC) was formed to assess the viability of whaling practices and the size of remaining whale stocks. To develop a systematic process for defining stocks of large whales within the management regime of the IWC, the Stock Identity Working Group of the Scientific Committee examined case studies for individual whale species. The objective of these case studies was to reveal how the different life history strategies of species affect population structure, as well as how the studies reveal the utility of various types of data for evaluating stock identity and structure within populations. In response to concerns about the conservation and management of gray whale *Eschrichtius robustus* population and stock structure, the current review provides an overview of their life history and ecology.

In this review, we use 'population' to refer to units where virtually no gene flow (less than one disperser) would be expected within a generation (approximately 20 years). Such a unit is sometimes called an evolutionarily significant unit (ESU) because gene flow is sufficiently low to allow meaningful differences to develop. 'Stock' refers to a unit with a level of gene flow greater than an ESU but still small enough to be demographically important for management (Taylor, 2005). For purposes of clarity, we suppose this level to be less than 1% dispersal between units per year. Each 'population' can be composed of one or multiple 'stocks'. See the introduction of the review of bowhead *Balaena mysticetus* stock identification paper (Rugh *et al.*, 2003) for further discussion of this terminology.

BACKGROUND

Gray whales are sufficiently distinctive relative to other cetaceans to be placed in their own family: Eschrichtiidae (Rice, 1998); however, recent molecular analysis has provided conflicting views regarding this taxonomy (Sasaki *et al.*, 2005). Although skeletal remains and sightings of live animals indicate that this species occurred historically in both the North Pacific and North Atlantic (Fig. 1), gray whales are believed to have been extinct in the North Atlantic since the early 18th century (Mead & Mitchell, 1984). It is possible that during interglacial periods in the distant past, e.g. massive glacial advances and retreats in the Quaternary (Pleistocene and Holocene), corridors were available across the Arctic, allowing for exchange of whales between the Pacific and Atlantic (Gilmore, 1978). During glaciations, sea levels dropped in the North Pacific exposing some or most continental shelf areas, which would have severely reduced gray whale habitat (as we currently know it) and eliminated their options to enter the Arctic basin, which was blocked at the time by the Bering Isthmus (Berta & Sumich, 1999). The more recent 'little ice age' investigated by Overpeck *et al.* (1997) suggests that Arctic-wide cooling and widespread glaciation within the last 400 years may have affected the distribution of the species in the North Pacific. Such an ice-driven southerly shift in their distribution could have facilitated the mixing of gray whales from the east and west sides of the North Pacific during these ice ages as has been suggested for bowhead whales (Dyke, Hooper & Savelle, 1996).

Of the two extant North Pacific populations, the western (also known as the Western North Pacific population or the Korean-Okhotsk population) remains critically depleted (Weller *et al.*, 2002) while the eastern (also known as the Eastern North Pacific population or the California-Chukchi population) has recovered from exploitation (Rugh *et al.*, 1999, 2005). The species began to receive protection from commercial whaling in the 1930s (see review in

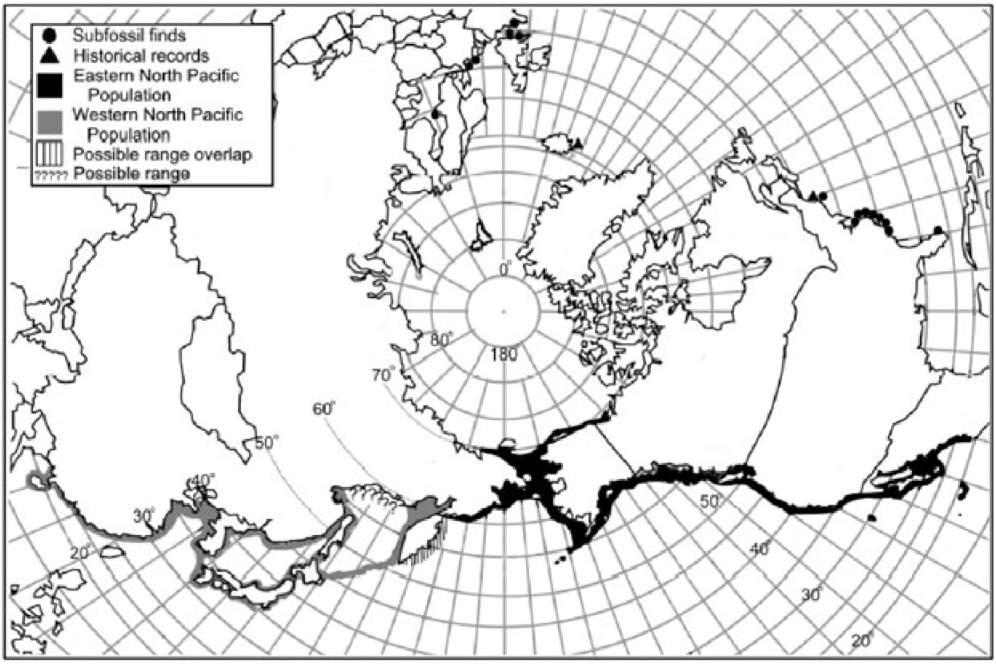

Fig. 1. The range of the gray whale, *Eschrichtius robustus*.

Reeves, 1984). However, hunting continued in the western population for many more years (Brownell & Chun, 1977). Currently, the IWC sets a quota allowing 169 gray whales to be caught annually from the eastern population for aboriginal subsistence use (IWC, 1998). In spite of the persistent subsistence hunt, the eastern population has recovered at a rate of 1.9% to a recent abundance estimate of nearly 20 000 animals (Rugh *et al.*, 2005). In contrast, the western population has shown no sign of recovery and may consist of only 100 whales (Weller *et al.*, 2002).

Management authorities, such as the US National Marine Fisheries Service and the IWC, regard both the eastern and western populations as separate management units (Rugh *et al.*, 1999; LeDuc *et al.*, 2002), and this division is supported by material presented in the current review. Under the US Endangered Species Act, these populations have separate listings as Distinct Population Segments, which are considered to be of evolutionary importance, and the populations are listed separately under the International Convention for the Conservation of Nature and Natural Resources, i.e. the IUCN (Baillie, Hilton-Taylor & Stuart, 2004). The objective of this document is to collate components of gray whale life history information (migration, feeding and reproduction), describe the two populations (relative to exploitation history, distribution and abundance), and note what tools are available for analysing population and stock differentiation (e.g. genetics, morphology and chemical signatures). Accordingly, this review will draw together a summary of what is known about population and stock structure of gray whales and provide a framework for management applications.

GENERAL BIOLOGY

Eastern North Pacific gray whales have been studied throughout their range for many years, which is not the case for the western gray whales. While many specific details of western gray whale life history are unknown, it can be expected that the general life history patterns are similar. Information on the general biology and life history, such as migratory routes, range and seasonal timing, provides a context for discussing possible population and stock differentiations or the lack thereof.

Migration timing and segregation

The migrations of most mysticete whales are thought to have arisen as an evolutionary response to the seasonal production of prey in polar regions (Lipps & Mitchell, 1976). Seasonally predictable sources of food shaped the life history of baleen whales into two periods: summers when whales feed in higher latitudes with abundant food and minimal sea ice; and winters when whales migrate to lower latitudes to escape inclement weather and to calve in warmer waters. Reduced predation by killer whales *Orcinus orca* in lower latitudes also may or may not have played a significant role in the evolution of migration of some mysticete whales (Corkerton & Connor, 1999; Clapham, 2001), but in gray whales it is unclear how this evolution is influenced by the predation that is known to occur during their northbound migration.

Gray whale migration has evolved into fall southward and spring northward migrations along the western North American coast for the eastern gray whale, and a similar seasonal migration along the eastern coast of Asia for the western gray whale. Comparatively little is known about the details of migration in the western population.

By late November, most eastern gray whales have started migrating south out of their Arctic summer feeding grounds (Rugh, 1984). The start of the migration coincides with the period of conception, which for most (but not all) gray whales occurs during a 3-week period centred in early December (Rice & Wolman, 1971). During this time, gray whales are concentrating in nearshore areas, improving opportunities for finding mates and for genetic mixing. Southward migrating gray whales are observed moving through coastal waters of the North Pacific from November to February (Rugh, Shelden & Schulman-Janiger, 2001). They begin arriving in their winter grounds as early as mid-December with peak numbers of whales passing the California coast in mid-January The southward migration for better-known eastern gray whale population generally ends in mid-February just as the northward migration begins, with the last of the southbound animals overlapping with the first northward migrants (Rugh *et al*., 2001). This overlap suggests that only a portion of this population is in the waters of Mexico during the winter, while the remainder are distributed in coastal waters of southern and central California (Swartz, 1986).

The southward migration of eastern gray whales is segregated by age, sex and reproductive status (Rice & Wolman, 1971); the first pulse is led by near-term pregnant females, followed by oestrous females and mature males, and the last phase includes immature animals of both sexes. Eastern gray whales reach maximum densities on their wintering grounds by mid-February (Jones & Swartz, 1984). While the majority of eastern gray whale calves are believed to be born within or near the coastal lagoons of Baja California, Mexico. Sightings of newborn calves migrating south past central and southern California in January and February have increased in recent years (Shelden, Rugh & Schulman-Janiger, 2004). Southward migration timing may be affected by how widely the population is distributed for foraging, and this is affected in part by the onset of winter and the extent of ice coverage in the Arctic.

As eastern gray whales arrive at the lagoons of Baja California, mainly in January, they segregated spatially and temporally such that their distribution, gross movements and timetable of lagoon occupation differ for each age–sex group (Jones & Swartz, 1984; Urban *et al*., 2003). Single whales (i.e. oestrous females and mature males) are found at highest densities near lagoon inlets and in adjacent coastal waters. By contrast, females with calves concentrate within the interiors of lagoons (Jones & Swartz, 1984). With the departure of adult whales without calves in late February, females with calves shift their distribution to lagoon inlets and adjacent coastal areas, essentially abandoning the inner lagoon nurseries (Jones & Swartz, 1984). This segregation of adult whales without calves from females with calves is an extension of the age and sex segregation seen during the spring and fall migrations (Rice & Wolman, 1971).

The spring northward migration of eastern gray whales occurs in two distinct phases segregated according to age, sex and reproductive condition (Poole, 1984; Swartz, 1986). The first phase centred in February includes newly pregnant females followed 2 weeks later by adult males and anoestrous females and another week later by immature whales of both sexes. The second phase consists of mothers with calves that begin to leave the lagoons after the first phase and are observed along the migration route from March to May, generally arriving on their summer Arctic feeding grounds from May to June

Feeding and prey species

Unlike more pelagic mysticete species that migrate and feed across deep ocean basins, eastern gray whales migrate along the western coast of North America where upwellings of nutrient-rich waters produce some of the world's most productive marine ecosystems and afford gray whales with a variety of potential prey species. Gray whales are primarily, although not exclusively, bottom-feeders. Their prey includes a wide range of benthic and epibenthic invertebrates such as gammaridean amphipods; these occur during the summer months in dense colonies on the continental shelf sea floor of regions like the Bering and Chukchi seas (Nerini, 1984). Limited feeding also occurs outside the primary feeding grounds, along their migration route and in some portions of their winter range (Oliver *et al.*, 1983; Nerini, 1984; Sanchez, Vasquez-Hanckin & DeSilva-Davila, 2001).

Reproduction and breeding behaviour

Gray whale females normally reproduce on a 2-year cycle, producing a single calf every other year, a cycle which is intimately tied to the whales' annual migrations and environmental conditions favourable for the early development of calves (Rice & Wolman, 1971; Swartz, 1986). Rice & Wolman (1971) examined 150 female gray whales during their migration near central California 1959–69, while the population was recovering from commercial exploitation. Their data showed that gray whale breeding is highly synchronous, with females coming into oestrus in a 3-week period from late November to early December; this coincides with the initiation of the southward migration out of the summering areas. If there is no conception, a second oestrus may occur 40 days later (Rice & Wolman, 1971) when the whales are in or near their winter grounds (Jones & Swartz, 1984; Swartz & Jones, 1984). Mating behaviour is observed during most seasons (Gilmore, 1960; Rice & Wolman, 1971; Jones & Swartz, 1984; Swartz, 1986; Berta & Sumich, 1999), but conception appears to be restricted to a fairly short period between late November and early January. Both female and male gray whales are promiscuous and copulate repeatedly with more than one mate (Jones & Swartz, 1984). With a gestation period of 13 months and a mean calving date around 10 January (Rice & Wolman, 1971), some calves are born during the southward migration (Shelden *et al.*, 2004). Calves stay with their mothers for 6–7 months and are weaned and independent while on the summer feeding grounds. Following weaning, adult females remain anoestrus for several months until they enter into a new oestrus cycle and are receptive to a new pregnancy in late autumn (Rice & Wolman, 1971). Mature male gray whales also have a marked seasonal cycle with a seasonal increase in testes weight and a peak period of spermatogenic activity that correlates closely with the time females come into oestrus (Rice & Wolman, 1971).

EASTERN POPULATION

Distribution

Although most of the eastern gray whale population summers on feeding grounds in the northern Bering and southern Chukchi Seas (Moore & Ljungblad, 1984), some whales in this population are distributed far to the east and west in the Arctic and along the coast as far south as California. In the Beaufort Sea, gray whales have been seen in arctic Canada (to 130°W) in August (Rugh & Fraker, 1981). In the East Siberian Sea, gray whales occur even west of Wrangel Island (to 174°E) in late September (Berzin, 1984; Reilly, 1984).

Observations of gray whales in summer months well south of Alaska are not recent occurrences and have been documented during periods of both low and high population abundance (Gilmore, 1960; Pike, 1962; Rice, 1963; Hatler & Darling, 1974; Patten & Samaras, 1977; Darling, 1984; Nerini, 1984; Mallonée, 1991; Avery & Hawkinson, 1992; Gosho *et al.*, 2001; Sanchez *et al.*, 2001; Calambokidis *et al.*, 2002). A number of identifiable individual gray whales, termed 'summer residents' or members of the 'Pacific Coast Feeding Aggregation', have returned to the same areas over the course of many summers in various locations from South-east Alaska to Vancouver Island, Canada, and off the states of Washington, Oregon and California (Hatler & Darling, 1974; Dahlheim, Fisher, & Schempp, 1984; Darling, Keogh, & Steeves, 1998; Gosho *et al.*, 2001; Calambokidis *et al.*, 2002). Photographic re-identifications suggest that these whales also range widely within other coastal areas as far south as northern California and north to Alaska, and these diverse movements could account for inconsistencies in year-to-year re-sightings of individuals at specific locations (Calambokidis *et al.*, 2002).

In the late fall/early winter, eastern gray whales migrate south along the eastern Pacific coast to their primary winter range along the west coast of Peninsula de Baja California (Fig. 1) (Gilmore, 1960; Swartz, 1986; Urban *et al.*, 2003) and along the Gulf of California (Findley & Vidal, 2002). Although there is repeated use of some lagoons, eastern gray whales do move between lagoons and spend some amount of the winter in waters outside of the lagoons (Urban *et al.*, 2003) and along the Baja California and southern California coasts.

History of exploitation

Eskimos have hunted eastern gray whales near the shores of the northern Bering and Chukchi Seas for thousands of years. Historically, Chukotka natives killed young gray whales (Krupnik, 1984), and until 1928, several Indian tribes between the Aleutian Islands and California hunted gray whales as a part of their cultural and religious traditions (O'Leary, 1984). Aboriginal whaling diminished in the mid-19th century caused in part by declines in gray whale abundance resulting from commercial hunting and native hunting and by changes in cultural traditions following contact with westerners (Krupnik, 1984). Commercial shore whaling took gray whales along the coast of California and Mexico from the mid-1850s to the early 1900s (Sayers, 1984). The first shore whaling station was established on Monterey Bay in 1854, and over the next 45 years, 15 stations were operated at various times from Crescent City (northernmost tip of California) to Punta Eugenia (Baja California); however, by the turn of the century, whales had become scarce along the coast, and shore whaling became economically unviable (Sayers, 1984).

From 1845 to about 1900, American 'Yankee' whalers utilized sailing ships that launched small oar-powered skiffs (i.e. longboats) to hunt gray whales on their winter grounds in Baja California as well as along their coastal migration routes and on their summer grounds in the sub-Arctic (Scammon, 1874; Henderson, 1984). Hunts in and near the lagoons greatly reduced the reproductive capacity of the population by killing the females with calves congregating there. By the turn of the century, whaling for gray whales was no longer commercially viable. Henderson (1984) estimates that between 1845 and 1874, approximately 11 300 gray whales were killed throughout the entire eastern Pacific.

Modern 'industrial' whaling (that utilized steam-powered catchers and explosive harpoons) for eastern gray whales around 1914 was pursued by the United States, Japan, Norway and the Soviet Union (Reeves, 1984). From 1914 to 1946, an estimated 940 gray whales were taken by factory ships and/or fleet whalers working in the North Pacific in all seasons (Reeves, 1984). With the signing of the International Agreement for the Regulation of Whaling in 1937, gray whales were protected from commercial whaling, at least by some countries (Reeves, 1984). That agreement included a provision for natives of Chukotka and Koryak to kill gray whales for subsistence use. Catches by Russians have averaged between 100 and 200 animals annually since 1948 (Zimushko & Ivashin, 1980; IWC, 1998). From 1959 to 1969, 316 gray whales were killed off central California under IWC special research permits to establish the status of the population (Rice & Wolman, 1971).

Abundance and current status

Scammon (1874) speculated that the eastern gray whale population numbered 30 000 in 1853–56, but by 1874, following commercial exploitation, the number did not exceed 8000–10 000 whales (Henderson, 1984). Henderson (1984) examined whaling records and made a qualitative conclusion that the population did not exceed 15 000–20 000 whales before the initiation of commercial exploitation in 1846. The most recent estimates of minimum population sizes following commercial exploitation are based on back-calculation analyses that utilize records of catch histories and a range of estimates of maximum sustainable yield rates. Reilly (1981) concluded that the most likely pre-exploitation size of the population was 24 000, which had been reduced to below 12 000 by the year 1900 as the result of commercial whaling. Minimum population size estimates range from 12 000 to 15 000 animals in 1846 at the beginning of commercial exploitation (Reilly, 1992) to only 4000–5000 or perhaps as low as 1500–1900 by 1900 (Butterworth, Korrûbel & Punt, 2002).

Direct estimates of current population size come from the analyses of systematic shore counts of southward migrating gray whales. These counts were initiated in 1967/68 near Monterey, California, where the majority of the population passes within 4 km of shore (Shelden & Laake, 2002). Abundance estimates from 1967/68 to 1997/98 showed a population increasing at an annual rate of 2.6% (S.E. = 0.28%), peaking at 30 000; however, in 2000/01 and 2001/02, the estimates dropped to about 18 000 (Rugh *et al*., 2005). The drop in abundance appears to indicate that this population is reaching carrying capacity (Wade, 2002).

Stock structure

Donovan (1991) noted that a management unit is defined such that specific management goals are met (e.g. commercial or aboriginal subsistence hunts do not lead to local depletions or extirpation). It would be useful to know if hunts of gray whales occurred at specific times or seasons and at locations containing genetically distinct stocks of the eastern population of gray whales. Preferential catches from such stocks could have the potential to extirpate or deplete those stocks and/or result in abandonment of portions of the popula-

WELLER **7 of 19** **NMFS Ex. 3-65**

tions' range as proposed for some species of whales (Clapham & Palsbøll, 1999; Clapham & Hatch, 2000).

When most receptive for mating, females are not concentrated in a specific breeding 'area'; rather, they are distributed along the migratory route, mostly in Alaska (Rugh *et al.*, 2001). This concentration of whales along the narrow migratory corridor may play a key role in helping these animals find mates at a critical time, and provide opportunity for genetic mixing throughout the population. There is no current information available to suggest that distinct sub-components of the eastern population segregate in any specific breeding areas.

There is evidence that gray whales segregate by age and sex on their northern feeding grounds, as reflected in the Russian aboriginal subsistence catches (Yablokov & Bogoslovskaya, 1984), but no genetic data are available to gain further insight into stock structure. In general, data on the habits and genetic identity of individual gray whales in the more northern feeding areas are lacking. Historical samples are unavailable to assess whether stock structure within the lagoons existed in the past.

In recent years, about 200 identifiable individual gray whales have returned one or more summers to the same areas at various locations along the Pacific North-west coast, perhaps as a function of seasonal abundance of prey (Darling *et al.*, 1998; Gosho *et al.*, 2001; Calambokidis *et al.*, 2002). These individual whales are believed to constitute the 'Pacific Coast Feeding Aggregation' which may or may not represent a genetically distinct stock of eastern gray whales, or just a recurring temporal aggregation of individuals that frequent this portion of the migration corridor during the summer. No definitive evidence is available to suggest that this 'Aggregation' represents a genetically distinct stock of eastern gray whales.

Examination of eastern gray whale hunting records (especially locations of takes), genetic analyses of animals killed and photographic identification research could be used to address the issue of population structure and fidelity throughout this population's range.

WESTERN POPULATION

Distribution

Historical sighting data and whaling records indicate that summer feeding grounds of western gray whales were in coastal waters of much of the northern Sea of Okhotsk (Yablokov & Bogoslovskaya, 1984; Henderson, 1990). However, gray whale sightings are now limited to the shallow-water shelf on north-eastern Sakhalin Island, Russia (Weller *et al.*, 1999). Recent research in the region results from a US–Russian environmental agreement initiated in 1995 to determine the status of the western population and to identify a means to mitigate ongoing threats to its survival (Weller *et al.*, 1999). The seasonal site fidelity and annual return of previously identified whales to this area, including mothers with calves, make the habitat off north-eastern Sakhalin Island of considerable concern relative to the conservation of these animals (Weller *et al.*, 1999). To date, no other feeding ground has been identified for western gray whales, underscoring the importance and potential fragility of the Sakhalin habitat.

In autumn, western gray whales migrate south along several possible routes, including down the coast of eastern Asia along the Korean Peninsula or along coastal waters of Japan (e.g. Kato & Tokuhiro, 1997). Migratory routes potentially include the waters off the coast of eastern Asia from Tatarskiy Strait to south of Korea or through coastal waters of Japan (e.g. Kato & Tokuhiro, 1997).

Wintering areas are unknown, but sightings, strandings and catches from 1933 to 1996 suggest the whales may be along the coast of Guangxi and Guangdong Provinces and around the nearby Hainan Island in southern China (Wang, 1984; Henderson, 1990; Zhu, 1998). The southernmost record of a western gray whale was from the east coast of Hainan Island (Rice, 1998). The long-held belief that western gray whales spend the winter along the south coast of Korea was based on unsupported conjecture (Rice, 1998).

The western North Pacific gray whale population is believed to be geographically independent from the eastern population because there is an apparent gap in distribution along the eastern shore of the Kamchatka Peninsula, between the Okhotsk and Bering Seas, at least as far east as the Commander Islands (IWC, 1993; Fig. 1).

History of exploitation

Although pre-exploitation numbers are unknown, the western gray whale population was probably never as numerous as the eastern population. It was intensively hunted during the past three centuries, and commercial whaling for the western population ceased in the 1960s. This period of exploitation reduced the population to only a fraction of its original size, and it was thought by some to be extinct (Bowen, 1974).

Japanese harpooners may have taken gray whales as early as the 16th century, and Japanese net whalers continued to take western gray whales during the 17th to 19th centuries (Omura, 1984). Groups of Koryak natives lived in the north-eastern Okhotsk Sea and may have hunted gray whales, perhaps even into the early 1900s (Krupnik, 1984). European and American ‘preindustrial’ whalers operating in the western North Pacific and Okhotsk Sea took gray whales from sailing ships and oar-powered ‘longboats’ between the late 1840s and early 1900s. With the advent of ‘industrial’ whaling with steam-powered catch vessels, Russian whalers took gray whales in the coastal waters of the Far East at the end of the 1800s (Henderson, 1984; Weller *et al.*, 2002). Mizue (1951) shows a dramatic decline in gray whale catches after 1910, with much of the effort attributed to the adoption of modern ‘industrial-type’ whaling in 1903.

Kato & Kasuya (2002) reviewed the catch history of western gray whales by Japanese and Korean modern whaling during the 1900s and revealed a period of peak annual catches of 100–200 whales occurred in the 1910s. This was followed by a rapid decline of the catch in the 1920s and 1930s, dropping to 10–20 whales per year for over 40 years until the hunt ended in the 1960s. Japanese and Korean whalers continued to hunt gray whales until as recently as 1966 (Brownell & Chun, 1977). It is estimated that a minimum of between 1800 and 2000 gray whales were taken during the whaling period between 1891 and 1966; Kato & Kasuya (2002) concluded that this last phase of continuing small-scale exploitation could have been a major factor in suppressing the recovery of this population.

Since the signing of the International Agreement for the Regulation of Whaling in 1937, western gray whales have been protected from commercial whaling, and no catch quotas have been established (IWC, 1998).

Abundance and current status

Only very rough approximations can be made of the original abundance of western gray whales. While not specifying a period of time, Yablokov & Bogoslovskaya (1984) reviewed records that suggested grey and humpback whales *Megaptera novaeangliae* were common and even abundant in the coastal waters of the northern Okhotsk Sea. They estimated that there were 1500–10 000 prior to the impact of commercial whaling. Bradford (2003) quantitatively back-calculated abundance estimates of 1000–1200 whales in 1900, which coincides with the qualitative estimate by Berzin & Vladimirov (1981) of 1000–1500 whales in 1910. Both of these estimates applied to a period prior to intensive modern whaling but after the population had already been substantially reduced by centuries of pre-modern catches.

Western gray whales were considered to be extinct or nearly so (Bowen, 1974) until records of catches and post-whaling sightings indicated the continuing existence of this population (Brownell & Chun, 1977). The population was listed as *Critically Endangered* by the IUCN in 2000 (Hilton-Taylor, 2000; Baillie *et al*., 2004) and is considered one of the most endangered populations of large whales in the world. Current population size estimates indicate that the western population contains approximately 100 individuals (Wade *et al*., 2003; IUCN, 2005; Weller *et al*., 2005), and its continued ability to survive is of considerable concern (Weller *et al*., 1999).

Stock structure

It is not known if stock structure exists or existed within the western gray whale population. While the western population was previously thought to have multiple migration routes between its summer and winter grounds, insufficient information is available to determine what, if any, implications multiple migration routes may have had for stock structure. Given this population's current small size, knowledge of stock structure would not likely influence conservation and management strategies for its protection and continued recovery.

METHODS USED TO INVESTIGATE POPULATION AND STOCK IDENTITY

Background

The IWC defines a management unit as a grouping of whales that, if subject to regulated hunts, would be sustained and not depleted or extirpated; both a population and a stock can be considered a management unit (Donovan, 1991). Historically, the data used to define such management units included: (i) demographic information on catch and sighting distributions; (ii) discontinuities in the distribution of animals on their feeding and breeding grounds; (iii) differences in biological parameters; (iv) length distributions; and (v) mark and recapture data. The advent of genetic data allows the information about the degree of connectivity between stocks to be considered. Information on rates of exchange among presumed management units allows estimation of the amount of time required for an extirpated management unit to recover and 'recolonise' its former range. Taylor (1997) illustrated cases of metapopulation dynamics important to management. For example, if a defined management unit was incorrectly assumed to be part of a larger population, its exploitation could result in its depletion and extirpation, with time to recovery difficult to estimate without some measure of dispersal of new individuals from some other source. Alternatively, if the proposed management unit was linked to a larger population, the management unit and its removals could be sustained owing to emigration and genetic exchange from the parent population, provided that dispersal rates were adequate to compensate for removals. Thus, management units must be defined by evaluating similarities and/or differences in demographic aspects of a population; the evaluation should include rates and degree of mixing and genetic exchange within and among adjacent populations (Taylor & Dizon, 1999). There are several tools that can be used to help delineate management units. The most powerful tool is genetics because of its ability to quantify similarities or differences between whales and provide a timescale for potential divergence. Other tools include morphology, chemical signatures, carbon isotope ratios, parasites, contaminants, photographic identification and trends in abundance, as described below.

Genetics

Molecular genetic methods have proven useful in clarifying the relationships between members of controversial taxa (e.g. Hillis & Moritz, 1990). Although the application of genetic techniques to the study of gray whale populations is ongoing, differentiation between eastern and western gray whales has been found (LeDuc *et al.*, 2002; Lang *et al.*, 2005; detailed below). Genetic analysis of structure within the eastern population has also been conducted (Ramakrsihman & Taylor, 2000; Steeves *et al.*, 2001; Goerlitz *et al.*, 2003).

LeDuc *et al.* (2002) used samples from eastern ($n = 120$) and western ($n = 45$) gray whales to document genetic differentiation on the basis of *mt*DNA haplotype diversities. Recent analyses used both *mt*DNA sequences and alleles from six microsatellite loci amplified from eastern ($n = 126$) and western ($n = 108$) populations of gray whales; the results supported previous studies and indicated that the populations are significantly different from each other (Fst = 0.062, $P \leq 0.001$, *mt*DNA data; Fst = 0.005, $P = 0.009$, microsatellite data) (Lang *et al.*, 2005). Differentiation in *mt*DNA sequences was due to differences in haplotypic diversity (0.95 in the east and 0.77 in the west) and in differences in the relative frequencies of haplotypes within each population. Of the 33 haplotypes present in the eastern sample set, the two most common were found in 10.3% and 9.5% of sampled individuals, illustrating the fairly even distribution of haplotypes. On the other hand, the two most common haplotypes (out of 20) in the western sample set were found in 36% and 33% of sampled animals, while 15 haplotypes were found in only one or two individuals. The high haplotypic diversity found in the eastern population indicates that there was a minimal loss of genetic diversity resulting from the historical reduction in population numbers. In contrast, the relatively low haplotypic diversity of the western population may be the result of a recent population bottleneck or of a small population size being maintained over long timescales. The high number ($n = 20$) of haplotypes found in the western population is surprising given what is known of the population's size and history. For comparison, the critically endangered North Atlantic right whale population contains only five extant haplotypes (Malik *et al.*, 2000) among an estimated 300 animals (Knowlton, Kraus, & Kenney, 1994).

Genetic analysis using nuclear DNA illustrated a relatively high level of microsatellite diversity (He = 0.724) in the western population; this diversity was lower but comparable to that found in the eastern population (He = 0.759) (Lang *et al.*, 2005). Although the results from the study by Lang *et al.* (2005) supported genetic isolation between the two populations, higher levels of differentiation were documented when only the females of each population were compared (Fst = 0.016, $P \leq 0.001$), and estimates of microsatellite differentiation were not significant when only the males were compared (Fst ≤ 0.001, $P = 0.423$).

Structure within the eastern population's southern feeding grounds has been examined using mtDNA. These studies found no evidence of matrilineal fidelity to the Clayoquot Sound, British Columbia southern feeding area among animals believed to constitute the 'Pacific Coast Feeding Aggregation'. Photo-identification records indicate long-term fidelity of whale to the area (Hatler & Darling, 1974; Darling, 1984), raising the possibility that the southern feeding group represents a learned cultural behaviour, similar to that seen for the feeding grounds of North Atlantic humpbacks, where knowledge of preferred feeding grounds is believed to be passed down from mother to offspring as evidenced in differences in their mtDNA (Smith *et al.*, 1999). However, significant differences in mitochondrial haplotyopes between whales in the Pacific Coast Feeding Aggregation and the general population were not found (Steeves *et al.*, 2001), indicating that either the southern feeding group has not been extant long enough to differentiate genetically, or that the gray whales are more flexible than humpbacks with regard to their learned behaviour (i.e. matrilineal fidelity is less strict).

Future studies may be able to better characterize the genetic composition of the whales in the southern feeding area by increasing sampling across the range. Recaptures in the photographic identification studies have shown a mixing across a large area. Simulation studies have suggested that even a recent colonization of the southern feeding areas along the Pacific North-west coast and elsewhere could be detected by genetic testing given sufficient sample sizes (Ramakrsihman & Taylor, 2000).

Analysis of *mt*DNA has also been used to explore matrilineal fidelity of eastern gray whales to wintering lagoons in Baja California (Goerlitz *et al.*, 2003). Weak but non-significant genetic differences were found between calving females in Laguna San Ignacio and in Laguna Ojo de Liebre, suggesting some level of natal philopatry to wintering lagoons. Differences in haplotype frequencies between calving females within and outside lagoons, as well as between single females and females with calves within each respective lagoon, were used to suggest that fidelity to lagoons might also be influenced by reproductive status (Goerlitz *et al.*, 2003). While natal fidelity of calving females to lagoons indicates that some substructuring of the eastern population occurs on the wintering grounds, this substructure may not be affecting gene flow, given that the majority of females are thought to conceive early in the migration (Rice & Wolman, 1971).

Morphology

There have been few comparative studies of the morphology and/or morphometrics of gray whales. Rice (1998) summarized several studies that found no clear differences in skeletons of gray whales from the Atlantic Ocean and from the western and eastern Pacific populations. Rice & Wolman (1971) examined 316 gray whales collected from the eastern population during migration past central California. Zimushko (1972 in Yablokov & Bogoslovskaya, 1984) compared data collected by Andrews (1914) on the external morphology of western and eastern gray whale populations and suggested that differences were sufficient to indicate the populations were distinct. Andrews (1914) examined 145 western gray whales caught at a whaling station in Ulsan, South Korea. He made detailed descriptions of gray whale morphology and collected two complete skeletons. Zimushko (1972) reported that the distance from the tip of the rostrum to the base of the pectoral flippers, from the tip of the rostrum to the eye, the maximum width of the pectoral flipper, and the length of the baleen plates were statistically greater in the western gray whales, and that western gray whales had fewer baleen plates and fewer throat grooves. Unfortunately, the details of these analyses were never published. There have been no additional published comparisons on the morphology of gray whales relevant to an analysis of population and stock structure.

Chemical signatures

Analysis of chemical signatures (e.g. heavy metals and organochlorines) as ecological tracers could also distinguish differences between populations or stocks of gray whales. Other animals that use inland Asian waters (e.g. North Pacific minke whales) have highly distinctive chemical signatures, characteristics which have been used to distinguish stocks within the same species (Fujise *et al.*, 2000; Nakata *et al.*, 2000). Tilbury *et al.* (2002) examined chemical contaminants from samples of gray whales killed by subsistence hunters in Russia and samples from gray whales stranded along the west coast of the USA during the northbound migration. These authors found that polychlorinated biphenyl (PCB) concentrations in whales killed in Russia were significantly lower than in stranded whales. This type of analysis of contaminant signatures could be used to discriminate small aggregations of whales that feed in a limited area with a persistent pollution feature. If there was no mixing of gray whales in the general population, then a chemical signature could theoretically identify a group of whales.

Carbon isotope ratios

Reliance on prey species unique to specific geographical locations could be detected by examination of carbon isotope ratio signatures found in hard tissues (e.g. baleen) compared with those found in prey species and, by proxy, the phytoplankton supporting the prey species found in specific locations over many years. Schell & Saupe (1993) and Schell (1998) examined the isotopic record in baleen plates from Western Arctic bowhead whales and constructed a prey-location specific feeding record that extends from 1947 to 1995. A similar study conducted on gray whale samples from catches and stranded animals throughout their range could provide indications of the prevalent use of prey from certain areas and the significance of annual feeding at those areas and, by inference, the potential for a subunit of the population representing a genetically distinct stock.

Parasites

Gray whales are heavily infested with ectoparasites and epizoites including a host specific barnacle *Cryptolepas rhachianecti* and three species of whale louse *Cyamus scammoni*, *C. ceti* and *C. kessler*, but gray whales have few endoparasites (Rice & Wolman, 1971). It seems that ectoparasites take advantage of the gray whales' habit of swimming slowly through shallow coastal waters rich in nutrients, but endoparsite concentrations are low because of the whales' long period of fasting each year. Although parasites can be used theoretically to recognize groups of whales that do not interact with the general population, there have been no comparative studies of gray whale parasites that could have bearing on stock structure.

Photographic identification

Photographic identification data indicate high levels of annual return and pronounced seasonal site fidelity for most whales identified on the western feeding ground (Weller *et al.*, 1999, 2002). Photographic identification has also been used to evaluate abundance, range and movements of gray whales in the Pacific North-west (Darling, 1984; Calambokidis *et al.*, 2002) and in the lagoons of Baja California (Jones & Swartz, 1984; Urban *et al.*, 2003). A recent effort to locate and combine historical photographic data sets with more recent photographs of eastern gray whales has resulted in the creation of a database that includes over 5000 images of individually recognizable whales photographed in the lagoons from 1960s to 2005 (S. Swartz, unpublished data). Analyses of these photographs along with future contributions to the database may yield additional information on the fidelity of individual whales to specific lagoons and possibly provide insight concerning the potential for stock structure within the eastern gray whale population.

Trends in abundance

The strongest evidence that the eastern and western gray whale populations are segregated is the lack of growth in the western population through a period in which the eastern population has made an excellent recovery. If there was a dispersal of individuals from east to west, the western population would likely have been repopulated by now, unless any immigration was offset by a currently unknown source of mortality. Mizue (1951, p. 72) points out that the take and subsequent decline of gray whales in the east sea area of Korea 'indicate[s] that the stock of gray whales in our adjacent waters was but a small one existing, as it were, independently, having no intercourse with the stocks of other waters'.

DISCUSSION

Gray whales have experienced major changes in their distribution with the periodic closure of the Bering Sea during the Pleistocene ice ages, and ice-driven contact between eastern and western populations could have occurred as recently as 400 years ago (Overpeck *et al.*, 1997). These Arctic cold periods are relatively recent events in the evolution of cetaceans, and we should expect to see the evidence of such history in the genetic composition of North Pacific gray whales today. The dramatic declines in abundance of gray whales brought about by commercial whaling occurred on such a recent timescale that fixed or nearly fixed genetic differences – criteria often used to signify evolutionary significance – would not be expected. However, differences in gene frequencies – i.e. criteria used as evidence for population structure meaningful to management – are likely to have developed on these timescales (LeDuc *et al.*, 2002). Such differences were observed in a preliminary analysis of mtDNA and microsatellites from two bowhead whale populations (i.e. Bering-Chukchi-Beaufort and Okhotsk) that were greatly reduced in numbers by whaling. There were small but significant differences in their respective gene pools, suggesting that postglaciation separation has been sufficiently long for genetic differentiation to develop between these two allopatric populations (LeDuc *et al.*, 1998). Analyses of genetic samples from both Pacific gray whale populations did indicate that the populations are significantly different from each other (LeDuc *et al.*, 2002; Lang *et al.*, 2005). The apparent genetic differences, different coastal migratory corridors, feeding and breeding areas, and the recovery of the eastern but not the western population are evidence of allopatry and cause for concern. The available data strongly indicate that western gray whales represent a population geographically isolated from eastern gray whales and that the two populations should continue to be managed separately.

For western gray whales, there are not sufficient data to assess the plausibility of stock structure within the population, owing to its extremely depleted state. Despite there having been a great deal of research on eastern gray whales, most of that effort has gone to documenting changes in abundance, feeding biology and behaviour. Nevertheless, enough is known about breeding behaviour and biology for separate breeding groups to be unlikely. If, as it appears, both males and females are promiscuous breeders (Swartz, 1986), then there is little opportunity for the nuclear genome to be anything other than well mixed, as is indirectly suggested by the high haplotypic diversity of the eastern population (LeDuc *et al.*, 2002).

Relatively little is known about how individuals choose feeding grounds throughout their lives. Photographic data from the Pacific Coast Feeding Aggregation indicate that some individuals show site fidelity over periods of at least years while others at least appear regularly in the same areas at particular times (Calambokidis *et al.*, 2002). Data from Russian hunts show segregation by age and sex on the high-latitude northern feeding grounds (Reeves, 1984), which is also seen during migration (Rice & Wolman, 1971) and within the wintering areas (Jones & Swartz, 1984). However, the available data are from only the small portion of the whales' range where the catches occur, relative to the entire known summer feeding grounds utilized by gray whales. A better understanding of site fidelity and potential stock structure will be gained through continuation and expansion of photographic identification and satellite tagging research on the feeding grounds coupled with comparisons of genetic and pollutant/chemical samples from animals in these areas.

In conclusion, it is unequivocal that the western and eastern populations of gray whales should be treated as separate management units, and there is a strong case for treating all gray whales within each of these populations as belonging to a single unit. Although there are repeated concentrations of whales in some areas, as described for the Pacific Coast

Feeding Aggregation and the tendency of some whales to reuse certain lagoons in Baja California, there is also evidence that there is mixing within each of the respective general populations. However, it would be prudent to closely monitor small, localized feeding groups, and management should be adapted to detect and avoid adverse population changes that would result from excess mortalities in any specific habitat.

ACKNOWLEDGEMENTS

The authors express thanks to all those researchers and wildlife managers who continue to find gray whales an interesting and informative species to investigate, both from the point of view of learning more about gray whales themselves and for the insights to other species revealed through studies of gray whale biology and natural history. Aimee Lang provided substantial material supporting the genetics section, bringing the review current with the latest information on gray whale genetic analysis. This manuscript was greatly improved by generous critiques and comments received from reviewers including: Jeff Breiwick, Robert Brownell, Jr, James Darling, Doug DeMaster, John Calambokidis, Phil Clapham, Mary Lou Jones, Tammy Steeves and an anonymous reviewer.

Abundance estimates for western North Pacific gray whales for use with stock structure hypotheses of the Range-wide Review of the Population Structure and Status of North Pacific gray whales

Justin G. Cooke[1]

ABSTRACT

Abundance estimates are derived for western North Pacific gray whales *Eschrichtius robustus* that correspond to the various stock structure hypotheses developed by the IWC Scientific Committee's Range-wide Review of the Population Structure and Status of North Pacific gray whales (IWC 2018a), by fitting an individually-based population model to photo-id data and other data collected off Sakhalin, Kamchatka and Mexico. Abundance estimates are presented for the putative Western Feeding Group and Western Breeding Stock in 1995 and 2015. Abundance estimates for the Western Feeding Group in 2015 range from about 130 to about 300 whales (aged 1 yr and over) depending on stock structure hypothesis, while abundance estimates for the putative Western Breeding Stock are all less than 100.

1 INTRODUCTION

This paper presents abundance estimates for gray whales in the western North Pacific that correspond to the various stock structure hypotheses developed by the IWC Rangewide Workshops on North Pacific Gray Whales (IWC 2018a). Estimates corresponding to some further plausible stock structure hypotheses are also presented.

To derive the esitmates, an individually-based model is fitted to photo-id data collected during 1995-2016 from Sakhalin Island and Kamchatka Peninsula (Burdin et al. 2017; Yakovlev et al. 2013, 2017), supplemented with sex determinations from biopsies (Lang 2010), photographic matches with wintering grounds in Mexico during 2006-12 (Urbán *et al.* 2012; 2013), and satellite tracking of some tagged individuals from Sakhalin towards their wintering grounds (Mate et al. 2015).

The generic individually-based population model structure and the method of fitting to data is specified in Appendix I. The specific implementation choices used for western North Pacific gray whales are described in the Methods section.

2 METHODS

2.1 Stock structure hypotheses

The stock structure hypotheses developed by the 4th IWC Rangewide Workshop on North Pacific Gray Whales (IWC 2018a) which were still under consideration for consideration after the 5th Workshop (IWC 2018b) are hypotheses 3a, 3b, 3c, 3e, 5a, 6b listed in Table 6 (JCRM 19(Suppl.):528).

The hypotheses posit the existence of up to two breeding stocks: an eastern breeding stock (EBS) which winters off Mexico, and possibly a western breeding stock (WBS) which winters at one or more locations in Asian waters. The hypotheses also posit the existence within the eastern breeding stock of a western feeding group (WFG) which visits Sakhalin and Kamchatka in summer, and a northern feeding group (NFG) which feeds in the Bering and Chuckchi Seas and possibly also off SE Kamchatka.

Of these, hypotheses 3a, 3c, 3e posit only a single breeding stock, and are mutually indistinguishable with respect to the data collected on western North Pacific gray whales.

Hypothesis 6b posits a western breeding stock (WBS) but it only occurs in areas for which no data are available, and is therefore effectively invisible with respect to the available datasets. With regard to observed whales in the western North Pacific, 6b is indistinguishable from the hypotheses with just one breeding stock (3a/3c/3e).

In order to implement the hypotheses, whales occurring off Sakhalin and Kamchatka were divided into four subgroups, whose numbers are to be estimated from the data:

Table 1. feeding subgroups defined for the purpose of implementing stock structure hypotheses

Subgroup	Description
S	Whales that visit Sakhalin but not Kamchatka
SK	Whales that visit Sakhalin and occasionally Kamchatka
KS	Whales that visit Kamchatka and occasionally Sakhalin
K	Whales that visit Kamchatka but not Sakhalin

The hypotheses and their definitions are listed in Table 2. In all the hypotheses considered by IWC (2018), whales seen off Sakhalin include WFG whales and possibly also WBS whales. Whales seen of SE Kamchatka include WFG whales and possibly also WBS and NFG whales. The hypotheses considered by IWC (2018) do not allow for the possibility that all whales seen off Kamchatka belong to the WFG. In view of the lack of evidence that any Kamchatka whales belong to the NFG, two further hypotheses were added (8 and 9) in which there are no NFG whales off Kamchatka.

Table 2. Definitions of stock structure hypotheses in terms of affiliations of feeding subgroups

Hypothesis	Description	WBS	WFG	NFG
3a/3c/3e	One breeding stock, some NFG in K		S, SK, KS	K
3b	Two breeding stocks, WBS in K	K	S, SK, KS	
5a	Two breeding stocks, some NFG in K	S, SK	S, SK, KS	K
8	One breeding stock, no NFG in K		S, SK, KS, K	
9	Two breeding stocks, no NFG in K	S, SK	S, SK, KS, K	

In each case, the initial population sizes of each feeding subgroup/breeding stock combination were modelled using a log-linear model with one intercept parameter with a uniform prior, plus a random effect term for the feeding subgroup/breeding stock combination.

2.2 Data

2.2.1 Photo.identification

Sampling with photo-identification was conducted in the summer feeding grounds off NE Sakhalin during 1995-2016 and off SE Kamchatka during 2004-12. There were two research teams working off Sakhalin and one off Kamchatka. Off Sakhalin, the Russian Gray Whale Project (RGWP, Pacific Geography Institute, Petropavlovsk, Kamchatka; a continuation of the former Russia-US project) has been collecting data since 1995 ((Burdin et al. 2017), and the Marine Biology National Research Center , (MBNRC, Vladivostok; formerly Institute of Marine Biology, IBM) has been collecting data since 2002 and cross-matched the results with photos from Kamchatka (Yakovlev et al. 2013, 2017).

A total of 287 distinct whales had been identified through the 2011 season, based on cross-matching of the individuals observed by each team. During 2012-2016, a further 56 whales were seen by the RGWP team and 73 whales by the MBNRC and Kamchatka teams, which have not been cross-matched.

Sampling also occurred in the wintering grounds off Baja California, Mexico. Because theses grounds are shared with the more numerous eastern North Pacific gray whales, only individuals matched with the western North Pacific were included in the analysis. Cross-matching was conducted between whales identified in Mexico during 2006-12 and all whales in the Sakhalin and Kamchatka catalogues up to 2011 (Urbán et al. 2012, 2013).

Because the matching rate in Mexico appeared to be strongly age-specific, only animals known to be at east 6yr old were considered as potentially samplable in Mexico, and only matches from those animals were used, for the reasons explained by Cooke (2016). Of 17 whales matched between Sakhalin and Mexico, 16 met this criterion. Of a further 4 whales matched between Kamchatka and Mexico, 2 met this criterion.

2.2.2 Additional features recorded

The additional features recorded for at least some identified animals were: sex; mother/calf status; breeding stock affiliation.

Sex. Sex was determined by biopsy for a total of 167 whales, including 156 by the RGWP project, 23 by the MBNRC project, and 12 by both projects. Of the 12 individuals sexed by both projects, 11 agreed with respect to sex. The one whale without agreement was deemed to be female, because it had been biopsied as female by the RGWP project on four separate occasions. Sex determination is assumed for modelling purposes to be 100% accurate.

Cow/calf status. Of 3,602 encounters of living whales off Sakhalin and Kamchatka (where "encounter" means an individual identified at least once by a team in a season) 205 were of cow-calf pairs and 71 were unaccompanied calves. It is assumed that all cow-calf pairs and accompanied calves were correctly identified by the RGWP team from 1995 and by the MBNRC team from 2003. The mother/calf status was not recorded by the MBNRC team in 2002. It is assumed that all unaccompanied calves were correctly identified by the RGWP team from 1995 and by the MBNRC team from 2007, which used the same criteria from this date. For the years 2003-06, MBNRC unaccompanied calf identifications were not used (they were treated as indistinguishable from other whales).

Of the 23 matching identifications from Mexico that were used in this analysis, 8 were of cows accompanied by calves, but the calf identifications were not available for this analysis.

Breeding stock affiliation

Three individuals sighted off Sakhalin were successfully tagged and tracked to the eastern North Pacific (Mace et al. 2015). It is assumed that the successful long-term tracking of an individual reveals its breeding stock affiliation (eastern or western). Individuals sighted in Mexico are also assumed to belong to the Eastern Breeding Stock (EBS).

2.3 Population model

The structure of the generic population model structure and the method of fitting to data is specified in the Appendix. The specific implementation choices used for western North Pacific gray whales are described here.

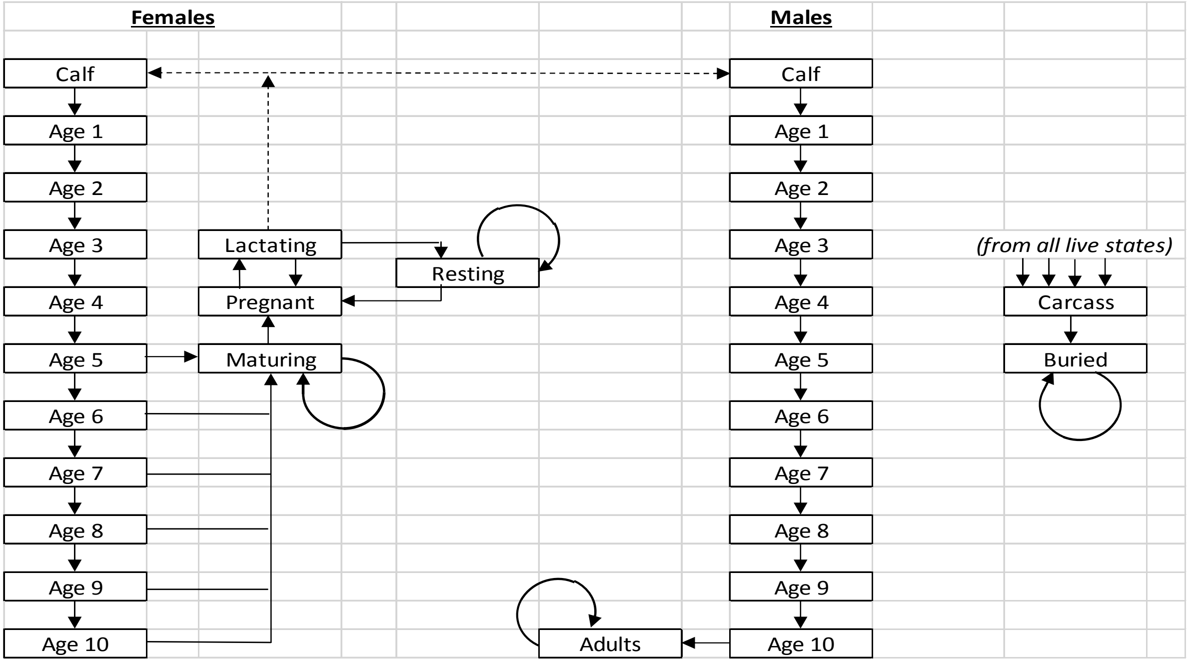
2.3.1 State space

The following attributes are represented in the state space:

- Life stage (sex, age and reproductive status, mortality status)
- Feeding subgroup affiliation
- Breeding stock affiliation
- Sampling availability (reflection of individual heterogeneity in capture probability)

The life stages and the possible transitions are shown in Table 3. Animals in any of these stages can die by entering a "carcass" state, where they have a (typically small) probability of being recovered and identified. From the following year they are assumed to be unobservable ("buried").

Table 3. List of living stages in the gray whale model



The youngest allowed age for a pregnant whale is 7 years and the youngest age for a lactating whale is 8 years. In the summer season, the "Age *x*" stage contains animals aged approximately x + ½ .

Feeding group and breeding stock affiliations are assumed to be maternally inherited and to remain constant throughout life.

Individual heterogeneity in availability was modelled using 1,3 or 5 availability classes. Each whale is born into a random class with equal probability. The individual availability class is assumed to be retained throughout life but not to be heritable. The purpose of including these classes is to reduce the bias in abundance estimation arising from capture probability heterogeneity.

2.3.2 Reproduction, mortality and other transitions

Each animal in the lactating stage has exactly one calf, assumed to be male or female with equal probability.

The calf mortality is modelled as a constant plus an optional annual random effect. The non-calf mortality rate is assumed to be constant.

The transition probability to the maturing class is assumed to be constant. The transition probability to the pregnant stage depends on the source stage (maturing, lactating or resting) plus an optional annual random effect.

2.4 Sampling model

2.4.1 Primary and secondary sampling occasions

The sampling in a season by a research team is treated as sampling occasion. Up to and including the 2011 season, each season of sampling by each team off Sakhalin and Kamchatka is treated as a primary sampling occasion (see Appendix section 2.1 for the definition). From 2012, two options were considered: (i) RGWAP team as primary team throughout, MBNEC and Kamchatka teams secondary from 2012; (ii) MBNRC and Kamchatka teams are primary throughout, RGWAP secondary from 2012.

Individuals sighted up to 2011 by a non-primary team only were treated as "identity lost" (see Appendix section 2.4) from 2012 onwards, because they might, unknown to the analysis, match whales seen by the primary team for the first time in 2012 or later. Sampling occasions in Mexico during 2006-12 are treated as secondary, because only whales matched with Sakhalin or Kamchatka were used.

2.4.2 Capture probability models

The capture probability model for the summer sampling includes a free parameter for each sampling occasion (team by year), and a parameter for each combination of feeding subgroup and location, where "location" means Sakhalin or Kamchatka. That is, each feeding subgroup may be differentially catchable in each location.

The summer capture probability model also contains optional random-effect terms for life stage, life stage × team interaction, and availability class. The life stages for this purposes were summarized into five stages: calves, subadults, lactating mothers, other mature females, and mature males.

The capture probability for the Mexican wintering grounds was estimated externally of this model, because the great majority of the animals there are eastern North Pacific gray whales. The average annual capture probability was estimated to be 0.054 (Cooke 2016).

Because only three identified carcasses were observed, a single value for the capture probability of carcasses was estimated. Unidentified carcasses were not used: each year, the observation of carcasses is treated as a secondary sampling occasion.

2.4.3 Additional features recorded

The additional features enter the likelihood through the Q factor in expression (A.13).

Sex is treated as a deterministically observed feature ($Q = 0$ or 1). Any gender bias present in the sampling of individuals is modelled through the capture probability model, which allows for sex-biased sampling.

The probability ($0 < Q < 1$) that a calf of the year was still with its mother when first sampled by a team in a season was modelled as a team-specific parameter, because the MBNRC team tended to observe the animals later in the season than the RGWP team, after more calves had been weaned.

Identifications of calves were assumed to be deterministic ($Q = 0$ or 1) in all years in which they were used (see above).

Individuals sighted in Mexico are automatically assigned belong to the eastern breeding stock (EBS), in the sense that the probability of sighting an animal from the western breeding stock (WBS) in Mexico is assumed to be zero ($Q = 0$).

Three individuals were successfully tagged and tracked to the eastern North Pacific were likewise assigned to EBS. It is assumed that, conditional on the location where they were originally sampled and tagged (in this case, Sakhalin) the probability of successfully tagging and tracking a sampled animal is independent of their breeding stock affiliation (that is, had the individuals been western breeding stock animals, this would have been verified).

2.5 Model selection

Model selection for the purpose of determining which nuisance covariates need to be included was performed with the AIC criterion applied to the large population approximation to the parameter likelihood (see Appendix, section 2.6.2). For this purpose, stock structure hypothesis 3a was used.

3 RESULTS

3.1 Model selection

The results of fitting various models are listed in Table 4 with the AIC criterion from the approximate parameter likelihood. The preferred model (F) includes the following factors: annual variability in calf survival and pregnancy rate; capture probability depends on: team/year interaction, stage effect and team/stage interaction, subgroup/location interaction and availability class (3 levels). Increasing the number of availability classes to 5 increased the AIC.

Fig 1 shows a comparison of the mean population trajectory using (a) the RGWP data; (b) the MBNRC data as the primary data set for the years 2012-16 (when no cross-matching was conducted). The difference in trajectories is seen to be negligible, and the RGWP data were treated as the primary data set for all other model fits.

3.2 Abundance and trends

Population trajectories for the aged 1+ population size for the WFG, the WBS and their sum, were extracted from the posterior distributions of the individual-based population trajectories for each stock structure hypothesis. The estimates of abundance for 1995 and 2015, and of the annual trend, are shown in Table 5. The reason for selecting years near the beginning and end of the data series is that the estimates for the two years have low covariance and together summarize the fitted population trajectories well. The mean abundance estimates for the western feeding group (WFG) in 2015 range from 132 to 287 depending on the stock structure hypothesis. The estimates for the western breeding stock (WBS) are all below 100. The estimate annual rate of increase from 1995-2015 is about 0.05 in all cases. Figs 2a-e show samples of population trajectories from the posterior distributions for each hypothesis.

Table 4. Results of model selection

Case	LogLike	Rank	AIC	Calf mortality	Pregnancy	Capture probability
A	-3806.9	60.0	7733.7	Constant	Stage	Team.Year + Subgroup.Location
B	-3773.9	64.1	7676.1	Constant	Stage	Team.Year + Subgroup.Location + Stage
C	-3697.2	71.6	7537.7	Constant	Stage	Team.Year + Subgroup.Location + Stage + Stage.Team
D	-3653.9	73.3	7454.2	Constant	Stage	Team.Year + Subgroup.Location + Stage + Stage.Team + AvailabilityClass
E	-3640.2	83.1	7446.5	Constant	Stage + Annual	Team.Year + Subgroup.Location + Stage + Stage.Team + AvailabilityClass
F	-3635.5	87.7	7446.4	Annual	Stage + Annual	Team.Year + Subgroup.Location + Stage + Stage.Team + AvailabilityClass

Table 5. Estimates of abundances and trends by stock structure hypothesis

			Abundance estimates (aged 1+)		
Year	**Hypothesis**	**Group**	Mean	SD	CV
1995	3a	WFG	74	4	0.05
1995	3b	WBS	33	6	0.17
1995	3b	WFG	75	4	0.06
1995	5a	WBS	27	6	0.24
1995	5a	WFG	47	7	0.16
1995	5a	WFG+WBS	74	4	0.05
1995	8	WFG	106	8	0.07
1995	9	WBS	27	6	0.24
1995	9	WFG	78	10	0.12
1995	9	WFG+WBS	105	7	0.07
2015	3a	WFG	200	6	0.03
2015	3b	WBS	86	11	0.13
2015	3b	WFG	202	5	0.03
2015	5a	WBS	67	14	0.20
2015	5a	WFG	132	14	0.11
2015	5a	WFG+WBS	199	6	0.03
2015	8	WFG	287	12	0.04
2015	9	WBS	67	14	0.20
2015	9	WFG	218	19	0.09
2015	9	WFG+WBS	285	14	0.05

Appendix

Specification of the generic individually-based population model

This Appendix specifies the generic individually-based population model, applicable to any mammal population with seasonal breeding and litter size 1. The implementation choices for the specific application are noted in the main text. The generic model consists of a biological model and a sampling model.

1 BIOLOGICAL MODEL

1.1 State space representation

The biological model is a stochastic, individual-based model with a fixed time step, usually 1 year. At each time step, each individual is in one of n possible states. There are up to N individuals in total, where N is chosen large enough to accommodate any individual alive at any time during the era of interest, which runs from time $t = 0$ to $t_{\max}$.

Each row of the $N \times n$ matrix S represents an individual biography, where S_{it} is the state of individual i in year t ($i = 1, \ldots N$; $t = 0, \ldots, t_{\max}$). The matrix S as a whole represents the individual-based population trajectory.

If the state of an individual is characterized by r attributes, and the jth attribute can take n_j values, then the number of possible states is up to $\prod_{j=1}^{r} n_j$ but may be less if not all combinations of attribute levels are allowed.

The attributes reflected in the range of individual states include those that are relevant for the population dynamics (such as age, sex, health and reproductive status) and those that are relevant for the sampling process, such as migration habits, behavior etc. These two categories of attributes typically overlap. The attributes of an individual that define its state may or may not correspond to observable features of the individual. Some attributes remain fixed throughout life, such as sex, while others, such as reproductive status, may change each year.

The possible states of an individual include live states, dead states, and the unborn state (individuals which have not yet entered the population).

Because an unborn animal cannot be observed, only one unborn state need be recognized. All attributes of an individual, including inherited attributes, can, without loss of generality, be deemed to be acquired at birth or on entry into the population. The unborns include not only individuals which are literally unborn, but also immigrants prior to their immigration. All individuals count as unborn prior to $t = 0$.

Post-mortem states can be divided into one or more freshly dead “carcass” states where there is still some chance that the animal will be found and identified, and a terminal “buried” state where the animal has, for the purpose of the analysis, become permanently unobservable.

In order to limit the number of parameters to be estimated, individual variation in an attribute, such as migration behavior or reproductive output, is modelled by allowing individuals to belong to a fixed number of notional classes with respect to that attribute. The number of such classes is deemed sufficient when further subdivision has negligible effect on the results.

Some of the individuals will be individually identified at some point during the era of interest. Individuals which are identified at any time during the era of interest are termed “known”, while those which are never identified are termed “unknown”. At any given time t, individuals identified prior to that time are termed “identified” otherwise “unidentified”.

The value of N need not be fixed in advance. Only those individuals which are alive and/or identified at some time within the era of interest need be represented explicitly in the model. Unknown individuals remain mutually indistinguishable with respect to the model until they are born. Whenever an unknown individual is born or otherwise enters the population, it can be taken from a presumed unlimited source of unborn unknowns, and the value of N incremented by 1. Where a distinction is required, N denotes the number of individuals alive at some point during the era of interest, N^+ denotes the indefinitely large number of potential individuals, and N^- denotes the number of known individuals.

The description of the population trajectory is completed by defining a vector of parents π, such that π_i is the parent (mother) of individual *i*. By convention, π_i is set to 0 (parentage unspecified) for individuals which are already alive at time $t = 0$, or which enter the population other than by birth to a member of the population, such as by immigration.

1.2 Aggregate population trajectory

The aggregate population trajectory is given by the matrix *P* where P_{kt} is the number of individuals in state *k* in year *t*. The aggregate population trajectory is related to the individual-based population trajectory by:

$$P_{kt} = \sum_{i=1}^{N} I(S_{it} == k) \quad \text{(A.1)}$$

I is the indicator function (1 for true, 0 for false) according to the equality of its arguments.

To fit a population trajectory to individually-based data, such as photographic or genetic identification of individuals, the full individual-based trajectory is required. To fit to aggregate data, such as abundance and trends, where individuals are not distinguished, the aggregate trajectory is sufficient. Many different individual-based trajectories share the same aggregate trajectory.

1.3 Population aggregates

Arbitrary linear population aggregates are defined as required. The value of the *j*th population aggregate in year *t* is a weighted sum of individuals by state:

$$A_{jt} = \sum_k W_{jk} P_{kt} \quad \text{(A.2)}$$

where the weight matrix *W* defines the population aggregates. Population aggregates can serve as explanatory variables for density-dependent effects.

1.4 Dynamics

The dynamics of the population are determined by two (time-varying) matrices, the transition matrix *T* and the reproduction matrix *R*.

For $j > 0$, the transition matrix entry T_{jkt} is the probability that an individual in state *j* at time *t* transitions to state *k* at time t+1. Some of the entries of *T* are constants, while others depend on unknown parameters, whose values are to be estimated. Entries of *T* that correspond to inadmissible transitions, such as sex change, are zero.

For any given source state $j > 0$, the set of allowed direct destination states (the set of values of *k* for which the entries T_{jkt} are non-zero), is assumed to be time-invariant. Let n_j denote the number of possible destination states from source state *j*, and let the integer-valued matrix U_{jl} (j=1,…, n; l = 1, … n_j) denote the *l*th possible destination state from source state *j*. Let φ_{jlt} denote the transition probability from state *j* to state *Ujl* during time *t* to *t* +1, conditional on the individual not having transitioned to any of the states $U_{j,1}$, …, $U_{j,l\text{-}1}$. The ordering of the allowed destination states is significant and forms part of the model specification. By definition, $\varphi(j, n_j, t) = 1$, because there are no further allowed destination states remaining.

Transition probabilities that depend on unknown parameters are modelled with a logit-linear model:

$$\varphi_{jlt} = 1 / (1 + \exp(-\zeta_{jlt}) \quad (l = 1, \ldots, n_j - 1) \quad \text{(A.3)}$$

where the values of ζ are unconstrained (can take any values from -∞ to +∞) and are modelled as linear combinations of unknown parameters:

$$\zeta_{jlt} = \sum_k X_{jltk} \beta_k \quad \text{(A.4)}$$

where β is the vector of parameters where the entries of the data matrix *X* are either constants or values of population aggregates.

The entries $T_{0,k,t}$, where $k > 0$, have a special meaning. $T_{0,k,t}$ represents the expected total number of individuals to enter the population in state *k* at time *t*, for example through birth or immigration. For convenience in formulae, $T_{0,0,0}$ is set to 1.

For $j>0$ and $k > 0$, The reproduction matrix entry $R_{j,k,t}$ is the probability that a female in state j in year t bears a calf that is in state k. The entry $R_{j,0,t}$ is the probability that an animal in state j does not bear a calf in year t. Entries of R which depend on unknown parameters are modelled in a similar way to the entries of T.

The entry $R_{0,k,t}$ denotes the expected number of individuals that enter the population in state k at time t other than by birth to a member of the population, for example by immigration. Expected numbers of immigrants that depend on unknown parameters are modelled in the same way as the expected initial numbers by state.

From these definitions of T and R it follows that:

$$T_{0,k,t} = \sum_{i=0}^{N} R_{i,k,t} \tag{A.5}$$

1.5 Initial conditions

The initial conditions for the population are handled by taking the initial time sufficiently far before the era of interest that the results are insensitive to the choice of initial conditions.

Expected initial numbers that that depend on unknown parameters are modelled with a log-linear model:

$$T_{0,j,0} = R_{0,j,0} = \exp(\psi_j) \tag{A.6}$$

where the values of ψ are unconstrained (can take any values from $-\infty$ to $+\infty$) and are modelled as linear combinations of unknown parameters:

$$\psi_j = \sum_l Z_{jl}\beta_l \tag{A.7}$$

where β is the vector of parameters and the entries of the data matrix Z are constants.

2 SAMPLING MODEL

2.1 Sampling occasions

The sampling process involves a fixed number of sampling occasions. Each sampling occasion involves sampling individuals randomly, without replacement, with a probability that can depend on the state of the individual. Each sampling occasion is tied to a specific time step. Multiple sampling occasions associated with the same time step are treated for analysis purposes as occurring in a specified order, even if in reality they overlap in time.

Sampling occasions can be *primary* or *secondary*. All individuals encountered on a *primary* sampling occasion are eligible for use in the analysis, including individuals identified for the first time. Individuals encountered on a *secondary* sampling occasion are eligible only if they are previously identified. Secondary sampling occasions include, for example, samples taken in areas or at times where conspecifics of other populations (other than the populations of interest) are also present.

The matrix entry J_{ij} takes the value 1 if individual i is eligible for sampling on sampling occasion j, 0 otherwise.

2.2 Sampling probability

Let p_{jk} denote the probability that an eligible individual in state k is sampled on sampling occasion j. The entries p_{jk} typically depend on unknown parameters, whose values are to be estimated. Sampling probabilities that depend on unknown parameters are modelled using a complementary log-log-linear model:

$$p_{jk} = 1 - \exp\left(-\exp(\eta_{jk})\right) \tag{A.8}$$

where the values of η are unconstrained (can take any values from $-\infty$ to $+\infty$) and are modelled as linear combinations of unknown parameters:

$$\eta_{jk} = \sum_l D_{jkl}\beta_l \tag{A.9}$$

where the entries of the data matrix D are constants, usually 0 or 1.

2.3 Observed features

When an individual is sampled, features of the individual may be observed, depending on the nature of the sampling occasion. They are called *features* to distinguish them from the *attributes* defined in section 1.1. The observation of features is conditional on the sampling of the individual.

Some features may be observed deterministically. For example, with genetic capture-recapture, the gender may be determined with effectively 100% certainty once the genetic sample has been analyzed. Any gender bias that may exist in the chance of being sampled would be modelled through the sampling probabilities p.

The observation of some features may depend on probabilities. For example, if an animal is suckling a calf, the probability of seeing the calf when the animal is sampled may be appreciably less than 100%.

Let Q_{fjkl} denote the probability that feature f an individual in state k sampled on occasion j is observed to have level l. For each f, j, k we require $\sum_l Q_{fjkl} = 1$. For deterministically observed features, the corresponding entries of Q are 0 or 1. Where the probability Q depends on unknown parameters, a normalized log-linear model is used for Q:

$$Q_{fjkl} = \frac{\exp(\theta_{fjkl})}{\sum_l \exp(\theta_{fjkl})} \tag{A.10}$$

where the values θ_{fjkl} are unconstrained (can take any values from -∞ to +∞) and are modelled as linear combinations of unknown parameters:

$$\theta_{fjkl} = \sum_i G_{fjkli} \beta_i \tag{A.11}$$

where the entries of the data matrix G are constants, mostly 0 or 1. There is no explicit time-dependence in the entries of θ, but they may depend on sampling occasion and thereby on time.

2.4 Loss of identity

Loss of identity can occur if artificial or natural marks are lost. Effective loss of photographic or genetic identity can also occur if the study is continued by a new research group without the possibility for cross-matching with the previous records. Loss of identity of an individual is modelled by appearance of a new individual into the same state as the old individual ("cloning"), coupled with the simultaneous transition of the old individual into an unobservable "lost" state.

2.5 Data

The data consist of a list or catalogue of identified individuals and an associated sampling history of each individual. Associated with each occasion on which an individual was sampled is a list of observable features that were checked for that individual, and the recorded levels of each observed feature.

The meta-data include a list of sampling occasions and any relevant properties of those occasions, such as the time or the primary/secondary attribute, and the number and nature of observable features that were checked (for at least some sampled individuals) on that sampling occasion. Let $\mathcal{T}_j$ denote the time of sampling occasion j, and m_j denote the maximum number of observable features checked on that occasion.

The sampling histories form a matrix Y where Y_{ij} is 0 or 1 according to whether individual i was sampled on occasion j. The entries in the array K_{ijf} are 0 or 1 according to whether feature f was checked for individual i on sampling occasion j. The matrix L_{ijf} specifies the observed level of feature f for individual i on sampling occasion j, when that feature is checked, otherwise 0.

2.6 Likelihood

We distinguish between the trajectory likelihood and the parameter likelihood. The trajectory likelihood is the likelihood of a single individually-based population trajectory. The parameter likelihood is the sum of the likelihoods all possible trajectories given those parameters.

2.6.1 Trajectory likelihood

The trajectory likelihood is the product of the simulation likelihood and the data likelihood. The simulation likelihood is given by:

$$\Lambda_S = \exp\left(-\sum_{t=0}^{t_{\max}} \sum_{j=1}^{n} R_{0,j,t} \right) \prod_{i=1}^{N} \left(\frac{R(S_{\pi_i,\tau_i},\, S_{i,\tau_i},\, \tau_i)}{R(S_{\pi_i,\tau_i},\, 0,\, \tau_i)} \prod_{t=\tau_i}^{t_{\max}-1} R(S_{i,t},\, 0,\, t)\; T(S_{i,t}, S_{i,t+1},\, t) \right) \tag{A.12}$$

where τ_i is the year of birth or entry into the population of individual i,

The first factor accounts for the fact that N includes only individuals born or alive during the era of interest. The first sub-factor of the second factor ensures that the birth probability of each individual is included only once, even though it is an event in the life both of the parent and of the child.

The probability of the data collected on individual i at time t, given the state k of the individual at that time is given by:

$$\phi_{ikt} = \prod_{j:\, \mathcal{T}_j = t} p_{jk}^{\,J_{ij} Y_{ij}} (1 - p_{jk})^{J_{ij}(1-Y_{ij})} \prod_{f=1}^{m_j} Q(f, j, k, L_{ijf})^{J_{ij} K_{ijf} Y_{ij}} \tag{A.13}$$

where the first product sign is over the sampling occasions that occur in time step t. The first factor contains the probabilities that individuals are seen (captured) or not seen on each sampling occasion, while the second factor contains the probabilities that various features are observed on the occasions on which an individual is seen.

The data likelihood is then given by:

$$\Lambda_D = \prod_{i=1}^{N} \prod_{t=0}^{t_{\max}} \phi(i, S_{i,t}, t) \tag{A.14}$$

The trajectory likelihood is then given by: $\Lambda_T = \Lambda_S \bullet \Lambda_D$.

2.6.2 Parameter likelihood – large population approximation

The exact computation of the parameter likelihood as the integral of the trajectory likelihoods for the given parameter values is seemingly intractable. The model describes a hidden Markov process, which can, in principle, be solved by applying the forward-backward algorithm to the probability distribution over states (Eddy1996). However, the size of the population state space is approximately n^N, which is too large for computation of the probability distribution over states to be feasible.

An approximation to the parameter likelihood is obtained by computing the probability distribution over states separately by individual, on the assumption that population aggregates that affect the trajectory of an individual can be treated as independent of the state of the individual (the large population approximation). Population aggregates that affect an individual include, for example: (i) the breeding population, which drives the probability that an individual will be born in a given year; and (ii) the feeding population, which may have a density-dependent effect on the survival or reproduction probability of an individual.

Using the large population approximation, the probability distribution of the population state can be approximated by an independent distribution of each of N individuals over n states. This reduces the effective dimension of the state space from n^N to $n \times N$.

We take the notional individual $i = 0$ to represent unknown individuals, so that:

$$\phi_{0,j,t} = \prod_{l:\, \mathcal{T}_l = t} (1 - p_{lj}) \tag{A.15}$$

We define the array Φ_{ijt} recursively as follows:

$$\Phi_{i,j,0} = T_{0,j,0} \quad (0 \le i \le N^- \, ; \, 0 \le j \le n)$$

$$\Phi_{i,j,t+1} = \sum_{k=0}^{n} \Phi_{i,k,t} \, \phi_{i,k,t} \, T_{k,j,t} \quad (0 \le t < t_{\max}) \tag{A.16}$$

The probability of the observed data for a known individual *i*, summed over all possible trajectories consistent with those data is then given by:

$$\Psi_i = \sum_{j=1}^{n} \Phi_{i,j,t_{\max}} \tag{A.17}$$

assuming that no data are available for time $t = t_{\max}$.

The approximate log-likelihood for all individuals is then obtained by summing the individual log-likelihoods, treating them as independent:

$$\log\left(\Lambda_P\right) = \sum_{i=1}^{N^-} \log \Psi_i - E(N^-) \tag{A.18}$$

where the final term is the expected number of known individuals. It accounts for the large potential number of unknown individuals, each of which has a vanishingly small probability of being born and identified (Poisson limit of the binomial). The final term can be computed by:

$$E(N^-) = E(N) - \sum_{j=1}^{n} \Phi_{0,j,t_{\max}} \tag{A.19}$$

where:

$$E(N) = \sum_{j=1}^{n} \sum_{t=0}^{t_{\max}} T_{0,j,t} \tag{A.20}$$

2.7 Priors

Where probabilities are modelled using generalized linear models, each term in the model is an intercept term or a random effect term.

The prior for each parameter associated with an intercept term is chosen such that the prior for the corresponding probability would be uniform on [0,1] if the model only included that intercept term. Thus, the prior for an intercept parameter in the transition probability model (A.3) is $\exp(\zeta) \Big/ \left(1 + \exp(\zeta)\right)^2$. The prior for an intercept parameter in the sampling probability model (A.8) is $\exp(\eta - \exp(\eta))$.

The prior for an intercept in a feature observation model of the form (A.10) is $\exp(\theta) \Big/ \left(1 + \exp(\theta)\right)^2$.

The prior for a random effect term is $N(0,\sigma^2)$ where σ^2 is either estimated or fixed at 1. If σ^2 is estimated, then $\log \sigma^2$ has an $N(0,1)$ prior.

The use of proper (normalized) priors ensures that the posterior distribution of each parameter is normalizable.

Typically, the model for sampling probabilities will have at least an intercept term for each sampling occasion, while the remaining terms, if any, are modelled as random effects.

2.8 Fitting the model and model outputs

The primary output of interest is the posterior distribution of individual-based population trajectories. From this posterior distribution, posterior distributions of any population parameters of interest can be calculated. The posterior distribution of individual-based population trajectories is obtained from the prior distributions of parameters and the trajectory likelihood in the usual way.

The validity of the resulting trajectory posterior does not depend on the large population approximation. However, in order to enable reasonably efficient sampling of the trajectory posterior, the parameter likelihood is maximized as a first step, and an approximate posterior distribution of the parameter values is obtained using a quadratic approximation the likelihood. This approximate parameter posterior is then used for importance sampling of the trajectory posterior. A poor approximation to the parameter posterior would not invalidate the resulting trajectory posterior, but would reduce the efficiency with which it can be sampled.

The estimates of parameter values and their nominal variances obtained by maximizing the approximate parameter likelihood can also be used directly, but the interpretation of such parameter values is, in general, model-dependent. Furthermore, the nominal variances of parameter values derived from quadratic approximation to the likelihood can be rather inaccurate.

2.9 Model selection

Preliminary model selection proceeds using the large population approximation of the parameter likelihood. The model selection is based on the Akaike Information Criterion (AIC; Akaike 1973).

For model selection using the trajectory likelihood, the Widely Applicable Information Criterion (WAIC; Watanabe 2009) is used. The definition of the WAIC is:

$$\mathrm{WAIC} \;=\; -2\bar{L} \;+\; \mathrm{var}(L) \qquad \text{(A.21)}$$

where $\bar{L}$ is the posterior mean of the log-likelihood and var(L) is the posterior variance of the log-likelihood.

The WAIC does not depend on the notion of a parameter count, which is not well-defined for individual trajectories, because the discrete individual transitions do not correspond to continuous, real-valued parameters. The WAIC coincides with the AIC in cases were the latter is applicable (i.e. where all parameters are real-valued and unconstrained, and the log-likelihood function is quadratic). Although the formula for the WAIC is not explicitly dependent on the prior distributions of the parameters, the priors affect the posterior distribution of the log-likelihood and hence the value of the WAIC.

A disadvantage of the WAIC is that its computation is subject to sampling error, because it is computed from a finite sample of the posterior distribution of the likelihood. This can make it difficult to measure small differences in WAIC.

Annex O

Report of the Sub-Committee on Cetacean Stocks That Are or Might Be the Subject of Conservation Management Plans (CMPs)

Members: Walløe (co-Convenor), Urbán-Ramirez (co-Convenor), Al Jabri, Arguedas, Baker, Baldwin, Bell, Bjørge, Bickham, Brandão, Brockington, Brownell, Burkhardt, Collins, Cooke, Crespo, de Freitas, de la Mare, Doherty, Donovan, Double, Enmynkau, Ferris, Fortuna, Frey, Fruet, Funahashi, Galletti Vernazzani, Gonzalez, Greig, Haug, Herr, Holm, Hubbell, Iñíguez, Isoda, Jackson, Jelić, Johnson, Kato, Kim, Konan, Lang, Langerock, Lauriano, Leaper, Lee, Leslie, A., Leslie, M., Litovka, Long, Lovell, Lundquist, Mallette, Mattila, Minton, Morita, H., Morita, Y., Moronuki, Nakamura, Nelson, Øien, Palka, Panigada, Parsons, Pierce, Punt, Redfern, Reeves, R., Reeves, S., Rendell, Reyes, Robbins, Rojas-Bracho, Rose, Rosel, Rosenbaum, Rowles, Santos, Scordino, Simmonds, Slugina, Stachowitsch, Stimmelmayr, Strbenac, Suydam, Sutaria, Thomas, Van Waerebeek, Vermeulen, Wade, Weinrich, Weller, Willson, Zerbini, Zharikov.

1. INTRODUCTORY ITEMS

1.1 Convenor's opening remarks

Walløe welcomed the participants. This is a new sub-committee this year. It will consider stocks (with a focus on progress with scientific work and information) that are:

(1) the subject of existing CMPs; or
(2) high priority candidates for a CMP.

It will also consider stocks that have previously been considered as potential CMPs, recognising that the Commission has stressed the need for Range States to support any IWC CMPs. Items related to the stock structure and abundance of these stocks are considered by the sub-groups on SD&DNA and ASI.

1.2 Election of Chair and Co-Chair

Walløe was elected Chair and Urbán-Ramirez was elected co-Chair.

1.3 Appointment of rapporteurs

Johnson was appointed to act as rapporteur.

1.4 Adoption of Agenda

The adopted agenda is given as Appendix 1.

1.5 Review of available documents

The documents available for discussion by the sub-committee included SC/67a/CMP01-03, SC/67a/CMP05-15, SC/67a/HIM14, SC/67a/HIM17, SC/67a/Rep04, SC/67a/NH03, SC/67a/NH11, SC/67a/SM04, SC/67a/SM12, SC/A17/GW07 and Gagnon (2016).

2. STOCKS FOR WHICH CMPS ARE IN PLACE

2.1 Southeast Pacific southern right whales

2.1.1 New information

SC/67a/HIM14 presented information on the entanglement and stranding of a southern right whale in February 2017 in southern Chile (for details see Annex J). The whale was first seen alive with clear scars caused by entanglement in fishing gear and a large number of cyamids with an abnormal distribution. Ten days later, the carcass stranded and was examined, where examiners concluded that although no ropes or nets were found on its body, the pattern of the marks observed suggested that the whale had been entangled and this was among the main factors causing its death. This is the third entanglement reported in Chile since 1986 and the second in the last two and a half years raising concerns about the negative impacts of entanglement to the recovery of this endangered population. The authors suggested that actions are needed to prevent further entanglements.

The sub-committee **reiterated** its previous advice that efforts should be made to avoid anthropogenic mortality for this stock, noting that this was a priority action for the CMP (see below).

SC/67a/CMP13 reported on progress made between December 2016 to April 2017 on the acoustic monitoring of eastern south Pacific southern right whales, first discussed in Suydam *et al.* (2016). The project, supported by the IWC Scientific Committee in 2016, proposed the use of moored hydrophones to investigate the seasonal distribution along the coasts of Chile and Peru. Additionally, a best-case scenario could inform the presence of breeding grounds using reproductive vocalisations (e.g. the 'gunshot' type). The potential information to be gained is crucial to facilitate the implementation of the CMP long-term monitoring programme. To date, a steering group and supporting staff have been established, consisting of experts on acoustics and right whales and governmental representatives and currently available data were reviewed. Consequently, the programme decided to first prioritise expanding temporal and spatial coverage of passive acoustic data and secondly the securing of funding for a postgraduate student to analyse current and future data sets. The project was presented to the CMP international coordination meeting (see Item 2.1.1) and the governments of Chile and Peru committed to supporting it within their capacities. Selection of deployment sites, including identification of existing and available moorings, is pending. Future work will include the selection and acquisition of acoustic devices, planning of their deployment and recovery, data analyses and training.

The sub-committee **welcomed** this information and the progress made. It was confirmed that the primary goal of the programme is to identify breeding areas of southeast Pacific southern right whales and the secondary goal is to use acoustic recordings to inform vessel-survey effort. Historically, vessel-survey effort has been allocated according to previous sightings, a method that has met with limited success.

The sub-committee **commended** the effort being put into finding the breeding grounds. It looks forward to future results from not only passive acoustic monitoring, but all research regarding this population. Furthermore, the sub-committee **thanked** the authors for coordinating work that spans international boundaries.

2.1.2 Progress with the CMP

SC/67a/CMP09 summarised results of the first international coordination meeting to implement the eastern south Pacific southern right whale CMP, held 7-8 March 2017 in Santiago, Chile. During the meeting, a Memorandum of Understanding between Peru and Chile to formalise co-operation on the CMP was agreed upon, a Bi-National Steering Committee for 2017-18 was established, priority actions were reviewed, an implementation strategy was proposed and a second meeting was scheduled for March-April 2018 in Peru. Short-term priority rangewide actions included the identification of a breeding area; increased photo-identification and genetic data; increased capacity regarding entanglement response; increased species identification capacity, with special emphasis on southern right whales; advice on whale watching regulations and the development of a strategy to raise citizens' awareness and increase the capacity of involved range states. Medium- to long-term actions were also discussed, but given the current level of available information, they continue to be difficult to implement, and therefore, they were postponed. The Steering Committee also identified and developed a list of stakeholders, associated experts for specific topics, agreed upon a co-ordination and reporting system, established an agenda of implementation with clear deadlines (Annex 4 of SC/67a/CMP09) and reviewed possible funding strategies in addition to the contributions made by IWC and range states.

The sub-committee **welcomed** this update on the work being undertaken within the CMP framework and the progress on scientific components such as the acoustic programme discussed under Item 2.1.1. It **commended** the work being undertaken and the international co-operation this entailed. It **stressed** its willingness to assist and provide advice on scientific matters.

2.2 Southwest Atlantic southern right whales

2.2.1 New information

SC/67a/CMP01 reported on aerial surveys conducted to estimate the relative abundance of southern right whales from the mouth of Chubut River (42°30') to Puerto Lobos (42°), with long-term efforts to document temporal changes in distribution by age and sex classes. The surveys were carried out along 350 n.miles (620km) of coastline using high-wing single-engine aircrafts (*Cessna B-182*), flown at an altitude of 500ft. A crew of four (pilot, recorder and two observers, one on each side of the plane) were used to cover an effective strip width of 1,500m, where the distance to the coast from the left-hand side of the plane was held constant at 500m. Sightings were recorded as: (a) cow-calf pairs; (b) solitary individuals; or (c) breeding groups, which usually included one adult female and several males. A number of models for the data were explored within the GLIM framework using various explanatory variables. In summary, the authors concluded that the data supports the increasing trend in abundance for southern right whales in the Península Valdés nursing area, while the rate of increase is decreasing. Additionally, it was noted that the rate of increase for calves is much smaller than previously reported and that the numbers of solitary individuals and breeding groups are no longer increasing, suggesting that whales are relocating within and out of the Península Valdés area.

For the discussion of this paper, carrying capacity with respect to the Península Valdés nursing area was defined as the capacity of the area to support whales during the breeding season in terms of space. The authors noted that once whales reach 2.5-3.0 per km^2 they begin to increase in density in less optimal habitat along the coast. Of the 620km of coast surveyed, whales mainly concentrated themselves in three areas, two located in the Golfo Nuevo and one in Golfo San Jose, but it remains unknown why. Feeding has been observed and could play a role. A similar phenomenon, though with higher densities, has been observed in the Auckland Islands, where cow-calf pairs are mainly found inside a sheltered bay and concentrations outside of the bay are mostly comprised of juveniles or cows without calves and additional bays remain unoccupied. Logbooks from whaling data can provide information on where whales used to be, but shifts in distribution have been noted in other areas and for other species, and, at this time, it may not be a fruitful effort to attempt to determine why whales shift in their distribution. Additionally, it was noted that documenting whales in all areas is currently not possible because of less than ideal survey conditions off of the outer coast and additional logistical limitations. Satellite tagging was proposed as a method to overcome these limitations.

The sub-committee **welcomed** this work and **recommended** that the aerial surveys continue noting the importance of long-term monitoring and recognising the value of investigating changes in distribution in the context of environmental and other variables.

SC/67a/CMP06 summarised information on southern right whales in San Matías Gulf, Argentina, from data on their distribution, abundance and social structure. The study area encompassed 354km of coastline from Puerto Lobos (42°00'S, 65°04'W) to the mouth of Río Negro (41°02'S, 62°47'W), in the Río Negro province of Argentina. Whales were observed from August to October, peaking in late August-early September, every year since 2007 during the annual aerial survey, with a maximum of 160 individuals recorded in early September 2015. Solitary whales were always the predominant group, but the proportion of breeding groups and cow-calf pairs typically increased in September and October, respectively. Non-social, active groups were present in every month in similar proportions. Whales were mainly found near the northwest coast of the San Matías Gulf, particularly from San Antonio Este to Caleta de los Loros. Since 2008, the areas in which whales were found concentrated along the coast of Rio Negro changed from mainly around Puerto Lobos (near Península Valdés) to the northern coast of the San Matías Gulf.

The presence, or lack thereof, of kelp gulls in areas utilised by these southern right whales was also discussed. The current kelp gull population abundance in the San Matías Gulf was unknown, but has been increasing. However, kelp gull harassment has not been recorded in areas outside Península Valdés.

SC/67a/CMP08 presented information on opportunistic sightings of southern right whales on the Patagonian shelf and shelf break off Argentina during austral summer, along with satellite-telemetry data from whales tagged off Península Valdés following the Committee's recommendation (IWC, 2017b). Encounter rates in the Patagonian shelf between 42°S to 46°S were substantially higher than south of 46°S and in the shelf break, which is consistent with satellite-telemetry data and indicated a probable feeding ground. The authors suggested that dedicated research efforts within the Patagonian shelf be increased to assess habitat use, estimate the availability and seasonality of food and exposure to biotoxins, pollution and infectious agents along the migratory and feeding grounds.

Traditionally, southern right whales have been photographed using aerial surveys and how to compare these photographs to photographs taken from research vessels was discussed. The authors noted that photographs were being analysed and they welcomed future discussions on how to reconcile these with aerial photographs.

The sub-committee **welcomed** future photo-identifications of whales from this area. Additionally, the sub-committee noted the paucity of biopsy samples from this area and **strongly encouraged** the collection of such samples. The sub-committee also **encouraged** the use and exploration of platforms of opportunity for data collection and **commended** the use of such platforms to collect data on this population, for which little is known.

The sub-committee was updated on actions developed during June 2016-April 2017 in Argentina for the southern right whale CMP for the southwest Atlantic (detailed in Appendix 2). Activities were proposed and carried out to: (1) ensure long-term monitoring of abundance, trends and biological parameters; (2) enhance existing stranding networks including the capacity for undertaking post-mortem examinations; (3) research movements, migration routes and the location of feeding grounds; (4) develop and implement a strategy to minimise kelp gull harassment; and (5) develop a strategy to increase public awareness.

The report highlighted telemetry studies, addressing (3), in particular for whales wintering near Península Valdés. The tagging programme was developed by a large group of collaborating organisations including NOAA, Cascadia Research, Wildlife Conservation Society, Aqualie, Fundación Patagonia Natural, Instituto de Conservación de Ballenas, University of California Davis and Laboratorio de Mamíferos Marinos-Centro Nacional Patagónico. Between 2014-16 ten location-only and six archival transdermal satellite tags were deployed on individuals of both sexes and different maturity/reproductive stages in Golfo Nuevo, Province of Chubut, Bahía San Antonio and Province of Río Negro (Zerbini *et al.*, 2015; 2016). Duration of fully-implanted tags varied between 10 and 237 days (mean=90 days). Data showed substantial individual and yearly variation, providing new insights regarding habitat use and the potential for connections with additional habitat along the coast of Argentina during the breeding and calving season. For instance, some tagged whales visited the outer Patagonian shelf east of Península Valdés, Southwest Atlantic Islands and the South Atlantic basin between 38 and 58°S within the same season. Nevertheless, state-space models suggested that the Patagonian shelf and the subtropical convergence and the continental shelf break around South Georgia Islands/Islas Georgias del Sur were of potential importance for foraging. Additionally, investigations of movement patterns relative to environmental data indicated that whales may be using oceanographic features (e.g. eddies) at the Subtropical Convergence for foraging. Diving profiles indicated potential differences in habitat use between juvenile and adult whales. Future studies are planned to continue the investigation of movement patterns off Península Valdés, with the ultimate goal of understanding their large-scale habitat use in the South Atlantic Ocean.

In discussion, it was noted that although six viable hypotheses have been proposed to explain the recent mortality event, to date, results remain inconclusive. The use of blow samples from drone data collection schemes were suggested as a method to assess health. Additional analyses will be available in 2018 with respect to relatedness of stranded individuals using multi-locus genotyping.

The sub-committee **acknowledged** the importance of the relevant CMP, as well as **recommended** the continued cooperation and collaboration between all research groups and stakeholders to build the knowledge needed to address mortality issues present in this population. The sub-committee **recommended** continuation of the work to understand habitat-use, dispersal and migratory patterns at different scales, in connection to overall population demography. The sub-committee **recommended** continued exploration of methods to encounter and observe live calves prior to death and to gather individual health information on both cows and live and recently deceased calves. The sub-committee **recommended** that more work be done to elucidate the differences between nutritional stress imposed on calves induced from the inability of cows to feed and other types of physiological stress resulting from open wounds (e.g. electrolyte and fluid loss and thermoregulation), energetic expenditure related to avoidance behaviours, and other stressors experienced by whales. Methods to advance such knowledge should include stable isotope analysis, nutritional condition and lipid content analyses, population genetic analysis, oceanography surveys, assessment of biotoxin presence and distribution and the continuation of behavioural observations and satellite tracking.

2.3 North Pacific gray whales

2.3.1 Rangewide assessment

Donovan presented a summary of SC/67a/Rep04, the fourth rangewide Workshop on the Status of North Pacific gray whales held from 27-29 April 2017 in La Jolla, California. This series of workshops originated in the need to consider new telemetry and photo-identification results indicating that the 'traditional' idea of two separate populations in the North Pacific ('eastern' and 'western') needed re-evaluation. The 2017 Workshop's primary focus was to review new information and build upon the excellent intersessional work undertaken by Punt since SC/66b.

The Workshop reviewed the new genetic and photo-identification information presented in the light of the stock structure hypotheses developed at previous workshops. It welcomed updated information on the analyses of whole genome sequences and SNPs presented last year (DeWoody *et al.*, 2016) and news that additional studies were ongoing to compare samples from Sakhalin Island and Mexico. New photo-identification data for PCFG whales was presented and the Workshop encouraged the development of a manuscript (including examples from PCFG and Sakhalin whales) related to affiliative behaviour on migration and potential implications for stock structure. The Workshop also reviewed new information on mixing rates for PCFG whales for use in the modelling framework. An important component of the discussion related to how to develop and include time series of bycatch (and ship strike) data in the assessment. Considerable progress was made and an approach was developed to capture and investigate the effects of the considerable uncertainty in such estimates. The Workshop received new abundance information and this was referred to the ASI working group for discussion at SC67a. Based upon the new information, the Workshop agreed to take four stock structure hypotheses forwards: 3(a), 3(e), 5(a) and 5(b). These are illustrated in fig. 1 and summarised in table 1 of the Workshop report. The revised trial structure is provided in Annex E to the report.

The Workshop agreed on an extremely ambitious workplan to try and provide results for consideration at SC/67a, recognising that this may not be possible given the short time between the close of the Workshop and SC/67a and the other commitments of the relevant scientists. In concluding his report, Donovan thanked Punt for his tireless computing work and Weller and the Southwest Fisheries Science Center for once again providing excellent facilities.

Donovan noted that not all aspects of the Workplan could be completed and Punt summarised the progress made on the modelling aspects of the workplan since the Workshop. He noted that the model specifications and associated code had been updated to treat entanglements and ship strikes separately, and to calculate survival rates for PCFG animals separately for animals that joined the population before and after 1999.

As noted above, the Workshop had referred new abundance estimates to the ASI Working Group (see Annex Q). Their conclusions are summarised briefly here and the estimates are included in the final abundance table in Annex Q. SC/A17/GW05 reported on abundance estimates based on mark-recapture modelling of photo-identification data for the period 1996-2015 for the PCFG gray whales. The estimates were endorsed and accepted for use in assessments. SC/A17/GW06 summarises abundance estimates for gray whales migrating southbound off the central California coast between December and February 2014/15 and 2015/16, using the counting and analytical methods described by Durban *et al.* (2015). The paper provided two new estimates of abundance for a time series starting in the mid 1960s. While suggestions were made of potential improvements to the models, the estimates were endorsed and accepted for use in assessments. SC/67a/NH11 provided abundance estimates using mark-recapture modelling of photo-identification data from Sakhalin Island and Kamchatka. The analytical approach has been updated from previous analyses (see Cooke, 2016). The estimates were endorsed and accepted for use in assessments but it was noted that the code will need to be verified formally for use in assessments.

In discussion, it was noted that integrating the abundance estimates provided in SC/67a/NH11 into the modelling framework would require some additional work for the stock structure hypotheses that assume that the southern Kamchatka sub-area is used by more than one feeding group and/or breeding stock. Within this sub-area, the existing SC/67a/NH11 estimates pertain to whales that feed predominantly in the Sakhalin sub-area and those that feed predominantly off southern Kamchatka, but do not explicitly address what proportion of the whales that feed off southern Kamchatka could be part of ‘other’ groups (e.g. northern feeding group whales in hypothesis 3a or Western breeding stock whales in hypothesis 3b). A small group discussed the issue and, subsequently, reported back that a method to address this issue had been identified and that modeling results incorporating the SC/67a/NH11 abundance estimates will be reported at the next rangewide Workshop.

Results of SC/67a/NH11 also have implications for inferring the extent to which the Sakhalin or the combined Sakhalin and southern Kamchatka feeding groups are reproductively closed. However, the modelling framework is not explicit with respect to mating between groups, and thus further reconsideration of hypotheses in light of this information was not warranted.

In discussion of the approach used to estimate bycatches and ship strikes, it was also noted that the mixing rates used in the model were informed by data from northwest Washington, and that these data do not represent a random sample of the North American west coast. It was suggested that telemetry data can assist in providing some inferences on residence time (although not in a direct quantitative manner) as can photo-identification data although they are limited to sampled areas. Recognising the difficulties of modelling bycatch and the associated uncertainty, the sub-committee agreed that the three scenarios agreed upon during the Workshop represented a reasonable way forward.

The sub-committee thanked the convenors and participants of the Workshop, especially Punt, for their effort and diligence in producing a report in such a short period. It welcomed the progress made and endorsed the report of the Workshop and its recommendations. It noted the endorsement of the abundance estimates and recommended that a 5th Workshop be undertaken with a view to completing the rangewide review at the 2018 Annual Meeting.

The sub-committee recognised that the results of the Workshop are relevant to the updating of the CMP in time for the stakeholder workshop planned to occur before the 2018 Commission meeting that had been endorsed last year. To facilitate this work the sub-committee **recommended** that a small drafting group meeting be held. The sub-committee also recognised the importance of the rangewide work to the ability of the SWG on the AWMP (Annex E) to provide informed advice on subsistence hunts for gray whales.

In recent years as part of the rangewide review, the Committee has recommended and encouraged the sharing of gray whale samples to better understand the stock structure of North Pacific gray whales. Japan kindly indicated its willingness to share samples collected by its scientists if a formal request was submitted (IWC, 2017a, p.24). The Data Availability Group (DAG) received and forwarded a request from the USA to Japan asking for gray whale samples for use in a genetic study extending work that was presented to the Workshop for Sakhalin and US samples. The request is now being reviewed by Japan. This sub-committee noted that such cooperation and collaboration is also facilitated through the Memorandum of Cooperation (MoC) ‘concerning conservation measures for the western gray whale population’ among the participating range states. The sub-committee **encouraged** the range states of other CMPs to follow this positive example of a MoC, noting the similar step of Chile and Peru noted under Item 2.1.2. In addition, the sub-committee encouraged the Russian Federation to continue to collect photo-identification data (including in Chukotka; see Annex E).

The sub-committee looks forward to receiving papers detailing analyses that incorporate the data from Japan, Russia and the USA.

2.3.2 Regional studies

2.3.2.1 RUSSIA

The sub-committee has had long-standing co-operation with the IUCN Western Gray Whale Advisory Panel (WGWAP) and there is a joint IUCN/IWC CMP for western gray whales. Reeves summarised activities and findings of the WGWAP since SC/66b (see Appendix 3). The Panel’s Noise Task Force met twice and focussed primarily on follow-up work related to monitoring and mitigation during Sakhalin Energy’s 2015 seismic survey off Sakhalin Island and development of a monitoring and mitigation plan for another large-scale seismic survey in 2018. The full Panel met in Moscow in November. Among the issues addressed at that meeting were: (a) the implications of an apparent long-term decline in amphipod biomass in the Piltun gray whale feeding area; (b) a proposal by Sakhalin Energy to increase speed limits for its crew-change vessels; (c) risks to gray whales of entanglement in salmon nets along the north-eastern Sakhalin coast; and (d) a document prepared for IUCN and submitted to the Russian Ministry of Natural Resources and Ecology entitled ‘Principles and Guidelines for the Monitoring and Mitigation of Impacts on Large

Whales from Offshore Industrial Activity in Russian Waters'. The sub-committee thanked Reeves for this update. It noted that a recommendation regarding the updating of the IUCN/CMP is included in the work plan (see Item 2.3.1).

SC/67a/NH03 reviewed findings from 2016 field studies conducted by the Russia Gray Whale Project (formerly the Russia-US Program) on gray whales feeding near Piltun Lagoon in the western North Pacific off Sakhalin Island, Russia. This research program has been ongoing since 1997 and represents the 20+ year time-series that has served as the foundation for the assessments of the population (see discussion of SC/67a/NH11 above). Photo-identification research in 2016 resulted in the identification of 56 individuals, including six calves and seven previously unidentified non-calves. No previously unidentified reproductive females were recorded in 2016, resulting in a minimum of 33 reproductive females observed since 1995. The general distribution of gray whales in 2016 was notably different to that in 2015, with most of the whales encountered south of the mouth of Piltun lagoon. The authors noted that potential impacts from nearby offshore oil and gas developments, including nearly annual seismic surveying, remain a concern for the wellbeing of the population (see Appendix to SC/67a/NH02). Additionally, the coastal salmon trap net fishery, which overlaps spatially and temporally with feeding gray whales during the summer and fall, continues to present considerable risk (SC/67a/HIM17) as is evidenced by the report of an entangled whale in September 2016. This fisheries-related risk is of particular concern because adult females and their calves show strong fidelity to this feeding area at a critical time when the females are recovering from pregnancy and lactation and the calves are being weaned.

There was a general discussion of the information from the Sakhalin and Kamchatka areas including the results of SC/67a/NH11. It was noted that the site fidelity of newly identified non-calves was confirmed to be relatively high. These newly identified individuals are typically assumed to be whales that were missed as calves rather than immigrants. In the model described in SC/67a/NH11, these animals enter the model with a probability distribution for their age depending on the current dynamics of the population. Cooke reported that future analyses will look at the model output to see which group new non-calves are predominately found within. It was suggested that biopsy samples from Kamchatka could provide valuable information to clarify the situation in this region. Additionally, it was suggested that survey work in the Kamchatka region be continued to determine if, for example, some individuals spend significant periods of time there in the summer and autumn feeding season and others just pass through.

The sub-committee commended the ongoing work in the region and recommended that studies in the Kamchatka area continue and if possible expand as they can provide valuable information for analyses regarding stock structure and status. The sub-committee noted the discussion of SC/67a/HIM17, discussed by the HIM sub-committee (see Annex J), that reviewed the available evidence of gray whale entanglements in the western North Pacific and reviewed the literature on gear types used in the Russian Far East that are known or suspected to catch gray whales. The Committee has previously expressed concern over the potential threat of fishing gear off Sakhalin (IWC, 2017a, p.38).

The sub-committee has recommended in the past that the two groups working off Sakhalin (the Russia Gray Whale Project and the Joint Programme of Sakhalin Energy and ENL) work together to develop a single publicly available photo-identification catalogue. This will improve analyses of abundance, movements and biological parameters and lead to a better understanding of the status of the animals there. Donovan provided a short report on efforts to facilitate the development of a single catalogue and related database, perhaps held under the auspices of the IWC. The sub-committee welcomed this news and **strongly encouraged** Donovan to work with the various data holders to facilitate the development of a single reconciled catalogue and database. Furthermore, the sub-committee **reiterated** the importance of the work of the Russian Gray Whale Project and recommended that it continue.

The sub-committee recalled that there had been a major seismic survey effort at Sakhalin in 2015 (IWC, 2017a). It noted that considerable monitoring data had been collected by two of the oil companies involved to enable analyses of potential effects of the surveys on gray whales in the area. The sub-committee was given to understand that such analyses were underway and noted that it would welcome presentation of the results of those analyses at a future meeting.

2.3.2.2 JAPAN

SC/67a/CMP02 reported on the recent status of conservation and research on gray whales in Japan. During the period May 2016-April 2017, no anthropogenic mortality has been reported while two opportunistic sightings of gray whales were made in Tokyo Bay on 22 February and 18-23 April. The Fisheries Agency promptly informed individuals of the occurrence and cautioned responsible local authorities to avoid entanglements of the animal(s) in fishing nets and prevent ship strikes. Fishermen are prohibited from capturing gray whales and set-net fishermen are asked to make their best effort to release any whales found in their nets.

Sightings from Izu archipelago and Shizuoka prefecture from 2015 to 2016 were identified as involving the same individual (Nakamura *et al.*, In press). Additionally, it was noted that Kato (TUMSAT) had been nominated as the coordinator of the Memorandum of Co-operation for Conservation of Western Gray Whales at the 2016 IWC Commission meeting.

In discussion, an additional report (sourced on Facebook) of a gray whale seen and photographed off Aogashima Island, Japan was noted. Whilst the photograph was clearly of a gray whale, the sub-committee noted that confirmation of the location can be more problematic in such cases unless the original source is contacted.

The sub-committee **welcomed** the information and especially that of the sightings off Japan. It **encourages** that sighting information continue to be collected. This can provide helpful information on the age classes using waters near Japan.

2.3.2.3 EAST CHINA SEA

The question of whether a western breeding stock is extant has been a key part of the discussions and hypotheses considered during the rangewide review. At the 2016 Commission meeting, Gagnon (2016) reported on recent acoustic detections made by the US Navy of what have been tentatively classified as gray whales in the East China Sea. These detections have been made on numerous occasions over the last six years (2011-16) using towed hydrophone arrays in mobile, high-precision acoustic monitoring systems (Surveillance Towed Array Sensor System-Low Frequency Active Sonar - SURTASS-LFA). Vocalisations were detected on multiple occasions in multiple years and were consistent in structure across years. Calls consist of a 55 Hz pulse about 1s in duration, which has multiple harmonics (110 and 165Hz strongest) and the calls are typically repeated two or three times by the same individual. These calls have been detected annually in relatively shallow waters between September and March. The whales remain in the same general areas for weeks at a time, but have generally been observed to be moving south in the autumn and north in the spring. These acoustic data have not yet been accompanied by visual observations to confirm species identification.

The sub-committee welcomed this information and expressed its appreciation to the author and the US Navy for bringing it forward. The author has expressed his willingness to collaborate with biologists familiar with gray whale calls with the goal of verifying species identification. If it is determined with high probability that these are gray whale calls, it will be important to develop a dedicated field-research effort to verify species identification with visual observations, photographs and biopsies.

The sub-committee endorsed the recommendation from the rangewide Workshop (SC/67a/Rep04) that every effort be made, in the first instance, to determine with high probability that the calls are from gray whales. If so a dedicated field effort should be launched to observe, photograph and biopsy the animals.

2.3.2.4 MEXICO

SC/67a/CMP11 presented the results of gray whale research conducted in the wintering lagoon of San Ignacio and the Bahía Magdalena complex. Overall, the number of gray whales and their seasonal occupation of the lagoons were slightly lower than seen in previous years, and the authors thought that this was probably due to cooler sea-surface temperatures. Conversely, the number of single animals observed in the Bahía Magdalena complex was notably higher in 2017. A total of 646 individual whales where identified in Laguna San Ignacio and 374 in Bahía Magdalena complex. In recent years, photographic re-captures of gray whales first photographed in Bahía Magdalena and subsequently photographed in Laguna San Ignacio during the same year, suggests that the direction of movement occurs south to north. Females can bear calves up to an age of at least 47 years.

The sub-committee also considered SC/A17/GW07 which had been presented at the intersessional Workshop. It provided an update and overview of results from shore-based counts of northbound eastern North Pacific gray whale calves conducted March-June from the Piedras Blancas Light Station on the central California coast each year from 1994-2016. Estimates of the total number of northbound calves displayed a high degree of inter-annual variability, ranging from 254 calves in 2010 to 1,528 calves in 2004. Calf production has been particularly high during the past 5 years (2012-16) with a total of >6,500 calves estimated during this period, including four of the highest years (>1,000 calves per year) since these calf counts began in 1994. The 2016 estimate of calf production (1,351) is about 5% of the reported total abundance (26,960; SC/A17/GW/06) for the eastern North Pacific population in 2016. A trend in median migration dates was observed, indicating that the midpoint of the migration is now occurring about a week later than it did in the mid-1990s.

The sub-committee **welcomed** the results of this long-term study, as had the Workshop. It **reiterated** the importance of such studies, particularly in light of analyses of abundance and calf production in conjunction with environmental factors. Such analyses can provide general as well as specific insights on the population dynamics of whales in response to environmental factors. The sub-committee looked forward to receiving additional analyses of these data in future years.

2.3.3 Other studies

SC/67a/CMP10 presented a study of steroid hormones in gray whales. Using the ELISA method, progesterone and testosterone were reported from biopsies of 14 western gray whales from Sakhalin Island including 2 immature males, 1 adult male, 2 males of unknown life-stage, 2 immature females, 1 adult female and 6 females of unknown life-stage. Progesterone concentrations ranged from below the limit of detection (8.57pg/mL) to 0.21 ng/g. Progesterone levels in pregnant gray whales have not yet been determined, but the female western gray whale progesterone values detected were below those reported in some non-pregnant mature individuals of other cetacean species, and it is likely that the female western gray whales in this study were not pregnant at the time of sample collection. Progesterone detected in male western gray whales was in the range reported in male humpback whales and bowhead whales. Testosterone concentrations ranged from below the limit of detection (5.67pg/mL) to 1.36ng/g. The values reported here are in the lower end of values reported in pubertal and immature male short-beaked common dolphins. This study also investigated the use of a nanoLC-MS/MS method to determine progesterone, testosterone, hydrocortisone, and cholic acid (as a surrogate internal standard) in blubber samples from 3 stranded eastern gray whales. Progesterone concentrations were detected in two of the three samples and were higher in the adult female than in the adult male. Testosterone concentrations were detected in both male blubber samples with the adult male having a higher testosterone concentration than the juvenile male. Future development of this work will include the addition of biologically relevant hormones, such as estradiol and other glucocorticosteroids.

The sub-committee welcomed these analyses and looks forward to future analyses and further validation of the method, noting that future work should include consideration of how health can be monitored using such data. Additionally, it was recommended that collaboration with field biologists be initiated to combine the laboratory findings with metadata to provide more accurate estimates of animal age and reproductive stage.

2.4 Franciscana

2.4.1 New information

SC/67a/SM04 provided a preliminary report on a project funded by the Government of Italy to assess characteristics of fisheries in Franciscana Management Areas Ia and Ib, two areas thought to have the smallest abundance. They are geographically disjoint from all other areas and thought to be subject to high levels of bycatch. Interviews of 76 fishers were carried out between May to September in 2016 and in March 2017 to evaluate the type of fisheries and fishing gear operating in the area. Of those fishers, 54 claimed to know of franciscana, but only 9 could accurately identify them based on illustrations. Five of these fishers reported having historically captured franciscana in bottom-set and floating gillnets, but the authors were unable to assess the relative proportion of franciscana in reported bycatch because of the difficulty in identifying bycatch to the species level. The authors plan on conducting additional interviews, funded by fisheries monitoring, and providing these results to SC/67b.

In discussion, it was noted that, typically, most fishers are able to identify franciscana in the field and that the improper identification of the species from photographs may have been an artefact of the photographs that were used or that fishers chose to falsely answer the question in the interest of securing access to fishing within these areas.

2.4.2 Progress with the CMP

SC/67/SM12 reported on the beginning of the implementation of the franciscana CMP (IWC/66/CC11) funded by the IWC CMP Voluntary Funds and WWF. A Steering Committee was initiated including representatives from Argentina, Brazil, and Uruguay, IWC Conservation Committee Chair, IWC Scientific Committee Chair, IWC CMP Standing working group Chair and IWC Head of Science, coordinated by Iñíguez and supported by an established panel of experts. The two main objectives of the CMP are to protect franciscana habitat and to minimise anthropogenic threats (e.g. bycatch) to the population. Consequently, the CMP includes seven actions of high priority, ranging from initiating public awareness to increasing capacity for activities such as research and mitigation. Specifically, the need to reduce bycatch was included, and the authors suggested that research be performed to assess the degree to which pingers could reduce bycatch of franciscana in the Buenos Aires gillnet fishery.

In discussion, it was highlighted that Brazil will be providing 1 million dollars for research and conservation work according to the National Action Plan of Franciscana in management areas II and III. Additionally, the authors noted that although initial efforts were initiated in areas in which they currently work, in the future, work will be conducted in additional range states.

The sub-committee **commended** the breadth of work that has been undertaken towards franciscana research and conservation and noted that this CMP is the first for a small-cetacean species and **welcomed** the development of more in the future, as appropriate. It also **commended** efforts being made to coordinate research across international boundaries and **recommended** that this collaboration continue, despite the difficulties involved.

The sub-committee **recommended** that it should conduct an in-depth review of franciscana soon, given that the last IWC review of franciscana was performed in 2004 (IWC, 2005). The review should include new estimates of franciscana mortality, as previously recommended by the Committee. Such estimates are still unavailable for Management Areas Ia and Ib.

Finally, the sub-committee **concurred** with need to investigate the possibility that pingers are suitable to reduce bycatches of franciscana.

3. PROGRESS WITH IDENTIFIED PRIORITIES

3.1 Humpback whales in the northern Indian Ocean including the Arabian Sea

3.1.1 New information

SC/67a/CMP14 summarised reports of humpback whales in the Persian Gulf from 1883 to 2017. In total, five specimens were recorded, but no sightings. The first record, from Bassore Bay, Iraq, is currently on display at the Paris Museum and is the holotype for *Megaptera indica Gervais* 1883. The remaining records included an individual potentially killed from ship strike at the port of Doha, Qatar, an individual struck by a ship's propeller in Kuwait, a juvenile entangled in a gillnet at Qeshm Island, Iran and a juvenile found floating near Akhtar, Iran. Initially, reports were assumed to be of rare stragglers from the Arabian Sea population, however, as additional records were accumulated, the authors hypothesised that perhaps humpback whales are normal visitors to the Persian Gulf, if not resident. The authors recommended that increased efforts be allocated towards systematic surveys in the Persian Gulf region.

The sub-committee **welcomed** this information. It **concurred** with the authors that additional systematic research be conducted within the Persian Gulf area to characterise the residency of whales reported in this area.

SC/67a/CMP05 reviewed published records of baleen whales (including blue whales, Bryde's whales and humpback whales) in Pakistan and an ongoing observer programme implemented in 2012. Prior to 2012, knowledge of whales in Pakistan included a limited number of sighting and stranding records and whaling data (Mikhalev, 1997; 2000; Minton *et al.*, 2015). In 2012, WWF-Pakistan implemented a programme to train the crew of tuna gillnet vessels to document sightings, entanglements and bycatch. Vessels are provided with a digital camera and are encouraged to photograph humpback whales. The programme now includes 75 vessels, and hundreds of bycaught animals have been released alive, including one humpback whale. Three humpback whales were photographed in 2014, and there were two confirmed sightings in 2015 and 12 in 2016.

In discussion, it was noted that the data is part of a larger dataset used to document bycatch by the Indian Ocean Tuna Commission, and that up until now observer reporting within this dataset has been poor for all areas, with Sri Lanka being an exception. Additionally, the cetacean data is stored in the regional archiving system available from the WWF.

The sub-committee **commended** the amount of work that has been conducted, work which has led to the availability of a large amount of data where previously there was none. The sub-committee **recommended** that this work be continued and be replicated, where possible, throughout the region, especially in regions where it is not feasible to conduct cetacean surveys.

SC/67a/CMP03rev1 summarised records of baleen whales from the Indian coast of the Arabian Sea from 2001 to March 2017. Previously, data were available only from the west coast of India (Sutaria *et al.*, 2016). Humpback whales were reported along the west coast, with most sightings occurring between February and May. Additionally, undocumented sightings were reported near the India-Pakistan border. In March 2017, at least one vocalising humpback whale was recorded off the Goa coast, and in prior years, vocalising whales were recorded near the Netrani islands, off the coast of Karnataka, in Kochi harbour in Kerala, and in offshore waters from Malvan-Sindhudurg in Maharashtra (Mahanty *et al.*, 2015). The authors recommended that efforts be made to conduct dedicated baleen whale surveys in Gujarat, Maharashtra, Goa and Karnataka and for the establishment of passive acoustic monitoring along the northwestern coast from Porbandarto the Netrani Islands. Additionally, they recommended an increased collection of samples from stranded whales, the establishment of a centralised repository for tissue samples and the enhancement of collaborative efforts with local regional authorities to facilitate in-depth analyses.

The sub-committee **welcomed** the report and its value to better understand this endangered population. The sub-committee **recommended** that further emphasis be placed on using acoustic methods to document cetaceans in these areas and other areas, particularly areas that are not safe to survey. Additionally, the sub-committee **recommended** that all documented entanglements and ship strikes be entered into the IWC database and that an enhanced effort be made to archive any tissue samples that are or become available in a central repository. No tissue samples are currently available for humpback whales. The sub-committee **thanked** the Government of India, Maharashtra Forest Department and the local office of the United Nations Development Programme for their support of this work.

SC/67a/CMP12 reported on the continuation of Oman-based satellite telemetry studies initiated in 2014. Telemetry data from nine whales showed whales spending 35% of their time in the Gulf of Masirah and 27% in Hallaniyat Bay. During a two-week survey in March 2017 no humpback whales were sighted in the Gulf of Masirah and only two individuals were encountered in Hallaniyat Bay, neither of which were tagged. The authors updated the sub-committee on the increasing threats to areas of critical habitat and high cetacean biodiversity, including increased numbers of gillnet fishing vessels in Hallaniyat Bay. Shipping traffic in the Gulf of Masirah is expected to increase in the next five years due to new investment and the further development of the port of Duqm and associated industrial area. The port in Duqm has supported and is currently supporting a management and mitigation plan, but continued effort is required to ensure research inform such plans. The authors noted that recent stranding records confirm the importance of addressing bycatch in this area.

The sub-committee noted that there is no specific management plan for marine resources within the area, although some vessels did abide by voluntary speed recommendations. The port actively disseminates mitigation information. Additional mitigation plans were discussed, including the use of the 'Whale Alert' system to act as a whale and shipping collision avoidance system for the port and to also aid in the collection of whale sightings in the area.

The sub-committee noted that satellite tagging offers a method to collect cetacean data in areas that can be constrained by inclement weather and piracy. It **recommended** that the work be continued noting its value in understanding the risk of animals to anthropogenic mortality recognising the increasing shipping activity within the two areas that the whales inhabited. Lastly, it was **recommended** that the collaborative efforts with industry shown in Duqm be adopted in other ports and harbours.

SC/67a/CMP15 reported on the use of an Ensemble Ecological Niche Modelling approach to predict humpback whale habitat throughout the Arabian Sea using vessel-sightings data and satellite-telemetry data (using a state-space modelling approach) from Oman. Ensemble models of both datasets predicted areas of suitability along the coast of Oman and Northern Arabian Sea between Iran and India for November to May. Model predictions fit well with historical locations of Soviet whale captures from the 1960s and co-occur with areas of high vessel-traffic density in the Northern Indian Ocean where container-shipping traffic increased threefold between 2004 and 2014 (Willson *et al.*, 2016). Telemetry data provided the most robust source of data, but models could be improved upon by incorporating data from other range states. The authors recommended that this work, together with recent blue whale modelling work (Redfern *et al.*, 2017), could help guide future research activities and mitigation efforts in the region through the use of a multi-species modelling approach.

In discussion, it was suggested that other sources of available data such as acoustic data also be included in the model, where additional data could allow the model to estimate habitat preferences specific to behaviour modes.

The sub-committee **welcomed** the work, and highlighted the immense amount of effort that was put forward to carry out such an analysis. The sub-committee **recommended** that the ensemble niche modelling presented in SC/67a/CMP15 be expanded to include data reported from Pakistan and India and be used to inform future research efforts, particularly where to concentrate efforts for passive acoustic research and to help determine where vessel-based surveys for photo-identification and biopsy work should be prioritised, when logistically possible. Additionally, it was **recommended** that ensemble niche modelling be applied to examine potential threats from shipping using AIS/Vessel traffic data, and fishing using any available data on fishing effort in the region.

3.1.2 Regional co-operation

SC/67a/CMP07rev1 summarised the progress of the Arabian Sea Whale Network (ASWN), an informal collaboration between researchers and conservation bodies working toward better understanding and the conservation of whales in the Arabian Sea. The document summarised the 12 reports prepared for SC/67a by ASWN members and colleagues working in the region, including contributions from Oman, India, Pakistan, Sri Lanka and the Persian Gulf. This represents an increase in the number of reports, the breadth of topics and the number of range states represented from the Arabian Sea presented to this meeting, demonstrating concrete progress toward increased awareness, data collection and capacity building in the region. Most recommendations proposed in 2015 (IWC, 2016) related to improved communication, awareness raising and capacity building have progressed adequately (e.g. ASWN infographics), but the raising of funds for shared regional-level projects has been challenging and limited to funds granted by the IWC and WWF. Progress was also made towards the implementation of regional online data platform, funded under IWC SH3B, where a contract between the IWC and the Emirates Wildlife Society (EWS)-WWF, who will host the project, was signed in February 2017. Co-funding from WWF and the Environment Society of Oman enabled EWS-WWF to sign a contract with Flukebook (a subsidiary of WildMe) allowing photo-identification data from Oman to be included in the online platform starting in June 2017. A fully functioning data platform with expanded capacity to archive and analyse sightings, strandings and genetic data, as well as photo-identification data should be ready to share at SC/67b.

The sub-committee **commended** the work performed by researchers in the Arabian Sea, noting the expansion of research topics and recognising the difficulty of establishing and maintaining such a network, which it recognised as important for the conservation and management of this highly endangered population. The sub-committee **recommend** further development of the online regional data archiving platform to facilitate regional analyses and the comparison of data between study sites and the identification of locations conducive to passive acoustic monitoring to inform directed effort for documenting basin-wide distributions. The sub-committee also **recommended** that the IWC Secretariat communicate the Committee's endorsement to the relevant range states. Lastly, the sub-committee repeated last year's **recommendation** to collect tissue sample where possible to facilitate the genetic identity of these animals.

3.1.3 Progress with international measures such as CMPs

The sub-committee was provided an update from the intersessional working group assigned to consider proposing the Arabian Sea as candidate for a CMP. To date, the working group has been unable to secure endorsement from range state members. Therefore, working group members initiated the regional ASWN as a way to build momentum

Table 1

Summary of the work plan for the sub-committee on Conservation Management Plans (CMP).

Item	Intersessional 2017/18	2018 Annual Meeting (SC/67b)
Southeast Pacific right whales	-	Review progress on scientific aspects of the CMP
South Atlantic right whales	-	Review progress on scientific aspects of the CMP
Gray whales	Workshop; CMP drafting group	Complete rangewide review
Franciscana	-	Prepare for in-depth review
Humpback whales in the northern Indian Ocean	-	-

Table 2

Summary of budget requests for the 2017-18 period. For explanation and details of each project see text.

Title	2018 (£)
Fifth Workshop on the rangewide review of the population structure and status of North Pacific gray whales	2,500
Drafting group to finalise the scientific components of the updated IUCN/IWC CMP for western gray whales	3,000
Total	**5,500**

towards the development of a regional CMP and to directly promote conservation initiatives in the region (SC/67a/CMP07). The IWC Scientific and Conservation Committees recently reiterated the value of an Arabian Sea CMP for this species (see Item 10.3.3 in IWC (2017a). It was suggested that the Convention on Migratory Species (CMS) may offer an alternative means of achieving more regional and inter-governmental collaboration towards whale conservation in the Arabian Sea.

The CMS has introduced a new mechanism with which to designate the status of species or populations as ‘Concerted Action’ (see CMS Resolution 11.13 in Convention on Migratory Species, 2014). Efforts are underway to draft and complete a proposal to obtain this recognition for Arabian Sea humpback whales during the next CoP of CMS parties in October 2017. It would be valuable if the IWC collaborates on this effort, following the model of the joint IWC-IUCN CMP for western gray whales. Efforts are also underway to obtain support from the relevant range states for this initiative, which, as a joint IWC-CMS initiative, would include all Arabian Sea humpback whale range states.

The sub-committee **reiterated** its serious concern about its status of the endangered Arabian Sea humpback whale population and the anthropogenic threats it faces. It **stressed** the value of regional initiatives and **encouraged** range states to explore the possibility of future collaboration either through a CMP or CMS ‘Concerted Action’ and encourages IWC co-operation in these initiatives. Finally, the sub-committee **stressed** the need for continued scientific efforts to improve the knowledge of Arabian Sea humpback whales to assist conservation efforts.

4. UPDATE ON PREVIOUSLY SUGGESTED POTENTIAL CMPS

No new information was provided for the following populations: (1) blue whales from the northern Indian Ocean; (2) sperm whales in the Mediterranean; and (3) boto in Amazonia. Donovan reported that efforts are underway to develop a CMP for fin whales in the Mediterranean by ACCOBAMS following the IWC model.

5. WORK PLAN AND BUDGET REQUESTS

5.1 Work plan and intersessional groups

The sub-committee work plan and intersessional groups are found in Table 1 and Annex W.

5.2 Budget requests

The sub-committee **recommended** the following two requests for funding (Table 2).

6. ADOPTION OF REPORT

The Report was adopted at 16:45 on 16 May 2017. The sub-committee thanked Walløe and Urbán-Ramirez for their excellent Chairmanship.

Appendix 1

AGENDA

1. Introductory items
    1.1 Convenor's opening remarks
    1.2 Election of Chair and Co-Chair
    1.3 Appointment of rapporteurs
    1.4 Adoption of Agenda
    1.5 Review of available documents
2. Stocks for which CMPs are in place
    2.1 SE Pacific southern right whales
    2.2 SW Atlantic southern right whales
    2.3 North Pacific gray whales
    2.4 Franciscana
3. Progress with identified priorities
    3.1 Humpback whales in the northern Indian Ocean including the Arabian Sea
4. Update on previously suggested potential CMPs
    4.1 Blue whales (northern Indian Ocean)
    4.2 Fin whales (Mediterranean)
    4.3 Sperm whales (Mediterranean)
    4.4 Boto in Amazonia
    4.5 Topic-based or area-based CMPs (e.g. bycatch)
5. Work plan and budget requests
6. Other business
7. Adoption of Report

Appendix 2

SOUTHERN RIGHT WHALE OF THE SW ATLANTIC: AN UPDATE ON THE CMP ACTIONS IN ARGENTINA (2016-17)

M. Iñíguez, G. Caille, E. Crespo, V. Reyes Reyes, M. Sironi and A. Zerbini

The Conservation Management Plan for the southern right whale (SRW) Southwest Atlantic population was adopted in 2012 following the recommendations of the IWC and particularly considering the SRW die-off event in Península Valdés (PV) area, Argentina. This plan started to be implemented after the meeting held in 2013 in Buenos Aires (Thomas *et al.*, 2013).

The overall objective of the CMP is to protect southern right whales (SRW) habitat and minimise anthropogenic threats to maximise the likelihood that SRW will recover to healthy levels and recolonise their historical range.

This appendix summarises those actions developed in Argentina and related to the CMP for the period June 2016-April 2017.

ACTIONS

MON-01: Ensure long-term monitoring of abundance, trends and biological parameters

The Marine Mammal Lab of the Centro Nacional Patagónico (LAMAMA-CENPAT) conducted 65 aerial surveys between May 1999 to December 2000 and from June 2005 to November 2016. The results of its work support that the SRW population is still increasing in the nursing area around PV. In spite that the number of whales in the surveyed area is increasing, the rate is steadily decreasing. Density has been also increasing and whales have been expanding their distribution to deeper waters during the last decade, and mothers with calves are using the more protected areas near the coast. These responses are expected as density-dependence response to population increase (SC/67a/CMP01). It was also observed a geographic distribution change from the west to the north coast of San Matías gulf, especially in areas with high-quality habitat. Mother-calf pairs, breeding groups, non-social active groups and solitary individuals were observed in the area, the latter being the predominant group type along the entire coast (SC/67a/CMP06)

Aerial surveys of SRWs off the coast of PV were conducted in September 2015 and 2016 by the Instituto de Conservación de Ballenas (ICB) and Ocean Alliance (OA). The purpose of the surveys was to document the presence and distribution of SRWs along the perimeter of the Península

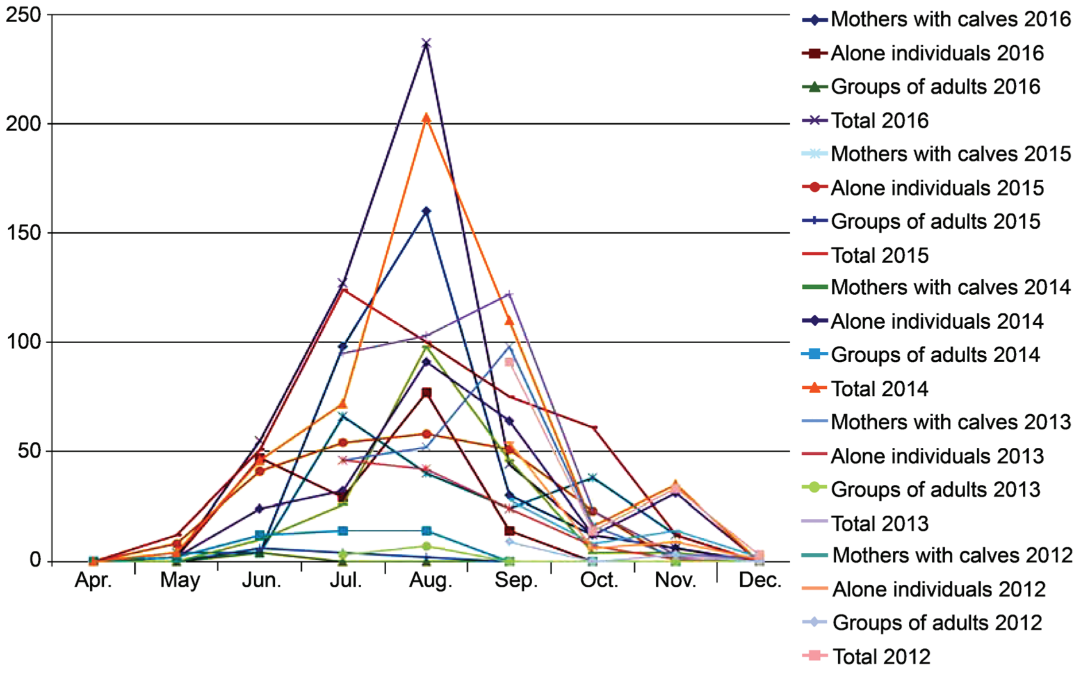

Fig. 1. Number of individuals (total and by category) registered for the 2012, 2013, 2014, 2015 and 2016 seasons.

Table 1

Analyses of photographs in the right whale catalogue of ICB/OA are available for the years 1970-2014. Number of individuals photo-identified: 3,100.

Date	Area	Mothers	Calves	Adults	Juveniles	Total
03/09/15	Golfo Nuevo	145	145	102	46	438
06/09/15	Golfo San José	48	48	8	7	111
06/09/15	Outer Coast	0	0	1	0	1
Total	**P. Valdés**	**193**	**193**	**111**	**53**	**550**
26/09/16	Golfo Nuevo	103	103	33	21	260
28/09/16	Golfo San José	57	57	7	3	124
Total	**P. Valdés**	**160**	**160**	**40**	**24**	**384**

by photo-identifying individuals from the callosity patterns on their heads and recording their locations and the presence of calves.

The following table summarises the basic results of the surveys each year.

Fundación Patagonia Natural (FPN) carried out 9 censuses on SRWs from the right whale observatory 'Punta Flecha', on the coasts of Golfo Nuevo (Chubut Province, Patagonia Argentina) in 2016. The total number of whales counted varied between a maximum of 237 individuals (24 August) and a minimum of 2 individuals (12 May) and 6 individuals (13 November). No whales were recorded in the first census (1 May) and in the last census (22 November). This seasonal data confirm that the months with the greatest number of SRWs, in the waters of the Golfo Nuevo front to the Natural Protected Area 'El Doradillo', cover July to September (3-4 months) and always with a predominance of mothers with calves.

MON-02: enhance existing strandings networks including the capacity for undertaking post-mortems

The Southern Right Whale Health Monitoring Program (SRWHMP) at PV began in 2003 with support from the US National Marine Fisheries Service. The Program is developing as collaboration between local NGOs, research centers, and governmental agencies. At present, the Program operates as a collaboration of the ICB, OA, University of California, Davis, University of Utah, Wildlife Conservation Society (WCS) and FPN, with funds from the member organisations and donations from private foundations and individuals.

Since its beginning in 2003, the Program has recorded 753 dead SRWs found on the shores of PV and surrounding areas, with an annual maximum of 116 dead whales in 2012 (McAloose *et al.*, 2016; Rowntree *et al.*, 2013; Wilson *et al.*, 2016). No other stranding research program in the world has documented such a high number of dead SRWs in one decade or created such complete database on the health of SRWs.

A Contact Network (CN) has been essential to the success of the Program. Members of the CN include: park rangers, fishermen, local people, whale watch companies, dive companies, tourism companies, nature guides, sailors, airplane pilots, artisanal fishermen, researchers, NGOs, and local authorities such as the Argentine Navy and the Argentine Coastguard. In addition to reports from the CN, the Program surveys the beaches in both gulfs in regions where the whales concentrate by land and air. Aerial surveys were opportunistic between 2006 and 2009, but have been systematic (minimum 6 and maximum 8 flights per season) since 2010. Regular aerial surveys encompass the entire perimeter of Golfo Nuevo and Golfo San José, and the external coast of the peninsula is added at least twice during the season.

In 2016, the Program studied and collected samples from a total of 16 stranded whales that died at PV and surrounding areas, including 14 calves (88%), 1 juvenile and 1 adult. The stranded whales included 9 females (56%), 6 males (38%) and 1 whale (6%) of unknown sex. Most whales (13) died in the southern gulf (Golfo Nuevo) followed by 2 whales in the northern gulf (Golfo San José) and 1 in Golfo San Matías, to the north of PV. They conducted post-mortem examinations on the stranded whales and when conditions permitted, biological samples were collected that will be analysed for infectious diseases, biotoxins, contaminants, nutritional

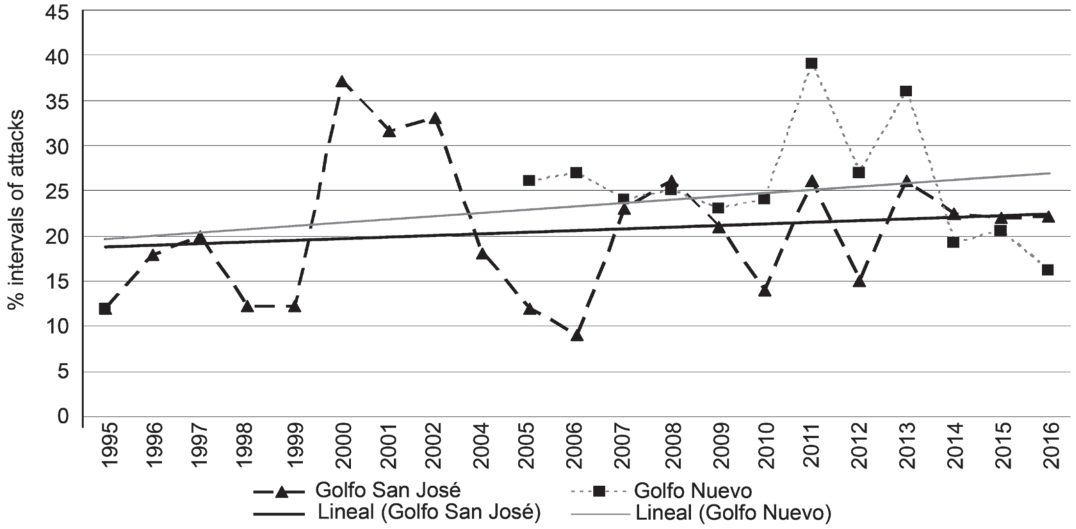

Fig. 2. Kelp gull attack frequency in Golfo San José and Golfo Nuevo, Península Valdés for the period 1995-2016.

status, foraging locations, diet, genetics, and other potential factors contributing to mortality. One live stranding was recorded in 2016: the individual in Golfo San Matías, which died after it, was found.

Among other observations and analyses, the Program's researchers quantified the number and size of kelp gull-inflicted lesions on dead whales through time to assess their potential systemic impacts on the whale's health and welfare. These data will help to develop and test novel diagnostic approaches to identify signs of stress, pain, dehydration and thermoregulatory effects of gull-inflicted wounds on whale calves. It is possible that increasing gull attack frequency and the level of physical and behavioural disturbance of SRW calves has reached a threshold in recent years that has led to the exceedingly high calf mortality levels observed between 2007 and 2014.

Two recent papers were published, Wilson *et al.* (2016) and McAloose *et al.* (2016).

RES-01: determine movements, migration routes and location of feeding ground(s)

Telemetry studies were conducted to assess movements and the location of the feeding grounds of whales wintering near PV. This project is developed by a large group of collaborating organisations including NOAA/Cascadia Research, WCS, Aqualie, FPN, ICB, University of California Davis, and LAMAMA-CONICET. Between 2014 and 2016, 10 location-only and six archival transdermal satellite tags were deployed in individuals of both sexes and different maturity/ reproductive stages in Golfo Nuevo, Province of Chubut, and in Golfo San Antonio, Province of Río Negro (Zerbini *et al.*, 2015; 2016). Duration of fully implanted tags varied between 10 and 237 days (average=90 days). Movement data provided new insights into habitat use within the gulfs and potential connections with other habitats along the coast of Argentina during the breeding/calving season. Migratory behaviour showed substantial individual and yearly variation. Tagged whales visited the outer Patagonian shelf east of PV and north of the Falkland Islands/ Islas Malvinas, the Scotia Sea near South Georgia Islands/Islas Georgias del Sur and the South Sandwich Islands/Islas Sandwich del Sur, and the South Atlantic basin between 38 and 58°S. In some cases, individuals visited these three regions within the same season. State-space models were used to estimate behavioural states and suggested areas of potential foraging importance in the Patagonian shelf (PS), the subtropical convergence and the continental shelf break around South Georgia Islands/Islas Georgias del Sur. An investigation of movement patterns relative to environmental data indicated that SRWs might be using oceanographic features (e.g. eddies) at the Subtropical Convergence for foraging. Dive profiles suggest potential differences in juvenile and adult whale habitat use and provide unprecedented information on diving behaviour of these animals. Future studies are planned to continue elucidating the movement patterns of PV SRWs with the ultimate goals of understanding their large-scale habitat use in the South Atlantic Ocean.

Line-transect visual observations were made by dedicated observers of Fundación Cethus on the Argentinean Shelf (including the PS) and shelf break during four surveys from two Argentinean Coast Guard's vessels used as platforms of opportunity: one in January, two in February, and one in December 2016. A total of 34 groups of SRWs were observed in the PS, totalising 58 individuals, and 4 groups in the shelf break, totalising 5 individuals, up to a depth of 970m. The highest encounter rate (ER) was estimated for the PS between 42° and 46°S in January. The estimated mean ER for the shelf was substantially lower than that from January in the northern area of the PS. Dedicated efforts of research within the PS should be made covering a wider area than already surveyed opportunistically including during different months of the year.

Since 2016 a systematic survey in Miramar, province of Buenos Aires, from April to November has been conducted by Fundación Cethus to establish the seasonality and habitat use of the species in the area. The peak of sightings occurred in August, with 194 whales, then declining towards November abruptly.

An aerial survey between Mar del Plata and Necochea to census and photo-identification SRWs was carried out. Thirteen whales in eight groups were sighted and many of them were photographed to create a SRW catalogue for the area.

MIT-02: develop and implement a strategy to minimise kelp gull harassment

Kelp gull (*Larus dominicanus*) attacks are a unique, increasing, and acute element of the life cycle of young SRW calves at PV. The physical injury of extensive gull lesions has been hypothesised to compromise the integrity and impermeability of a calf's surface layers and lead to dehydration, loss of thermoregulatory capacity, and an increased energy outlay to wound healing and metabolic stasis. Documented behavioural consequences of gull attacks include increased high energy reactive or flight behaviour and reduced time resting and probably nursing.

Researchers from the ICB and the OA have recorded the frequency of the attacks at different sites of PV annually since 1995 as a way to gauge the success of efforts to curb gull attacks. This is the longest database in the world on this parasitic behaviour (Maron *et al.*, 2015; Rowntree *et al.*, 1998; Sironi *et al.*, 2009).

ICB/OA monitored the attack frequency in September of 2015 and 2016. The following figure shows the annual frequency of gull attacks in Golfo Nuevo and Golfo San José since 1995.

A proposed hypothesis to guide the evaluation of the possible contribution of gull attacks to the ongoing calf mortality at PV states that 'high levels of harassment by kelp gulls that peck on a calf's exposed skin and then feed on the underlying blubber, cause significant physical injuries, energetically expensive avoidance behaviour, and reductions in suckling time. This syndrome may result in, *inter alia,* decreased food intake, increased energy expenditure, exhaustion, catabolism, dehydration, and thermoregulatory stress, with cumulative and cascading effects that can lead to calf death' (Thomas *et al.*, 2013). Gulls aim the vast majority of their attacks at newborn calves, which raises concerns about the impact that this parasitic behaviour has on the health and welfare of this highly sensitive age class.

Monitoring and controlling the gull harassment problem has become a joint initiative with NGOs and national research centers (CENPAT-CONICET) and government officials of Chubut Province.

Drone-derived measures of respiratory microbiome and girths: non-invasive indicators of right whale health

Understanding the relationship between health and environmental stressors is important for large whale conservation. However, robust measurements of health are challenging to acquire, but methodology to non-invasively assess the health of large whales is being developed. In 2015 we began a study to assess the health of SRWs at PV utilising drones to: (1) collect blow samples of the respiratory microbiome (the assemblage of microorganisms residing in the respiratory tract), which is the most common source of cetacean disease; and (2) acquire high resolution vertical images to assess body condition from girth (fat) levels and gull lesion markings. Using the drone APH-22 (Aerial Imaging Systems) with a high resolution still camera we took 1,220 vertical overhead images of 57 whales. The photographs will be used to take accurate measurement of length and width profiles for morphometric analyses, photo-identification and visual assessment of skin lesions. Using another drone (*Yuneec Typhoon/Tornado*) with sterile Petri dishes we collected 22 blow samples that were preserved in liquid nitrogen. Results of photographs and blow samples are still pending.

The study is a collaborative effort between ICB and the SRWHMP from Argentina and OA, Woods Hole Oceanographic Institution, NOAA SW Fisheries Science Center, and University of California, Davis from the USA.

PACB-01: develop a strategy to increase public awareness

On 20 and 21 April 2016 a responsible whale watching workshop was held promoting land-based whale watching in Miramar, province of Buenos Aires, as part of a joint project between Fundación Cethus and the Municipality of General Alvarado.

PROGRESS REPORT ON IUCN WESTERN GRAY WHALE ADVISORY PANEL (WGWAP) WORK FROM JUNE 2016 TO MAY 2017

R. Reeves, D. Weller, J. Cooke and G. Donovan

The Western Gray Whale Advisory Panel (WGWAP)[1], which is convened by the International Union for Conservation of Nature (IUCN), continued to provide advice to various parties, but particularly to Sakhalin Energy Investment Company (SEIC), concerning the gray whales that feed each summer off Sakhalin Island, Russia. Since SC/66b, there has been no major change in the Panel's composition and remit although a reduced budget has required scaling back the Panel's range of activities. Reeves and Donovan continue as Co-chairs and Cooke and Weller as members. IUCN and Sakhalin Energy have agreed to extend the WGWAP project for a third five-year tranche from 1 January 2017.

Three formal meetings took place between June 2016 and May 2017:

(1) 11th meeting of the Noise Task Force (NTF-11), November 2016 in Moscow, Russia;
(2) 17th meeting of the Panel (WGWAP-17), November 2016 in Moscow, Russia; and
(3) 12th meeting of the Noise Task Force (NTF-12), March 2017 in Gland, Switzerland.

Final reports of Panel and Noise Task Force (NTF) meetings are available on the WGWAP website. In addition, all recommendations made by the WGWAP and its predecessor IUCN western gray whale panels can be viewed on a searchable database[2].

The objectives of the 2016 and 2017 NTF meetings were: (1) review progress on analyses of data collected during the 2015 seismic survey; (2) receive updates on the proposed 2018 seismic survey and proceed with development of a Monitoring and Mitigation Plan (MMP); and (3) review non-seismic issues as time allowed. A major element of the NTF's work was a simulation analysis by Cooke of the implications of Sakhalin Energy's 2015 MMP to determine: (a) to what extent the mitigation measures contributed to reducing sonic exposure of gray whales; and (b) the effects on predicted exposure of the decisions that were made to relax certain measures that had been implemented in the company's 2010 seismic survey. The Panel recommended that Cooke carry out a similar analysis for the planned 2018 seismic survey once more details on timing, mode (streamer *vs* ocean bottom node) and other aspects are available.

The ongoing collaboration between the IWC and the WGWAP in 2016/17 led to further progress with model testing of gray whale stock identity hypotheses, updating and revision of scientific components of the IUCN/IWC Western Gray Whale Conservation Management Plan, and preparations for a western gray whale stakeholder workshop in early 2018.

Important new information was received at WGWAP-17 on gray whale observations in the western Pacific outside the Sakhalin feeding areas. There were reports of two dead gray whales in Japan in the spring of 2016 and a mother-calf pair of gray whales was photographed in Gizhiginskaya Bay (north-eastern Okhotsk Sea) in late June 2016. The Panel also received the report on acoustic data from the US Navy suggesting that small groups of gray whales are present annually in the East China Sea, moving southwards in the autumn and northwards in the spring that had been presented to the IWC Conservation Committee (Gagnon, 2016). Efforts are underway for independent confirmation of species identity by acoustic experts.

In its WGWAP-17 report, the Panel again emphasised the importance of regular updates to the population assessment and expressed appreciation for the work of the Russian Gray Whale Project (formerly the Russia-US Program), which has provided the long time-series of data used in Cooke's regular assessments. An updated assessment by Cooke is presented at this meeting (SC/67a/NH11).

The Panel expressed concern about an apparent long-term decline in amphipod biomass in the Piltun feeding area because of the implications for gray whale feeding. It recommended that the joint research programme of the two oil and gas companies (SEIC and Exxon Neftegas Limited) explore the nature and causes of this apparent decline in greater detail and provide a report on findings at the next Panel meeting.

In response to a proposal by Sakhalin Energy to increase the speed limit for its crew change vessels from 21 to 35 knots in areas outside the main feeding grounds, the Panel advised that from a conservation perspective, such an increase would be acceptable for a provisional period of 2 years, pending more refined estimation of the risk of ship strikes. The Panel recommended that within the provisional 2-year period, consideration be given to installing dashcams on each vessel that would monitor the sea surface area in front of the bows and that accelerometers be installed with continuous recording, or selective recording of large accelerations. The Company gave assurance that it would carry out the recommended monitoring to enable a risk analysis and also attempt to make the recommend installations on its vessels.

A collaboration between IUCN and the Project 'Mainstreaming Biodiversity into Russia's Energy Sector Practice and Policy' of the United Nations Development Programme (UNDP)/Global Environmental Facility (GEF)/ Ministry of Natural Resources and Ecology of the Russian Federation (MNR) resulted in a final document issued by UNDP titled 'Principles and Guidelines for the Monitoring and Mitigation of Impacts on Large Whales from Offshore Industrial Activity in Russian Waters'[3] for consideration by Russian authorities. This work was presented to Russian authorities immediately ahead of the November 2017 WGWAP meeting in Moscow.

Finally, the issue of gray whale entanglement in fishing gear continued to be a significant concern, as evidenced by a gray whale entangled in fishing gear (net and rope) sighted off Sakhalin in September 2016. An Associate Scientist (Vladimir Burkanov) was enlisted in 2016 to assist the Panel in preparation of a document for the attention of Russian fishery authorities and for submission to the Scientific Committee (see SC/67a/HIM17).

Whaling in Chukotka from 2013 till 2017

Sergei V. Zagrebelnyy

INTERNATIONAL
WHALING COMMISSION

Whaling in Chukotka from 2013 till 2017

Sergei V. Zagrebelnyy

Marine Mammals Laboratory Chukotka Branch of the Pacific Scientific Research Fisheries Centre (TINRO-Centre), 56 Otke Str., Anadyr', Chukotka region, Russia, 689000

e-mail: tinro@anadyr.ru

ABSTRACT

During 2013-2017, whaling in Chukotka was conducted by sea-hunters from 9 communities (14 whaling settlements), but whaling only by people from 4 villages (Lorino, Inchoun, Lavrentiya, Uelen), which makes over 70% of the whaling limit. For the last 5 years the average catch per year is 123 gray and 1-2 bowhead whales. The average size of the gray whales from 2013 to 2017 varies from 9.4 up to 10.9 meters for females and from 9.4 up to 10.6 meters for males. Mostly young females are currently whaled – annually females make up 52% to 69% of the slaughtered animals. Whales caught on Chukotka's Arctic coast are statistically larger (by more than 1 meter) and fatter (by 30%) than the whales harvested on the eastern coast. The natives population of Chukotka has risen by 11% (in 2010 - 17,900; in 2015 - 19,140 people) since 2010 and also considering the biomass of the harvested whales being currently almost 2 times less than it was in the 1980s-1990s, so the needs of local people are not met.

KEY WORDS: gray whale, bowhead whale, whaling, Chukotka, traditional use, harvest

INTRODUCTION

At all times and under all circumstances, harvesting of marine mammals guaranteed survival and cultural continuity for Chukotka's indigenous people. Whale harvest in Chukotka has, at least, two thousand years of history. Thanks to traditional fishing and the use of whales and other marine mammals, Chukotka's natives were able to survive the economic collapse caused by Russia's transition to a market economy. However, this transition adversely affected the structure of the whaling industry.

In the 1980s and early 1990s (during the Soviet period), whaling was an integral part of the unified Soviet economy and was organized through state farms. Whaling itself was done from whaling ships (for example, vessel «Zvezdny»). The average weight of a whale in that period was nearly 18 tons. From 1991 to 1995, the government support was reduced to a minimum, state farms ceased to exist, people organized whaling brigades and communities, and turned to traditional methods of whaling using small boats (whaleboats and canoes; fig.1). All this accounted for the decrease in the average weight of the harvested whales by half (up to 8-9 tons), which continued until the early 2000s (Litovka, 2008). And the total biomass of the harvested whales before the decline in whaling in the 1990s was 2.7 times bigger than the biomass of the currently harvested whales (fig.2).

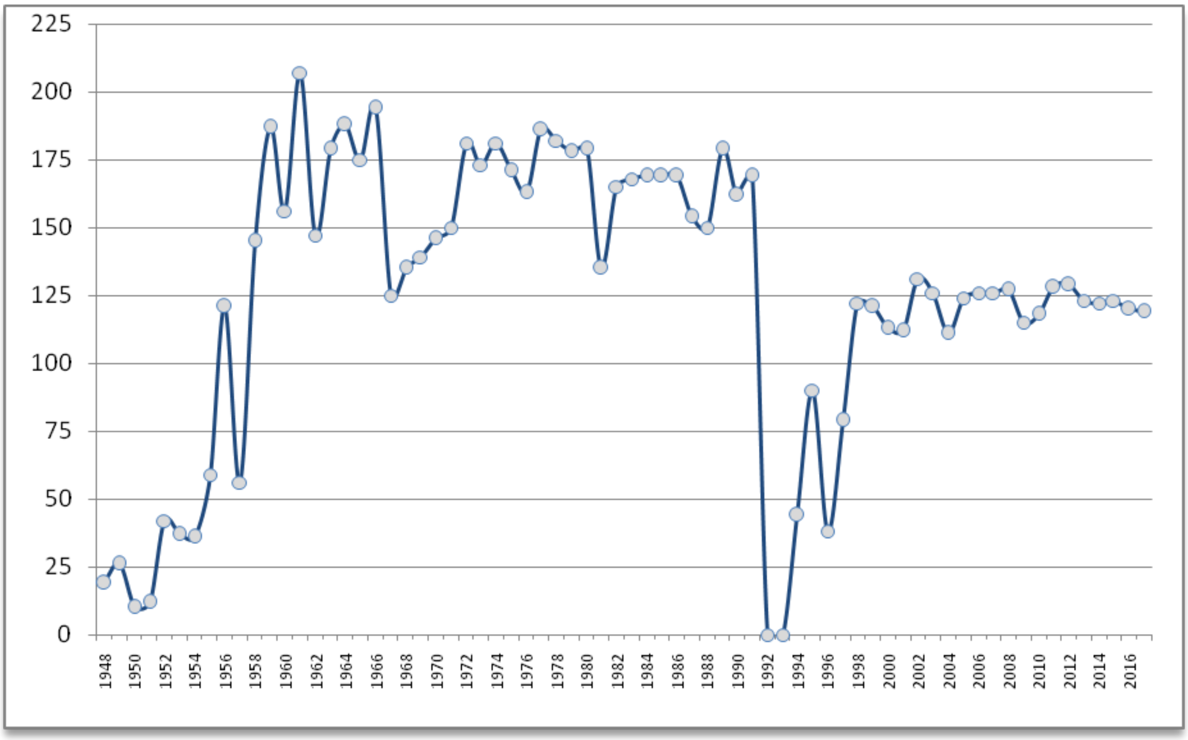

Figure 1. Total number of the harvested GW from 1949 till 2017

It is believed that the eastern (Californian-Chukchi) population of gray whales, inhabiting the Bering and Chukchi seas, has reached the optimum level. Despite this, the population size for as yet unexplained circumstances fell from 26,6 to 21 thousand individuals (Buckland et al., 1993; Gerber et al., 1999; Rugh et al., 2005; Blochin et al., 2011). According to the published data, the West-Arctic (Bering-Chukchi-Beaufort) population of bowhead whales is slightly more than 16,7 thousand individuals (Givens et al., 2013).

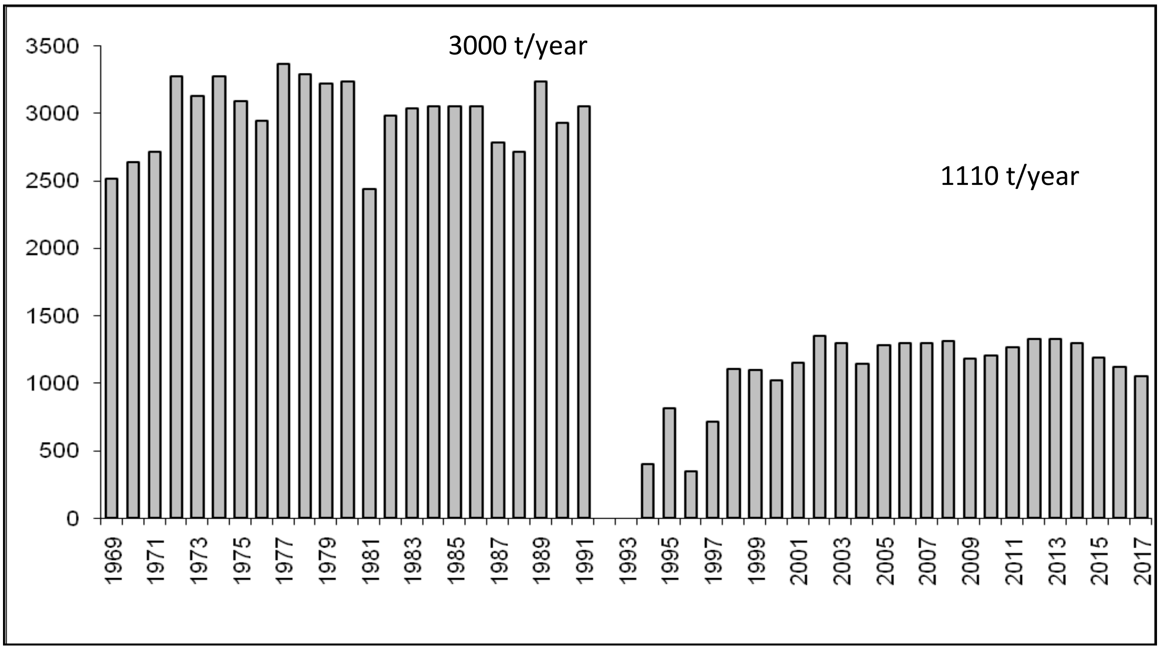

Figure 2. The total weight of the harvested gray whales

This is a total reserve of gray and bowhead whales shared by the Russian Federation and the United States. It serves as the basis for calculating the whaling ratio primarily to satisfy needs of Chukotka and Alaska’s natives.

In accordance with the decisions of the 65th Int.Whaling Commission’s session, the indigenous people of northern Russia (Chukotka Region) were given 6-year whaling quotas for the period of 2013-2018. The Russian share in the gray whales block quota is 135 heads per year (96.4%), 5 heads are given annually to the Maca tribe (Washington, USA). The Russian share of the bowhead whales is 5 heads per year (7.7%), and the US share is 60 bowhead whales. In total, Russia can harvest 720 gray and 30 bowhead whales within 6 years. As agreed by the Russian and American sites, it is possible to redistribute the quotas on gray and bowhead whales between them.

RESULTS

During 2013-2017, whaling in Chukotka region was conducted by sea-hunters from 9 communities (14 whaling settlements) in the traditional way: from canoes, whaleboats, and motor boats using rifles, American large-caliber darting guns, and rotary harpoons. Whaling was mainly done by people from 4 villages - Lorino (282 whales were caught during 5 years), Inchoun (60 whales), Lavrentiya (58 whales), Uelen (50 whales), which makes over 70% of the whaling limit. The other 10 settlements hunt from 1 to 7 animals per year each (fig.3).

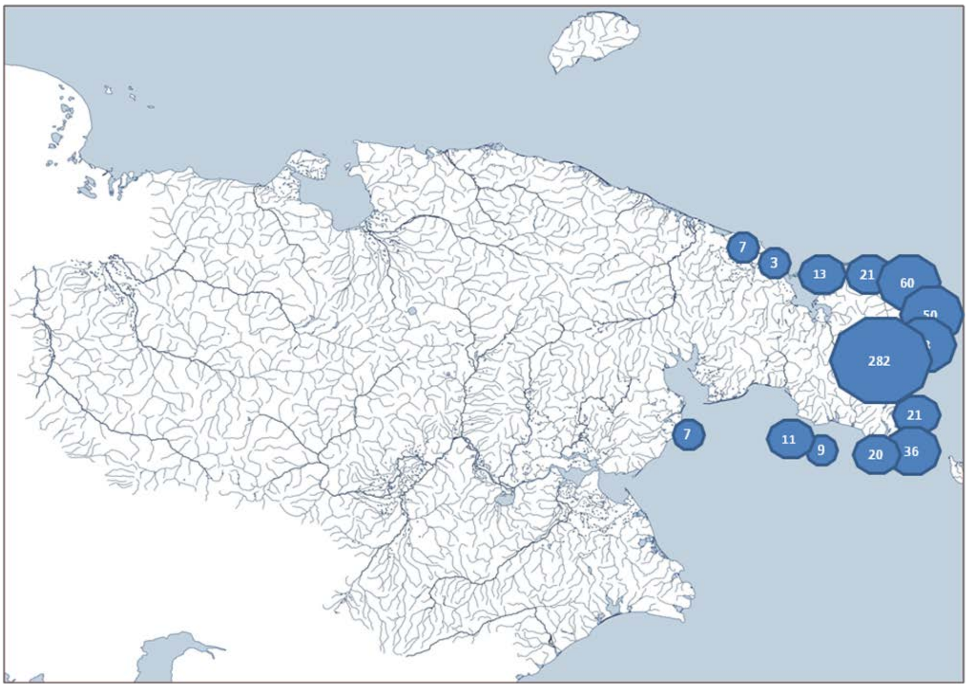

Figure 3. Gray whale harvest level

Until the early 1990s, more than 175 gray whales were harvested annually. For the last 5 years, it has been allowed to catch no more than 135 gray whales every year. Nevertheless, the average catch per year is 123 gray and 1-2 bowhead whales (not every year).

The annually harvested animals are mostly from 8 up to 10 meters long (fig.4, 5). The average size of the gray whales from 2013 to 2017 varies from 9.4 up to 10.9 meters for females and from 9.4 up to 10.6 meters for males.

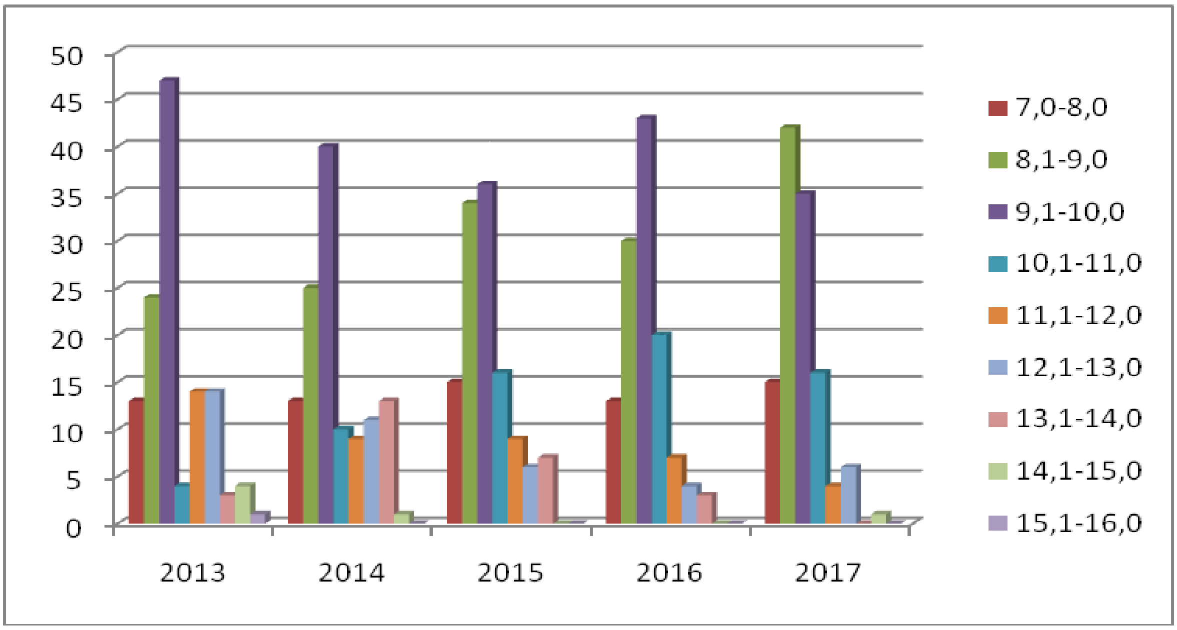

Figure 4. Length of harvested Gray whales

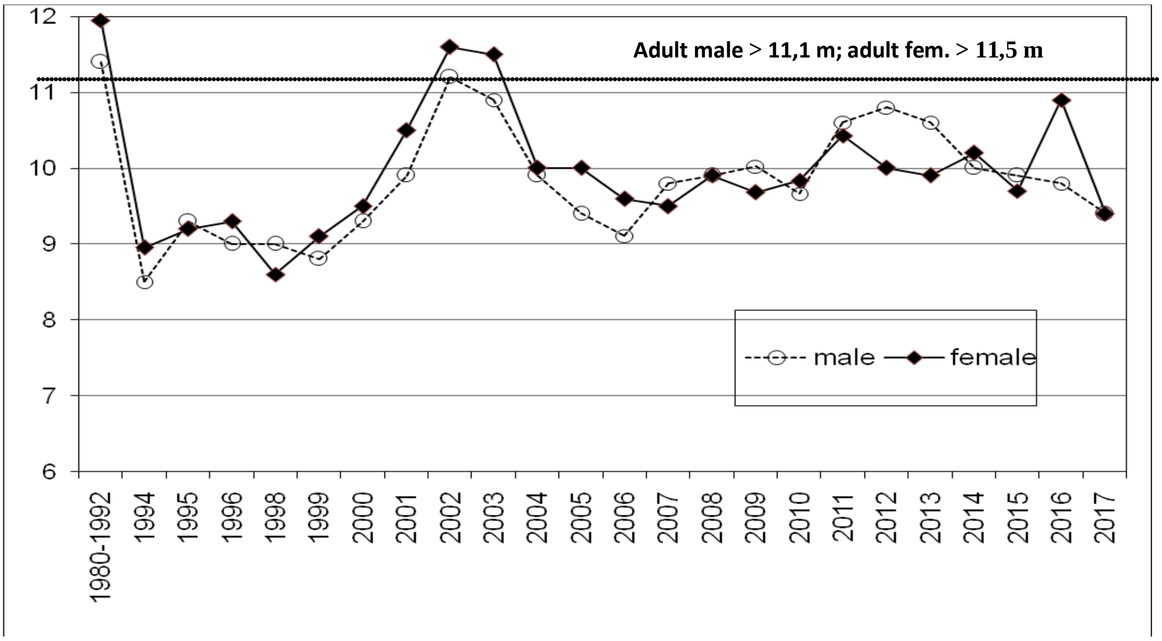

Figure 5. Average length of harvested gray whales

According to the data mentioned above, mostly young females are currently whaled – annually females make up 52% to 69% of the slaughtered animals. Adult animals (larger than 11 meters) constitute only a small part of the catch (fig. 6), and animals larger than 13-14 meters are rare (due to difficulty in whaling and transporting such large whales).

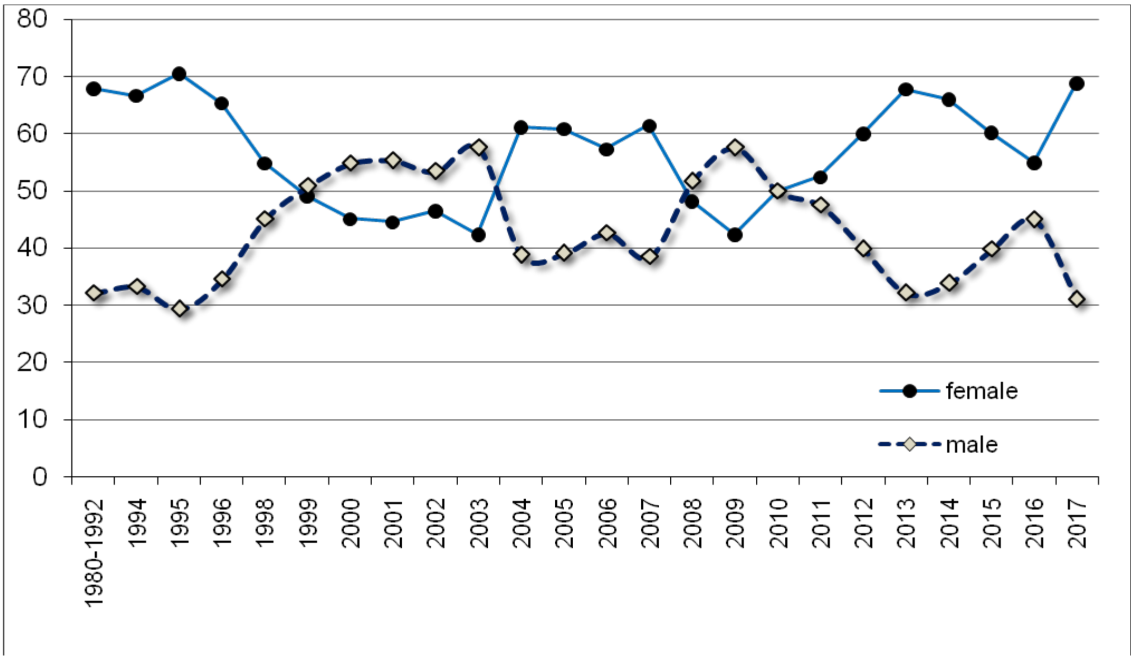

Figure 6. Sex ratio of harvested gray whales

Whales caught on Chukotka's Arctic coast are statistically larger (by more than 1 meter) and fatter (by 30%) than the whales harvested on the eastern coast (fig. 7). Probably, adult animals pass through the Bering Strait into the Arctic, and youngsters stay to feed near the eastern coast of Anadyr Bay.

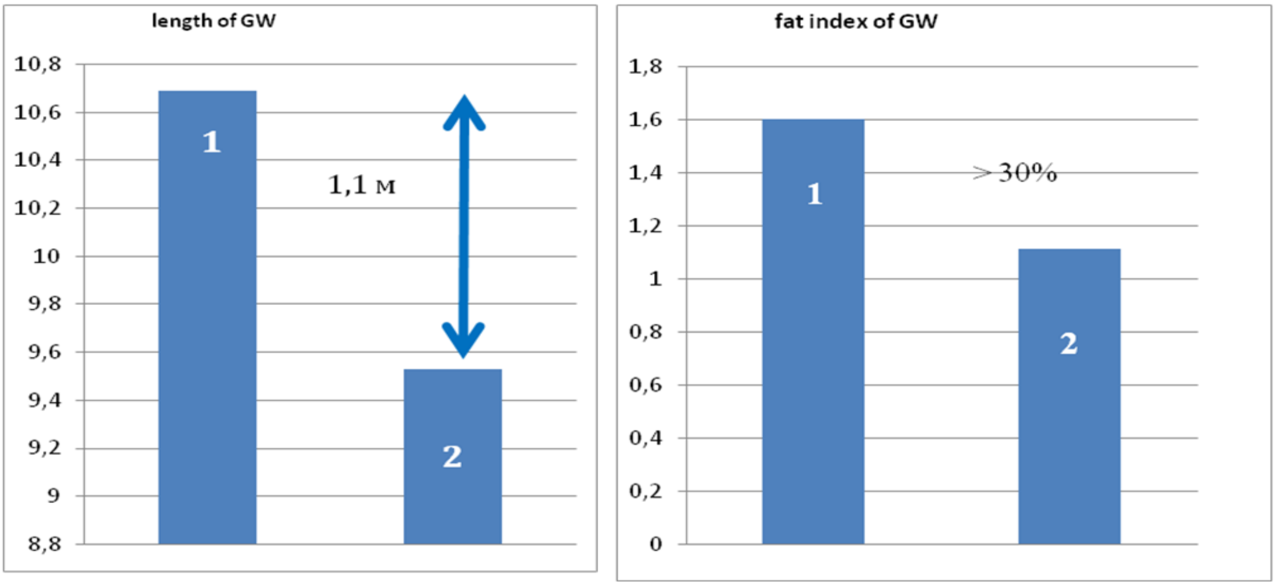

Figure 7. Average length and Fat Index of gray whales harvested in Arctic (1) and eastern shores (2) of Chukotka

Almost every year there are animals in the total catch of whales which are not taken into account in the quota (or subsequently excluded from the catch). These are animals lost due to aggressiveness or a sharp change in the weather during transportation of a whale ashore or because of their specific odor. In both cases, a relevant document is drawn (about the loss or disposal of the whale). From 2013 to 2017, five whales were lost and 4 harvested whales had specific odor.

From 2013 to 2017, four bowhead whales (2 females and 2 males) were harvested near Chukotka, mainly in Anadyr Bay. The average size of the whales was 14.5 meters (minimum 13.0, maximum 17.0 meters).

SUMMARY

- Despite planned whaling being over approximately 25 years ago, hunters continue to catch small, immature grey whales;
- basically immature female whales are harvested which suggests sex and age-based segregation of the grey whales group during the summer-fall period in the western Arctic;
- the size characteristics of the whales harvested on the Arctic coast of Chukotka are higher than of those caught on the eastern coast of the same region. It is quite possible that more mature whales migrate to the Arctic via the Bering Strait compared to those remaining in Anadyr Bay although we do not exclude the possibility of our mistake;
- the current grey and bowhead whales harvesting in Chukotka is below a maximum of the sustainable level recommended by the IWC Scientific Committee for both whale species. The natives population of Chukotka has risen by 11% (in 2010 - 17,900; in 2015 - 19,140 people) since 2010 and also considering the biomass of the harvested whales being currently almost 2 times less than it was in the 1980s-1990s. That is why subsistence needs of aboriginal population are not satisfied.

ACKOWLEDGEMENTS

We are grateful for the support and assistance provided by the Department of Natural Resources Chukotka Governments and members of the indigenous communities also.

Dive Characteristics and Movements of Radio-Tagged Gray Whales in San Ignacio Lagoon, Baja California Sur, Mexico

James T. Harvey and Bruce R. Mate

Introduction

The study of baleen whale biology has traditionally relied on collected specimens or observations of individual whales for short periods of time. Continuous long-term observations of whale behavior and activities are infrequent because individuals are difficult to identify, can travel long distances underwater without detection, and may remain at the surface only for short periods. Recent radio miniaturization and attachment techniques have provided an alternative mechanism for continuous (24-hr) tracking of specific whales traveling great distances.

Gray whales, *Eschrichtius robustus*, are excellent subjects for the attachment of radio tags because they travel near shore and may occupy confined embayments during

ISBN 0-12-389180-9

winter. These animals tolerate large numbers of epizoic organisms and thus appear to be adapted to foreign objects in the skin. Additionally, in the breeding and calving lagoons of Baja California Sur, Mexico, some "inquisitive" gray whales can be closely approached (Gilmore, 1961). Gray whales, however, are less than ideal animals for radio-tagging studies because they rub against the seafloor while feeding and against each other during mating and raising of the young, thus increasing the chances of displacing an attached tag.

Recent studies of gray whales in Baja California have been conducted in Ojo de Liebre and Guerrero Negro lagoons (Rice *et al.*, 1981), San Ignacio Lagoon (Swartz and Cummings, 1978; Swartz and Jones, 1979, 1980, Chapter 14, this volume) and in Bahia de Magdalena (Norris *et al.*, 1977; Chapter 15, this volume). These studies did not concentrate on dive and surface patterns. Previous tagging efforts with gray whales involved the use of belly bands attached to restrained calves (Norris and Gentry, 1974) and a radio tag surgically sutured to a captive yearling (Evans, 1974; Sweeney and Mattsson, 1974).

The purpose of our study was to collect long-term information on the dive and surfacing characteristics and local movements of individual radio-tagged gray whales in San Ignacio Lagoon, Baja California Sur, Mexico.

Methods

San Ignacio Lagoon (26°50′N, 113°10′W) is a relatively small protected area and offers the possibility of closely approaching "inquisitive" whales, those which approach boats and often allow themselves to be touched. Two camps were established to monitor the activities of tagged whales. The base camp was located approximately halfway up the eastern shoreline of the lagoon, and the second camp was placed on Bronaugh Point on the north shore of the lagoon entrance (Fig. 1). The lagoon was arbitrarily demarcated from the ocean by a line between Bronaugh and Holcomb Points roughly approximating the position of the breaking surf.

The radio tag and its method of application have been described by Mate *et al.* (1983). The radio transmitters were 3.8 × 3.6 × 2.5 cm and transmitted pulsed signals between 148 and 149 MHz. Radio tags transmitted on one of six different frequencies with pulsed signals at one of six different rates. The tag was suspended from a tag applicator at the end of a 5-m pole; therefore, only whales within 3 m of the boat could be tagged. We only attempted to tag inquisitive whales because our previous experiences indicated it was difficult to closely approach other whales.

Tags were placed 1–2 m behind the blowhole on the middorsal line such that, at most surfacings, the tag's antenna was exposed and signals could be transmitted. Each tagged whale could be distinguished by its combination of signal frequency and transmission rate. A tagged whale could breathe without a signal being transmitted only when it raised its head vertically out of the water, which is a rare event.

From February 8 through March 20, 1980, radio-tagged whales were monitored

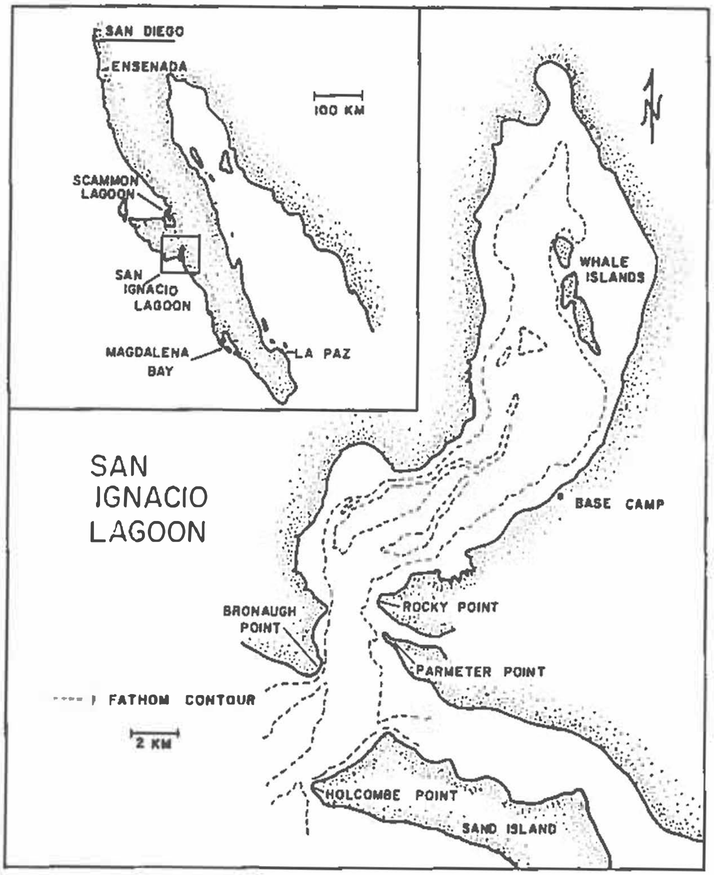

Fig. 1. *San Ignacio Lagoon, Baja California Sur, Mexico was the location of all tagging activities. A base camp and field camp at Bronaugh Camp were established to monitor radio-tagged whales. The lower lagoon was arbitrarily demarcated from the ocean by bearings originating from Bronaugh Point to Holcombe Point.*

from four platforms; base camp, Rocky Point, Bronaugh Point, and by boat. Rocky Point served as the monitoring location March 18–20 and Bronaugh Point was used from March 21 through the completion of the field season on April 29. At the base camp and Bronaugh Point, two 14-element yagi antennas were mounted perpendicularly to each other and separated vertically by 1 m on a 10-m mast. A switch box allowed reception from either antenna or both. Maximum reception range for these antennas was approximately 10 km. A direction finding (DF) antenna also was mounted on top of a 6-m mast and provided information on the bearing of the radio tags up to 10 km from camp. Handheld 2-element Yagi antennas and DF antennas were used for receiving signals while monitoring from boats. Each morning, afternoon, and evening, checks were made for tagged whales from the land camps. Weather permitting, daily boat surveys also were made to locate radio-tagged whales. During such times that a tagged whale was

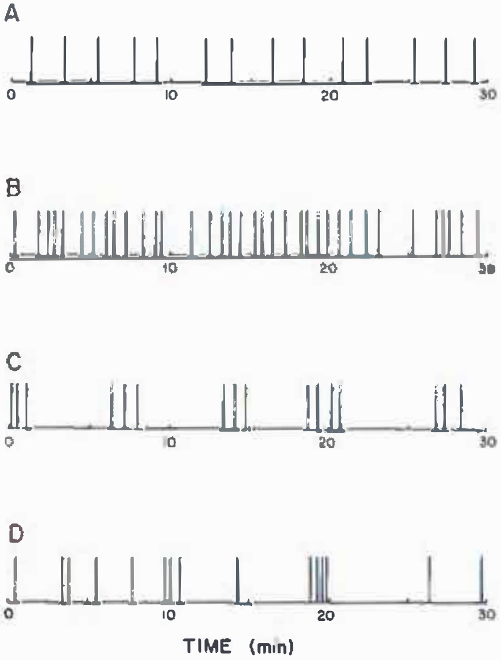

Fig. 2. *Examples of three dive patterns (from Whale 100R) which are typical of gray whales in San Ignacio Lagoon. (A) Regular–long, (B) regular–short; (C) clumped. The irregular or unpatterned dive series is shown in (D). Each vertical line represents a series of signals received when a whale surfaced.*

within monitoring range of the camps, nearly continuous data were collected on its activities.

As a whale surfaced, the times of the first and last signal received were recorded. Dive duration was defined as the time between the last audible signal during a surfacing and the first signal pulse upon resurfacing. Surface duration was defined as a period of continuous signal pulses. Relative signal strength was noted (strong, moderate, weak, or very weak). Records of very weak signals were not analyzed. The bearing of a tagged whale was determined approximately every 2 hr. Visual observations of tagged whales were made opportunistically from boats or 6-m observation towers at the shore camps.

Idealized diving and surfacing patterns were modeled (with the assistance of Fred Ramsey and Richard Hanlen) for each of three discernible patterns as a first-order Markov process, using transition matrices. The three patterns used were (1) "regular–long," regularly spaced dives greater than 1 min in duration; (2) "regular–short," dives less than 1 min in duration; and (3) "clumped," a long dive of greater than 1 min followed by two to six shorter dives of less than 1 min each (Fig. 2). W. Watkins (personal communication) has used the term "clustered" for a pattern similar to our "clumped." In addition, an irregular or unpatterned catch-all category was established for dives that did not fit the criteria of the other patterns. The dive pattern data were summarized from a series of seven dives at a time. A computer program calculated the probability that an observed series of dives fit a particular pattern by comparing the series of seven dives with the modeled, idealized dive patterns.

Results

DIVE AND SURFACE DURATIONS

Ten gray whales were radio tagged and tracked in San Ignacio Lagoon in 1980; three single adults (two females, one of undetermined sex) were tagged in early February, and the remaining seven whales were females with calves tagged between early March and mid-April (Table I). All remained in the lagoon at least 2 days. One female with calf (100R), tagged on March 19, lost her tag after 11 days (154.3 hr of monitoring). This animal was seen in the lagoon on 3 separate days subsequent to tag loss. Two other whales were monitored 4 and 5 days each during mid-March and early April. Seven of the tagged whales were later relocated along the Baja California and California coasts (Chapter 25, this volume), indicating that the tags had remained attached after the whales left the lagoon (Table I).

Duration of dives and surfacings were determined for radio-tagged gray whales monitored for a total 303.7 hr. Mean dive duration was 1.57 ± 0.02 min (SE) ($n = 11{,}080$ dives). Fifty-one percent (5,651) of these dives were less than 1 min duration, and 99% (10,969) were less than 6 min (Fig. 3). The mean dive duration for 5,455 dives longer than 1 min duration was 2.71 ± 0.03 min (Table II).

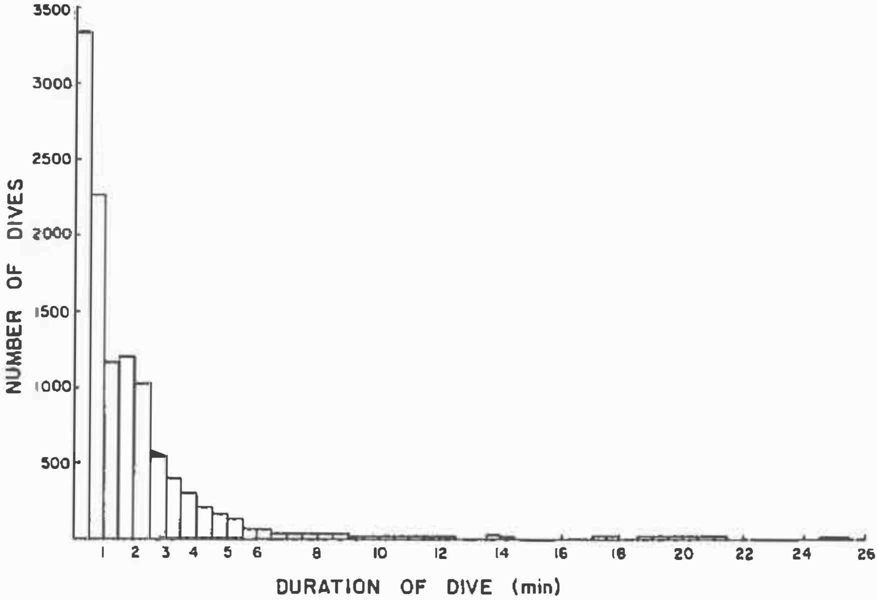

Fig. 3. *The frequency of distribution of 11,080 dive durations from 10 different radio-tagged whales monitored for 303.7 hr in San Ignacio Lagoon. The mean is 1.57 ± 0.02 (SE) min.*

	147.3[a]	7.15	140.15	5580	1.51	4.9

[a] Does not include 7 hr of data collected during periods of less than 10 min duration.

Mean dive durations for individual whales ranged from 0.96 to 2.58 min with a maximum dive duration of 25.88 min (Table II). Means for dives longer than 1 min ranged from 2.27 to 5.74 min. Whale 100R, for which we have the most data, was monitored for 154.3 hr and had a mean dive duration of 1.51 ± 0.02 min. Mean daily dive durations for 100R ranged from 1.14 to 1.66 min (Table III). The mean dive duration for single whales (50Y, 80Y, and 160Y) was generally longer than that of females with calves. No significance was attached to these data because a model is currently being generated to analyze the skewed distribution of duration of dives.

The mean surface duration for all 10 tagged whales was 0.07 ± 0.01 min (or 4.4 ± 0.6 sec). The maximum continuous surface duration was 51.62 min (whale 80Y). Mean duration per surfacing for individual whales ranged from 0.02 min (whale 50B) to 0.50 min (whale 80Y) (Table II). Overall, tagged whales spent 4.5% of the time at the surface (i.e., percentage of total time monitored that the antenna was above the water's surface). The percentage of time spent at the surface varied from 1.5 (whale 140R) to 16.3% (whale 80Y).

The mean rate of surfacing for tagged whales was 35.6 ± 0.8 surfacings/hr (Table IV). These were quite variable among individuals and ranged from 19.4 to 62.5 surfacings/hr. Gray whales surfaced significantly more often during the day ($x = 37.1 \pm 1.3$ surfacings/hr) than at night ($x = 30.3 \pm 1.5$ surfacings/hr) [$t(.05, 200) = 4.33$, $p < .05$]. The variation in surfacing rate was great among all 10 animals, and mean surfacing rate was not significantly different between morning, midday, and afternoon (weighted ANOVA, $p > .05$).

SURFACING PATTERNS

Surfacing patterns were analyzed for tagged whales 100R and 120R. During 30.07 hr of analyzed surfacing patterns, whale 100R surfaced 1108 times. Forty-five percent of

Table V
Amount of Time and Number of Surfacings for Specific Surfacing Patterns from Two Radio-Tagged Gray Whales in San Ignacio Lagoon[a]

	Surfacing patterns				
	Clumped	Regular–Long	Regular–Short	Unpatterned	Total
Whale 100R					
Time in hr*	8.72	6.62	1.20	13.53	30.07*
Surfacings**	321	211	111	465	1108**
Whale 120R					
Time in hr*	7.94	8.34	1.59	21.85	39.72*
Surfacings**	368	284	134	869	1655**

[a] The total time and number of surfacings for each whale is in parentheses.
*Significant difference ($\chi^2 = 31.43$, $p < .05$).
**Not significant ($p > .05$).

the time (42% of the surfacings) the surfacings did not fit one of the previously described patterns (Table 5). The "clumped" pattern (Fig. 2) was most frequently observed for this whale: 29% (321) of the surfacings and 29% (8.72 hr) of the total time were represented by this pattern. The "regular–long" pattern was the second most common pattern, occurring 22% (6.62 hr) of the time and representing 19% (211) of the surfacings. The "regular–short" pattern occurred only 4% of the time (1.20 hr), or 111 dives.

Whale 120R surfaced 1655 times during the 39.72 hr analyzed for surfacing patterns. Forty-four percent of these surfacings fit into one of the three recognized patterns. The "regular–long" pattern of surfacings was recorded 21% (8.34 hr) of the time, and the "clumped" pattern occurred 20% of the time (7.94 hr). As with whale 100R, "regular–short" surfacing patterns were only observed 4% of the time (1.59 hr) (Table V). There was a significant difference between whales for the amount of time spent in each pattern ($\chi^2 = 31.43$, $p < .05$), but no difference was found for number of surfacings per pattern ($p > .05$).

LOCAL MOVEMENTS

Movements of three tagged females with their calves were monitored for the 4,5, and 11 days, respectively, that each pair remained in the lagoon vicinity after tagging. Female 120R and her calf were monitored for 4 days. They moved out of the lagoon during darkness (between 0100 and 0500) on two separate occasions, for 40 and 7 continuous hr, respectively, before returning to the lagoon. Whale 50R was monitored for 5 days in the vicinity of the lagoon; this whale moved out of the lagoon twice at 0100, for 2 and 8 hr, respectively.

The greatest amount of movement information was collected from whale 100R, who was monitored for 11 days. This whale and her calf went outside the lagoon on 7 occasions (Table VI). Six of these exits occurred in darkness between 1800 and 2300, and six of seven returns to the lagoon occurred during daylight. This whale moved out of

Table VI
Location and Activities of Whale 100R within the Vicinity of San Ignacio Lagoon[a]

[b] Movement out of the lagoon.

[c] Movement into the lagoon.

the lagoon against the tide 44% (three times) of the time. In general, there was no significant relationship between whale movements out of the lagoon and ebbing tides ($\chi^2 = 1.2$, $p > .05$).

Discussion and Conclusions

DIVE AND SURFACE DURATIONS

Wyrick (1954) and Evans (1974) reported maximum dive durations for migrating gray whales of 12 and 16.5 min, respectively. The maximum recorded dive duration for a gray whale tagged in San Ignacio Lagoon was 25.9 min. All dives longer than 12 min in the lagoon were associated with resting animals, typified by a whale floating at or slightly below the water surface for periods up to 51.6 min and then submerging for 12–26 min. These dive and surface durations are 2 to 250 times greater than those recorded for active whales and are not expected to be the same for traveling animals.

The average surfacing rates for tagged adult whales indicated a breathing rate of approximately 36 breaths per hr. Norris *et al.* (1977) recorded a breathing rate of 50 breaths/hr for one female gray whale with a calf in Bahia de Magdalena. Although tagged whales made from 16.0 to 67.0 surfacings/hr (Table IV), our large sample size of surfacings and the certainty of detection of tagged whale signals suggests that a breathing rate of 36 breaths/hr is representative of gray whale activities in the lagoon.

Surfacing rates and surface durations are useful statistics in developing sightability correction factors for surveys. Many factors affect the sightability of a whale, such as weather, area covered, speed of sighting platform, and whale species and behavior. One important factor in sightability is the amount of time a whale is visible; radio tags can be used to estimate this time.

Surfacing rates of tagged whales were generally consistent throughout the day. Lower surfacing rates (15–20 surfacings/hr) appeared to be associated with resting animals and not with animals actively diving for long times. Swartz and Jones (1980) reported a midday reduction in whale activity, based on movements of whales in front of their observation tower. Tagged whale activity was not reduced in the midday using surfacing rates as an index.

Radio tags attached to whales can provide information on their behavior. Long dive durations, extremely long surface durations, and low surfacing rates were observed for whales resting at the surface. Whale 80Y, which had the longest average dive duration (2.58 min) and lowest surfacing rate (18.6 surfacings/hr) was found to be resting for 7 of the 20 hours that this whale was monitored. Surfacing patterns for other whales indicated resting periods up to 4 hr duration. Short average dive and surface durations and high surfacing rates were indicative of directed swimming. Whale 50B swam at a moderate speed (4 km/hr) for 2 of 7 hr monitored; he/she had an average dive duration of 0.96 min and a surfacing rate of 59.3 surfacings/hr. In the future, additional visual observations of behavior with data collected from radio tags attached to whales may allow further correlations between whale behavior and signal patterns from tags. The signal patterns from radio tags on whales then may allow continuous collection of behavioral information day and night, in bad weather, and when the whale is out of view.

SURFACING PATTERNS

The clumped surfacing pattern described in this study has been documented for migrating gray whales (Wyrick, 1954; Gilmore, 1961; J. Sumich, personal communication) and for whales occupying the breeding and calving lagoons (Norris *et al.*, 1977; Swartz and Jones, 1979). The regular pattern, however, has not been previously reported. This pattern occurred approximately 20% of the time and was observed almost as frequently as the clumped pattern. The regular surfacing pattern was probably a consequence of the behavior associated with lagoon residency. Whales in the lagoon, especially females with calves, spent many hours milling within the lagoon oriented into the current and remaining fairly stationary or resting. The regular surfacing pattern may therefore be a product of this inactive period.

LOCAL MOVEMENTS

Swartz and Jones (1980) observed gray whale movements from a tower positioned at Rocky Point in San Ignacio Lagoon. They reported a preponderance of whales moving northward into the upper lagoon areas in the morning; the predominant direction of travel in the afternoon was southward toward the lagoon entrance. These observations were made approximately 6 km from the lagoon entrance, so the observors could not determine if the whales actually moved out of the lagoon. Our study supports their observations; radio-tagged whales generally left the lagoon during the night and returned in the morning hours. Swartz and Jones (1980) also found that gray whales moved with the direction of the tide, especially in the shallow upper lagoon. The movement of radio-tagged whales out of the lagoon did not significantly coincide with tidal flow. They did, however, move with more often than against the tide.

The reason for nighttime movements of gray whales out of the lagoon is not known at this time. Swartz and Jones (1980) suggested that aggregations of shrimp, which occur near the lagoon mouth at night, may provide a food source for whales. Examination of two stranded yearling gray whales in the lagoon did not reveal evidence of shrimp predation, however (J. Harvey, unpublished data).

LAGOON RESIDENCY

Tagged whales in general did not remain in the lagoon for extended periods of time. Seven tagged whales were later located by radio signals along the Baja and California coasts, indicating the tags had remained attached beyond monitoring periods in the lagoon. The short residence time for single tagged whales was expected, because single animals appear to be somewhat transitory and use the upper lagoon only infrequently (Swartz and Jones, 1979). The peak abundance of females with calves in the lagoon occurs from mid-March to early April (Swartz and Jones, 1980). The three tagged females with calves, which remained in the lagoon for the longest time, were tagged during this period. By April, whales begin to leave the lagoon and move northward. The last four whales tagged (April 9–14) left the lagoon after 1–2 days, presumably commencing their northward migration.

The short residence time in the lagoon and daily movements for many of the tagged whales suggest that there is a considerable turnover in the lagoon population. Estimates of whale abundance in San Ignacio Lagoon fluctuated between consecutive daily counts (Swartz and Jones, 1980). This implies that some whales may be continuously moving out of the lagoon while others replace them. Estimates of the total number of whales using a particular lagoon, therefore, cannot be made simply from visual counts. Further tagging studies may help in developing turnover rates, which will allow the number of whales using a lagoon to be calculated based on visual surveys.

Radio tags attached to whales can provide a large amount of information on whale behavior that can be very difficult or impossible to collect using other techniques. The potential data which can be gathered is expanded to include 24 hr (continuous) observations during bad weather and when the whale is out of visual range. The coupling of visual observations of whale behavior with reception of radio-tag signals can be used to develop profiles of surfacing behavior for whales throughout the day. Additionally, radiotelemetry can collect physiological and hydrographic data as long as the tags remain attached.

Dive and surface durations and surfacing rates may be used to calculate sightability correction factors for cetaceans. Knowledge of time spent at the surface and the rate of surfacings may provide better estimates of whale abundance.

Summary

Ten gray whales, *Eschrichtius robustus*, were radio tagged and monitored in San Ignacio Lagoon, Baja California Sur, Mexico, from February 9 to April 15, 1980. Mean duration of dive for individual whales varied from 1.0 to 2.6 min ($\bar{x}$ = 1.6 ± 0.02 min). Ninety-nine percent of the 11,080 dives recorded were less than 6 min and 49% less than 1 min in duration. The longest dive was 25.9 min. Tagged whales averaged 4.4 ± 0.6 sec at the surface per surfacing. Eight of the tagged whales averaged less than 2.9% of the time at the surface (range, 1.56–16.3%). The tagged whales averaged 35.6 surfacings per hr. Three surfacing patterns were documented (regular–long, regular–short, and clumped) which accounted for approximately one-half of all dive sequences analyzed for two whales. Three radio-tagged whales were monitored for 4, 5, and 11 days, and moved into the ocean on 2, 2, and 7 occasions, respectively. Most oceanic movements were at night and 40% were against the tide. Seven of the tagged whales did not remain in the lagoon for more than 2 days.

Acknowledgments

We sincerely thank B. Blakesley, N. Dimeo, R. Gillette, M. L. Mate, R. Sanchez, R. Starr, and M. Yoklavich for their fine work and good humor in the field. We appreciate the talents and contributions of O. Batdorf, D. Beaty, and staff of Telonics, Inc., R. Maiefski, and R. Moeller. S. Swartz, M. L. Jones, M. Symons, J. and S. Sumich, T. Starr, Fisherman's Landing, and H & M Landings provided logistical help, equipment, and ideas. We thank R. Brown, J. Sumich, S. Swartz, W. Watkins, and M. Yoklavich for reviewing the manuscript; F. Ramsey, R. Hanlen, and S. Shiboski for statistical consultation; and N. Brown for assisting in manuscript preparation. This work was carried out under a Mexican scientific research permit issued by the Departamento de Pesca. Funding was provided by the Bureau of Land Management, Outer Continental Shelf Program (Contract #AA-730-79-4120-0109), and the Office of Naval Research (contract #700014-79-C-004).

Abstract

Reactions of humpback whales, *Megaptera novaeangliae,* to the taking of skin biopsies and to associated activities were studied on one of their principal West Indies breeding grounds on Silver Bank (Dominican Republic). Results were in some cases different from those reported from a similar study of this species in a high-latitude feeding area. Almost half (44.1%) of 565 biopsied whales showed no immediate reaction to a hit, while a further 22.5% showed only low-level reactions. A total of 375 (87.8%) of 427 misses involved no reaction. Only one strong reaction was recorded. Behavior changes were recorded following 31 (5.5%) of 569 hits, and 18 (4.5%) of 404 misses. Evasive behavior related to vessel approach was exhibited prior to 72 (12.0%) of 598 hits and 100 (24.1%) of 415 misses. Mothers showed significantly fewer reactions to hits than other whales, and a similar frequency and type of behavior changes, although they tended to be more evasive before a shot was made. Presumed males in competitive groups also showed significantly fewer reactions to shots, and very few behavior changes. Overall, this study supports the belief that the biopsy itself has little effect on a whale and that, if the associated vessel approach is conducted with care, samples can usually be taken with minimal disturbance to the target animal. However, approaches may affect the probability of obtaining fluke photographs for individual identification.

Key words: biopsy sampling, genetics, humpback whale, *Megaptera novaeangliae.*

In recent years the application of molecular genetics to studies of cetaceans has produced significant insights into the biology and behavior of several species (summarized *in* Hoelzel 1991). Since such techniques potentially provide answers to questions that in many cases cannot be addressed by other means, they represent an invaluable investigative tool for studies concerning both the biology and conservation management of endangered species. Samples for such analyses are obtained in the form of either skin biopsies (Lambertsen 1987) or as sloughed skin left behind in the water (Whitehead *et al.* 1990, Amos *et al.* 1992, Clapham *et al.* 1993). Skin biopsies are typically taken using a dart fitted with a sampling tip and fired from a crossbow (Lambertsen 1987, Palsbøll *et al.* 1991).

Reactions to the biopsy procedure have been studied in three species of baleen whales. Brown *et al.* (1991) described reactions of right whales (*Eubalaena glacialis*) as minimal and short-lived, a characterization similar to that given by Mathews (1986) for responses of gray whales (*Eschrichtius robustus*). Weinrich *et al.* (1991, 1992) concluded that for humpback whales (*Megaptera novaeangliae*) in the southern Gulf of Maine a biopsy represented a momentary painful or surprising stimulus that typically caused only short-term behavioral disturbance. To date, no study of this type has been published for humpback whales in their breeding range. In this report we summarize data on the behavioral responses of North Atlantic humpback whales to approximately 1,000 biopsy attempts (both successful and unsuccessful) and associated vessel approaches made on this population's principal breeding and calving ground in the West Indies. This study provides further support for the belief that, if conducted with appropriate care, the biopsy procedure represents a minimal intrusion into the life of an animal and has no long-term effect on behavior.

MATERIALS AND METHODS

Study area and sampling methods—In February and March 1992, as part of the large-scale project known as Years of the North Atlantic Humpback (YONAH), several hundred biopsies were obtained from humpback whales on Silver Bank, a limestone platform reef off the Dominican Republic's northern coast. Silver Bank represents the most important mating and calving area for North Atlantic humpbacks (Balcomb and Nichols 1982, Mattila *et al.* 1989), with as many as two or three thousand individuals present during the peak of the season.

Biopsies were taken using a 68-kg draw crossbow and modified bolt fitted with a stainless steel sampling tip (similar to designs described in Palsbøll *et al.* 1991); the tip is 4 cm long with a diameter of 9 mm. Tips were cleaned thoroughly between each sampling event and were sterilized by immersion in ethanol. Darts were fitted with a 2.5-cm diameter stop to ensure recoil after penetration of the whale, and with flotation for easy retrieval from the water. A retrieval line was not used. Biopsies were preserved in a saturated sodium chloride solution with 20% dimethylsulfoxide as described by Amos and Hoelzel (1991).

Whales were approached for sampling from inflatable boats which varied in length from 4 to 5.5 m, and which were powered by a single 25-hp or 30-hp outboard engine. Each boat was crewed by a driver, a photographer, and an archer. Virtually all sampled whales were photographically identified using variations in ventral fluke pattern (Katona *et al.* 1980) and in the shape, size, and scarring of the dorsal fin.

Definitions and categorization of responses—In this report the term "sampling procedure" refers to the entire process of obtaining, or attempting to obtain, a

Table 1. Reactions of all whales to hits and misses.

	Total recorded	None	Low	Moderate	Strong
Hits	565	249	127	188	1
Percent	100	44.1	22.5	33.2	0.2
Misses	427	375	28	24	0
Percent	100	87.8	6.6	5.6	0
Total	992	624	155	212	1
Percent	100	62.9	15.6	21.4	0.1

skin biopsy from a humpback whale. This includes both the vessel approach and the firing of the dart from the crossbow. The firing event is referred to here as a "shot," and includes both hits (where the dart struck the target animal) and misses.

Reaction: the term "reaction" refers solely to the immediate response of a whale to a shot (whether hit or miss). Reactions were categorized hierarchically as follows: (1) none: the whale exhibited no observable response; (2) low: the whale reacted with either a brief startle (a flinch), or a quick submergence, or both; (3) moderate: the whale reacted with one or two tail flicks; or (4) strong: the whale reacted with multiple tail flicks and/or lateral tail thrashes, and/or with high-energy behavior. The latter was defined as one or more instances of a breach, a tail breach, a lobtail, or a flipper slap. This categorization is similar to that employed for a study of southern Gulf of Maine humpbacks by Weinrich *et al.* (1991).

Behavior change: while we were unable to allocate time to a standardized control period prior to vessel approach, observers attempted to categorize the behavior of target animals when first encountered in order to assess whether this behavior changed as a result of the sampling procedure; in all cases, behaviors were categorized by individuals having many years of experience with humpback whales on a breeding ground. A difference between the behavior recorded before a shot and that noted afterwards is termed a "behavior change." Changes from non-curious to curious behavior (in which the animal approached and investigated the vessel), or from evasive to non-evasive behavior, were classified as "positive." All other behavior changes (*e.g.*, from travel to evasive) were considered negative. We did not include fluking to non-fluking as a behavior change; this was dealt with separately (see below).

Because animals exhibiting evasive behavior prior to a shot would not have been classified as showing a behavior change if they remained evasive afterwards, we have also reported the number of cases in which evasiveness was observed before a shot was made, irrespective of the subsequent behavior. Because multiple approaches were sometimes made to the same animal, a behavior recorded *before* a particular shot was taken may also have *followed* a preceding shot. An evasive behavior is defined as that in which the animal actively attempted to move away from the vessel, or exhibited decreased surface time, or both. Evasive whales often dove for shorter periods than in pre-approach behavior; consequently, a whale exhibiting shorter dive times and other evasive behavior was recorded as evasive but not as also showing a shorter dive. Behavior changes described here as "shorter dives" or "longer dives" involved no evidence of evasion but simply a pronounced modification of previous diving behavior, defined as the dive time changing by five minutes or more.

Class definitions—In order to test whether group size or behavior role affected the reactions of whales to hits and misses, each animal was assigned to one of the following categories: singleton (a lone whale), member of a pair, member of a non-competitive trio, mother, calf, escort to a mother/calf pair, or participant in a competitive group. The latter category was further divided according to the whale's role within the group, according to definitions given by Clapham *et al.* (1992): Nuclear Animal, Principal Escort, Challenger, or Secondary Escort. Nuclear Animals are generally female, while other participants in competitive groups are invariably male (Tyack and Whitehead 1982, Clapham *et al.* 1992). The Nuclear Animal category does not include lactating females in competitive groups; these were classified as mothers for the purpose of analysis.

RESULTS

Reactions to shots—Table 1 summarizes data on reactions to a total of 992 hits and misses. Almost half (44.1%) of 565 biopsied whales exhibited no detectable reaction to a hit, while a further 22.5% showed only a low-level reaction. A total of 375 (87.8%) of 427 misses involved no reaction by the target whale. Only one instance of a "strong" reaction was recorded: this involved a Nuclear Animal who reacted with two tail flicks followed by several lateral tail thrashes, after which she resumed her previous behavior in the group.

Variation in reactions by class—Figure 1 shows the frequency of reactions of different classes to hits. Chi-square tests were used to test these differences. In general, mothers were characterized by fewer reactions than any other class; with the exception of Nuclear Animals, competitive group members were also notably less reactive to being struck than were other whales (except mothers). Specific results were as follows ($\alpha = 0.05$, df = 2 except where noted):

(1) Competitive group members reacted significantly less to being struck than all other classes combined ($\chi^2 = 11.386$, $P < 0.005$), but significantly more than mothers ($\chi^2 = 11.599$, $P < 0.005$, Nuclear Animals excluded). Within competitive groups, Nuclear Animals reacted significantly more than Principal Escorts, Challengers, and Secondary Escorts ($\chi^2 = 18.071$, $P < 0.001$). Pairwise comparisons of the latter three categories revealed no significant difference (df = 1) in reactions. The reactions of Nuclear Animals were not significantly different from those of singletons, pairs, trios, escorts and calves, combined.

(2) Mothers reacted significantly less to being struck than all other classes combined ($\chi^2 = 46.025$, $P < 0.001$), and less than all other classes excluding Principal Escorts, Challengers, and Secondary Escorts ($\chi^2 = 70.814$, $P < 0.001$).

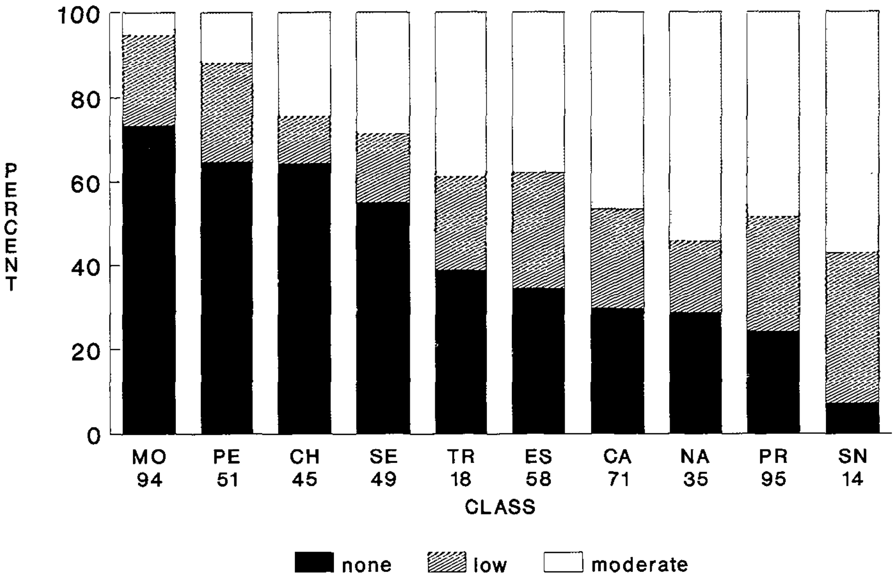

Figure 1. Reactions of different classes to hits. Abbreviations: MO mother; PE Principal Escort; CH Challenger; SE Secondary Escort; TR member of a trio; ES escort to a mother/calf pair; CA calf; NA Nuclear Animal; PR member of a pair; SN singleton. The single strong reaction recorded (by a Nuclear Animal) is not included.

(3) Calves reacted significantly more than all other classes combined, including mothers ($\chi^2 = 9.538$, $P < 0.01$). However, when mothers, Principal Escorts, Challengers, and Secondary Escorts were removed, there was no significant difference between the reactions of calves and those of the remaining classes combined.

(4) Pairwise comparisons showed no differences among the following classes (df = 1): pairs, trios, calves, Nuclear Animals, or escorts to mother/calf pairs. The sample size (n = 14) for singletons was too small to test against the other categories.

Unlike with observed reactions to hits, chi-square tests showed no differences between any of the classes in reactions to misses.

Behavior changes and evasiveness—Behavior both before and after a shot was recorded for a total of 973 hits and misses. A behavior change was recorded following 31 (5.5%) of 569 hits, and 18 (4.5%) of 404 misses. Table 2 summarizes the types of behavior change recorded. Three (9.7%) of the 31 changes after hits, and three (16.7%) of the 18 changes following misses, were classified as positive.

Behavior preceding a hit or a miss was recorded in 1,013 cases. Of these, 172 (17.0%) involved evasion, specifically 72 (12.0%) of 598 hits and 100 (24.1%) of 415 misses. No pre-shot evasive behavior was recorded for singletons (n = 55 approaches), non-lactating Nuclear Animals (n = 54), Principal Escorts (n = 78), Challengers (n = 65), or Secondary Escorts (n = 69). Evasive behavior before a shot was recorded for pairs (8.4% of 191 approaches), trios (8.3% of

Table 2. Observed behavior changes following hits and misses.

36 approaches), escorts to mother/calf pairs (30.7% of 101 approaches), and mother/calf pairs (33.5% of 364 approaches).

Effect on fluking rate—Data on the rate of fluking on terminal dives were recorded prior to, and during or after (we did not distinguish between the two), approaches to 20 whales of various classes. Whales fluked on 28 (50.0%) of 56 terminal dives before an approach was made, but on only 17 (23.0%) of 74 terminal dives during or after the sampling procedure. This difference is significant ($\chi^2 = 4.909$, $P < 0.05$, df = 1).

Stuck darts—In ten cases on Silver Bank, the dart stuck in the target whale, eventually falling out after periods ranging from 2 to 45 min. Reactions associated with stuck darts ranged from none ($n = 4$), to low ($n = 4$) to moderate ($n = 2$).

Discussion

The results reported here provide further support for the belief that the biopsy sampling procedure, if properly applied, does not result in significant behavioral disturbance to humpback whales. The frequency with which target animals reacted to both hits and misses was considerably lower than that reported by Weinrich *et al.* (1991) for humpbacks on a feeding ground in the southern Gulf of Maine. In the latter area, 11.6% and 64.2% of animals showed no reactions to a hit and a miss, respectively; this compares to 44.1% and 87.8% from the present study. The difference is probably attributable in large part to the low frequency of reactions on the part of certain classes of whales in the breeding range, notably mothers and whales engaged in competitive groups. The latter primarily consist of mature males fighting for access to a female (Tyack and Whitehead 1982, Clapham *et al.* 1992); such groups are often fast-moving and violent, and it is therefore not surprising that the minimal stimulus of a skin biopsy goes unnoticed by animals who are presumably already in a high state of arousal, and who are expecting tactile stimuli. The lower frequency of reactions among mothers may be related to the fact that they are continually being touched by nursing calves and are therefore less likely to be surprised by a tactile stimulus.

The greater number of reactions to hits than misses observed in whales of all classes is hardly surprising given the tactile nature of a hit. That whales reacted in similar ways to many misses suggests that a large component of any reaction (hit or miss) is a startle response; whales may simply be surprised at the sudden stimulus (whether tactile in the case of a hit, or auditory in a miss) and react accordingly.

As more studies of this type are conducted, it is becoming clear that the various components of the sampling procedure elicit different levels of response. In particular, the actual biopsy is less likely to elicit a behavior change than the associated approach of the vessel. This was most noticeable in mothers, who showed little reaction to being struck, but who were consistently more evasive than other classes of whales. Weinrich *et al.* (1991) noted that mother/calf pairs in the southern Gulf of Maine did not differ significantly from other classes in their response to the sampling procedure, and our own work on this same feeding ground supports this (unpublished data). It is not surprising that mothers on the breeding grounds are more sensitized to vessel approach given that their calves are younger by weeks or months than those encountered in high latitudes. Furthermore, humpback whales in the Gulf of Maine are arguably more habituated to vessel approach than those of any other population (Watkins 1986). By contrast, many whales in the West Indies come from areas such as West Greenland which have little boat traffic and where they may still be hunted.

For all classes except competitive groups, the manner in which a vessel approaches a group of whales has a major influence on the probability that a negative response will be elicited. Again, this proved to be particularly true with mother/calf pairs. We experimented with many different approaches during this study, and it was clear that a slow, patient approach to groups (including those containing a calf) produced less evasion and yielded a higher probability of sampling success than more aggressive techniques. While individual variation guarantees that some whales will be unapproachable no matter how careful the boat driver, most whales (even mothers) seem to habituate to the presence of a vessel given sufficient time. This, in combination with the results of this study, strongly suggest that, for both efficacy of sampling and the well-being of the animals, such a careful approach is warranted, notably to mother/calf pairs in the breeding range. If conducted in this manner with experienced, trained personnel (this is essential), biopsies can be obtained from mothers and their calves with little effect on the animals; this is gratifying, since samples from related pairs are of particular importance in genetic analyses. It is likely that the high frequency of evasive behavior on the part of escorts to mother/calf pairs is a result of evasiveness on the part of the latter to any vessel approach, with the escort following the movements of the mother. Escorts are invariably males who are believed to associate with a lactating female in order to enhance their probability of mating with her.

This study also suggests that aggressive approaches can decrease the probability that a whale will fluke when diving, thus making it more difficult to obtain photographs for the purpose of individual identification. We would therefore recommend that, where possible, fluke photographs be obtained prior to the initiation of the sampling procedure. Our sample size was too small to allow us to test whether the observed change in fluking rate differed significantly among classes; if it does, this would be of particular concern since if not taken into consideration it would introduce the bias of heterogeneity of capture into estimates of population numbers. It is possible that whales may begin to fluke again after all approaches have ceased, but because we generally abandoned groups shortly after sampling we could not determine whether an additional investment of time would result in successful photographic capture of such individuals.

The virtual absence of strong reactions to shots is similar to observations made by Weinrich *et al.* (1991), who noted that the few cases where such reactions were observed involved either fouling with a retrieval line or a stuck dart. We did not use a retrieval line, and the ten cases in which a dart stuck in a whale produced no strong reactions. As noted above, the sole instance of a strong reaction during this study involved a Nuclear Animal in a competitive group. The only other strong reaction that we have observed in the West Indies involved a logging (resting) whale in Samana Bay (unpublished data), which presumably was awakened by the biopsy. This individual breached three times when struck, after which it resumed its previous resting behavior.

The occurrence of six instances of what we have termed "positive" responses (curious from non-curious, or non-evasive from evasive) following a shot is interesting, although we stress that the term "positive" is a label assigned by us and may not reflect the experience of the whale. As noted by E. Mathews (personal communication), responses such as curiosity may be somewhat negative for the whale in that they may detract from more critical behaviors such as nursing or courtship.

We have not attempted to assess the long-term effects of biopsying on individual humpbacks. There is good evidence that the procedure has no influence on rates of either within-season resighting or annual return (Weinrich *et al.* 1991), and the resighting of several biopsied animals during our studies in the West Indies supports this belief.

Overall, we conclude that the taking of skin biopsies has no significant effect on the animals concerned, although particular care should be taken in approaches to mother/calf pairs. Furthermore, regional differences in habitat use (*i.e.,* feeding versus breeding) produce different frequencies of short-term responses, notably among mother/calf pairs and whales engaged in breeding-related behavior.

ACKNOWLEDGMENTS

Biopsy samples were collected under a permit issued to the Center for Coastal Studies and YONAH by the government of the Dominican Republic, Silver Bank Sanctuary Commission. We thank Lisa Baraff, Bob Bowman, Philip Hamilton, Per Palsbøll, Ditte

Rendtorff, Irene Seipt, Ruell Sloan, Oswaldo Vâsquez and Fred Wenzel for assistance in the field, and Bryan Rourke for assistance with data analysis. We also thank Beth Mathews and Finn Larsen, whose thoughtful reviews improved the manuscript. The field work for this study was funded by the U.S. National Marine Fisheries Service and by the U.S. National Fish and Wildlife Foundation.

ABSTRACT

Behavioral responses to biopsy sampling of four species of northwestern Atlantic balaenopterid whales summering in the estuary and Gulf of St. Lawrence, Quebec, from 1990 to 1995 were studied to determine if this technique was an important disturbance to the whales. A total of 447 biopsy samples were taken using a small punch-type biopsy tip fired from a crossbow. Biopsies were successfully taken from 91.2% of the whales approached. Whales displayed no reaction to 45.2% of the successful biopsy attempts. Whales that responded to biopsy sampling typically resumed their normal behavior immediately or within a few minutes. Most humpback whales displayed a hard tail flick, and the majority of fin and blue whales submerged following biopsy sampling. Significantly different frequencies and intensities of responses were found between whale species. Minke and humpback whales were found to be more sensitive to biopsy sampling than fin and blue whales. Response frequencies were similar between females and males for all species, with the exception of fin whales where females had a higher response frequency than males. Biopsy sample length, *i.e.,* penetration depth, did not explain variations in response intensity but may influence response frequency to biopsy sampling. Group size, geographical region, and number of biopsies taken per whale were not factors that explained variation in behavioral responses. The biopsy technique was found to be an efficient method for obtaining high-quality whale skin and blubber samples with limited behavioral disturbance to balaenopterid whales.

Key words: balaenopterid, biopsy, behavior, response frequency, intensity of response.

Biopsy sampling is a method for obtaining very small cores of skin and underlying blubber from free-ranging cetaceans with a modified crossbow or gun. This method has been successfully used on both mysticetes and odontocetes (*e.g.*, Winn *et al.* 1973; Mathews *et al.* 1988; Whitehead *et al.* 1990; Brown *et al.* 1991, 1994; Kasamatsu *et al.* 1991; Palsbøll *et al.* 1991; Weinrich *et al.* 1991, 1992; Clapham and Mattila 1993; Barrett-Lennard *et al.* 1996).

DNA extracted from skin biopsies has been used to obtain information on gender, lineage, social organization, identity of stocks and individuals, and genetic variation between stocks (*e.g.*, Amos and Hoelzel 1990; Baker *et al.* 1990, 1991, 1993; Pasbøll *et al.* 1992). Skin biopsies have also been used for determination of mixed function oxidase (MFO) activity (Fossi *et al.* 1992). Blubber portions of biopsy samples have been used for analysis of persistent lipophilic contaminants (Aguilar and Nadal 1984, Woodley *et al.* 1991, Marsili and Focardi 1996, Gauthier *et al.* 1997) and of feeding habits through analysis of fatty acids (Borobia *et al.* 1995).

An important consideration is to minimize disturbance to whales, while obtaining a satisfactory sample for research. Biopsy sampling has become widely used, yet studies on the behavioral effects of this technique have been largely limited to humpback whales (*Megaptera novaeangliae*) (Weinrich *et al.* 1991, 1992, Clapham and Mattila 1993, Brown *et al.* 1994). This study provides information on the effects of biopsy sampling on three other balaenopterid species and on interspecific comparisons using the same methodology. This study also provides novel information on the effect of biopsy sample length on the frequency and intensity of response in balaenopterid whales.

Frequency, intensity, and category of immediate response to biopsy sampling of minke (*Balaenoptera acutorostrata*), fin (*Balaenoptera physalus*), blue (*Balaenoptera musculus*), and humpback whales were determined according to species, sex, group size, geographical region, number of biopsies taken per whale, and length of biopsy sample.

METHODS

Study Area and Biopsy Sampling Conditions

Biopsy samples were taken from free-ranging whales in summer and fall from 1990 to 1995 (23 biopsies in 1990, 78 in 1991, 121 in 1992, 106 in 1993, 76 in 1994, and 43 in 1995). Whales were biopsied on their feeding grounds in the St. Lawrence estuary and Gulf of St. Lawrence, Quebec (Fig. 1). Whales were approached with a 5- or 7.5-m hard-bottom inflatable boat with a 70- or 90-hp outboard motor, respectively. To reduce the chances of biopsying the same individual twice, fin, blue, and humpback whales were photographed according to procedures described by Sears *et al.* (1990), and morphological features and natural body marks were recorded to aid in the photoidentification of individuals. Minke whales were not photoidentified because their surface times were too short to allow time for both photoidentification and biopsy sampling using the procedures in this study. When pos-

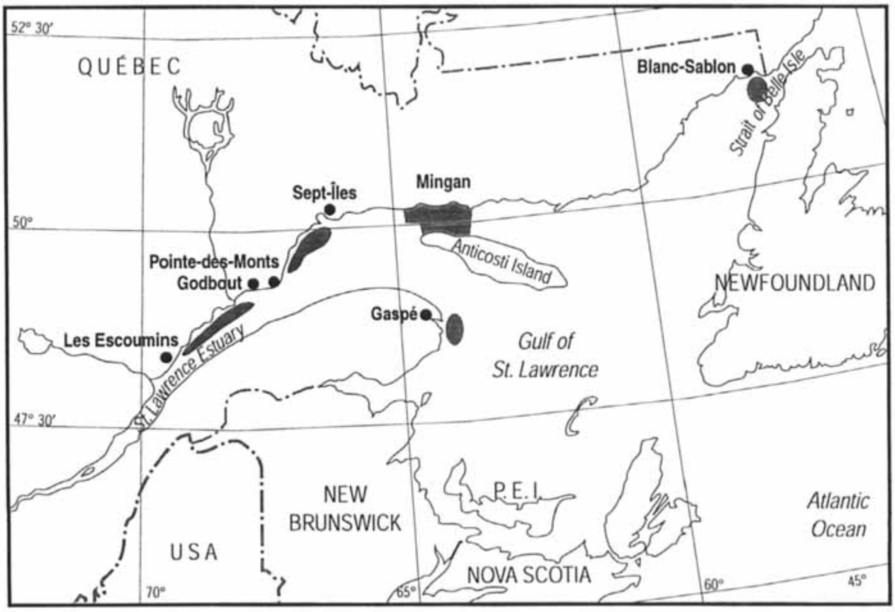

Figure 1. Map of study area showing balaenopterid whales summering in St. Lawrence estuary and Gulf of St. Lawrence, Quebec, biopsied in five different regions (shaded). Samples sizes in each localized geographical region for minke, fin, blue, and humpback whales, respectively, are: Mingan = 23, 109, 21, and 64; Strait of Belle Isle = 0, 0, 0, and 141; Godbout to Escoumins = 2, 3, 56 and 0; Sept-Îles to Pointe-des-Monts = 0, 1, 18, and 0; Gaspé = 0, 0, 8, and 1.

sible, group size was recorded. In this study, a group was defined as a concentration of whales of the same species inside an approximate diameter of 50 m. Although these groups may be associated with a larger and more-dispersed group, more-distant whales were not included in the analyses.

According to our criteria, a whale responded to biopsy sampling when it immediately modified its behavior observed before the biopsy attempt. These immediate reactions were recorded by constantly observing the selected whale with the naked eye, usually by two observers, throughout the entire sequence: the approach, the pursuit, and the pre- and postbiopsy periods. Observations were ended when the whale resumed its initial behavior or was out of sight. Individual behavior categories, such as a flipper flick, flipper slap, lobtail, startle, tail flick, hard tail flick, tail rise, tail slash, and trumpet blow, have been defined by Weinrich *et al.* (1992), Brown *et al.* (1994) and Lambertsen *et al.* (1994). In this study, tail flicks were either categorized as 'tail flicks' or 'hard tail flicks'. Tail flicks were light in intensity and caused little spray, while hard tail flicks were higher in intensity and produced much spray. Flipper rises are analogous to tail rises as described by Weinrich *et al.* (1992). Other individual behavior categories are described as follows:

Acceleration—Whale increased its speed if it was initially traveling, or otherwise swam rapidly away from boat for a short time period (quick burst of speed).

Breach—Whale emerged sideways from the water, rotated a half-turn, and landed on its back, producing a large splash.

Change in direction—Whale changed its traveling course in any direction different from that in which it was initially traveling without increasing its speed during otherwise normal swimming behavior.

Defecation—Whale defecated at the water surface without any other observable change in behavior.

Dive—Whale rapidly arched its back in a typical diving posture, with or without bringing its flukes above the surface. Although diving may have occurred regardless of biopsy attempt, it was assigned as a response only if it occurred immediately after the event or within a series of closely time-related reactions after the event, in the case of combined responses.

Forceful breath—Whale blew loudly during exhalation at or just below the surface, but without the wheezing sound produced by a trumpet blow.

Roll—Whale turned on its right or left side, either towards or away from the boat, during otherwise normal swimming behavior.

Submerge—Whale slowly submerged parallel to the water surface without arching its back, during otherwise normal swimming behavior.

Tail sweep—Whale moved tail laterally once on the water surface producing light water frothing. This movement was lighter in intensity than the tail slashes described by Weinrich *et al.* (1992).

Tail wave—Whale lifted tail out of the water and waved it laterally with light intensity.

In order to compare our results with those of other studies, the intensity of the response to biopsy sampling for each whale was classified according to Weinrich *et al.* (1991) or Clapham and Mattila (1993) as either no response or low-, moderate- or strong-level response, as follows:

No response—Whale continued its prebiopsy behavior with no observed reaction.

Low-level—Whale modified its prebiopsy behavior with brief and relatively mild responses (*i.e.*, change in direction/defecation/dive/flipper flick/flipper rise/roll/submerge/startle/tail flick/tail rise/tail wave).

Moderate-level—Whale modified its prebiopsy behavior in a more forceful manner, but gave no prolonged evidence of behavioral disturbance (*i.e.*, acceleration/forceful blow/hard tail flick/tail sweep/trumpet blow).

Strong-level—Whale modified its prebiopsy behavior to a succession of forceful activities (*i.e.*, numerous trumpet blows) or to high energy behavior (*i.e.*, breach/flipper slap/lobtail/tail slash).

Response categories cited for each level were either observed singly (individual responses) or in combination (combined responses). Combined responses which included responses from different levels were assigned to the strongest level (*e.g.*, submerge + hard tail flick = moderate level).

Biopsy Technique

Biopsy samples were taken using a small stainless-steel punch-type biopsy tip fired from a 76-cm, 1.8-kg Barnett WildCat crossbow. Draw weight of the bow was either 57 or 68 kg. The crossbow and biopsy tip were similar to the Barnett-type bow and tip described by Palsbøll *et al.* (1991), but no retrieval line was used. The arrow was kept afloat after it became dislodged from the whale's blubber with a buoyant, highly visible, cone-shaped stop collar designed to limit the penetration of the biopsy tip.

The approach process for biopsy sampling was similar to the method described previously by Sears *et al.* (1990), and target distance was 6–20 m. All biopsy attempts were carried out by the same four archers. Most biopsies were obtained at an angle perpendicular to the back of whales forward of the dorsal fin. This was the desired sampling location, in order to avoid the head and tail area and to increase the chances of a successful biopsy if the whale suddenly dove. Nineteen samples were obtained from the caudal peduncle, usually taken at a 30°–45° oblique angle. More skin but less blubber were obtained from these caudal-peduncle samples. The tip was cleaned with ethanol after each shot to minimize wound infection and bacterial contamination of the sample. Skin was cut from the blubber and placed in dimethyl sulphoxide (DMSO)/saturated saline solution and stored at 4°C. Skin samples were flown to Denmark for sex determination by Per Palsbøll and Martine Bérubé at the University of Copenhagen using the polymerase chain reaction (PCR) with SRY gene primers (5′CAT TAT GTG CTG GTT CTT TTC TG 3′ and 5′GTA TTT CTC TCT GTG CAT GG 3′) (Palsbøll *et al.* 1992). Blubber samples were frozen and used for organochlorine contaminant analysis and fatty acid determination. When possible, length and weight of blubber samples were recorded on thawed tissue.

Statistical Analysis of Data

Chi-square analyses (Minitab Software Inc., version 8, State College, PA) were used to compare behavioral responses in relation to species, sex, geographical region and group size. Chi-square analyses were conducted if the average expected frequency (n/rc, where n is the total of expected frequencies, c is the total number of columns and r is the total number of rows of the contingency table) was at least 6.0 when testing for $\alpha = 0.05$ (Roscoe and Byars 1971, Zar 1996). A regression was done to verify if the length of samples (blubber core length) was a good indicator of the size of the biopsy sample (Minitab Software Inc., version 8, State College, PA). The non-parametric Kruskal-Wallis test (Systat Inc. software, 1990, Evanston, IL) was used to compare blubber core length (mm) of the biopsy sample to the intensity of response. All statistical analyses were tested for $\alpha = 0.05$.

Table 1. Summary of unsuccessful and successful biopsy attempts on balaenopterid whales sampled in the St. Lawrence estuary and Gulf of St. Lawrence.

Attempt	Minke	Fin	Blue	Humpback	Total
Miss (hit water)	2	2	1	5	10
Hit/no sample (hit whale)	0	7	9	17	33
Hit/sample	25	113	103	206	447
Total	27	122	113	228	490

RESULTS

Relative Success of the Biopsy Technique

In 490 attempts on 443 whales, 447 biopsy samples were obtained (91.2% success rate) (Table 1). Of 447 biopsies, 433 yielded both skin and blubber and 14 only skin.

Ten arrows (2.0%) missed the whale and hit the water, and 33 attempts (6.7%) struck a whale but resulted in no sample (Table 1). In 39 of the 43 cases, a second biopsy attempt was successful. A third attempt was successful for three of the four whales which were unsuccessfully biopsied in the second attempt. A fourth attempt was successful for the remaining whale. Behavioral responses were recorded for 20 (9 misses and 11 no-samples) of the 43 unsuccessful attempts. For nine missed attempts, no reaction was observed for one minke, two fin, one blue and four humpback whales, and one fin whale dove when the arrow hit the water. Out of 11 hits which did not yield a sample, four did not elicit any response from fin and blue whales, and five were followed by a low-level response from one blue and four humpback whales, one by a moderate-level and one by a strong-level response from two humpback whales. These responses included hard tail flicks, flipper flicks, diving, changes in traveling direction, trumpeting, and rolling towards the boat. Repetitive attempts to biopsy a whale resulted in responses of similar or reduced intensity, with the exception of one humpback whale that responded by a low-level reaction at the first missed attempt and by a moderate-level reaction at the second and successful attempt.

On five occasions the biopsy tip stayed lodged in the blubber of humpback whales and this resulted in a reaction for four of the five whales. Two of these tips stayed lodged in the whale's blubber for 6 and 13 min, respectively, and resulted, in both cases, in strong-level responses which lasted until the tip was freed.

Photoidentification of whales indicated that certain whales were inadvertently biopsied more than once during the course of the study (Table 2). Most of these whales were biopsied in different months or years, but five fin, three blue and one humpback were biopsied twice within a week. Intensity of the behavioral response appeared to be similar at first and subsequent biopsy for the three species. Chi-square analyses were not conducted because the average expected frequency was smaller than 6.0 for all species.

Table 2. Intensity of response of balaenopterid whales inadvertantly biopsied more than once (*i.e.*, 2–4 times) during the course of the study.

		First				Second				Third				Fourth			
Species	*n*	NR	L	M	S	NR	L	M	S	NR	L	M	S	NR	L	M	S

Blue	14	11	3	0	0	9	5	0	0	1	0	0	0	0	0	0	0
Humpback	21	7	9	4	1	10	7	3	1	2	2	0	0	1	0	0	0

NR = no response, L = low-, M = moderate-, and S = strong-level responses.

Analysis by Species and Sex

Response frequency—Response frequencies to biopsy sampling for each species are presented in Table 3. No reaction to biopsy sampling was observed in 45.2% of cases. Minke whales responded the most often (84.0%), followed by humpback (65.5%), fin (50.4%), and blue (31.1%) whales. When data were analyzed using a 2 × 2 chi-square contingency table, response frequencies between all combinations of species were significantly different (minke and fin: $\chi^2_1 = 9.38$, $P = 0.002$, minke and blue: $\chi^2_1 = 23.23$, $P < 0.001$, fin and blue: $\chi^2_1 = 8.35$, $P = 0.003$, fin and humpback: $\chi^2_1 = 6.94$, $P = 0.008$, blue and humpback: $\chi^2_1 = 32.84$, $P < 0.001$), except between minke and humpback whales ($\chi^2_1 = 3.47$, $P = 0.06$).

Sex was determined for 400 of the 443 biopsied whales. Response frequencies by sex for each species are presented in Table 4. Only in fin whales were the response frequencies significantly different between sexes ($\chi^2_1 = 4.48$, $P = 0.03$), with females (65.7%) having a higher response frequency than males (44.2%).

Intensity of response—Analysis by 2 × 3 or 2 × 4 chi-square contingency tables of the intensity of response (no-, low-, and moderate-level with or without strong-level) for all combinations of whale species showed significant differences in all cases (minke and fin: $\chi^2_3 = 14.70$, $P = 0.002$, minke and blue: $\chi^2_3 = 34.58$, $P < 0.001$, fin and blue: $\chi^2_2 = 11.24$, $P = 0.004$, fin and humpback: $\chi^2_3 = 21.96$, $P < 0.001$, blue and humpback: $\chi^2_3 = 52.24$, $P < 0.001$), except between minke and humpback whales ($\chi^2_3 = 5.77$, $P = 0.123$). Blue and fin whales most frequently showed no-level responses and minke and humpback whales most often displayed moderate-level responses (Table 3). Strong-level responses were observed at low frequencies only in minke and humpback whales. Only three humpback whales had prolonged strong responses to biopsy sampling and two of these cases were related with retention of the biopsy dart in the whale. Whales typically resumed their normal behavior immediately or a few minutes after biopsy.

Differences in intensity of response between females and males were significant in fin whales ($\chi^2_2 = 8.13$, $P = 0.02$), but not in blue and humpback whales ($\chi^2_2 = 0.03$ and $\chi^2_3 = 4.19$, $P = 0.983$ and 0.123, respectively). However, differences between female and male fin whales reflected only the greater frequency of low-level responses compared to no-level responses in

Table 3. Frequency and intensity of response to successful biopsy attempts of balaenopterid whales.

Species	*n*	Response frequency			Intensity of response		
		No response	Response	% response	L	M	S
Minke	25	4	21	84.0%	9	11	1
Fin	113	56	57	50.4%	34	23	0
Blue	103	71	32	31.1%	25	7	0
Humpback	206	71	135	65.5%	38	87	10
Total	447	202	245	54.8%	106	128	11

L = low-, M = moderate-, and S = strong-level responses.

Table 4. Frequency and intensity of response to successful biopsy attempts of female and male balaenopterid whales.

			Response frequency			Intensity of response		
Species	Sex	*n*	No response	Response	% response	L	M	S
Minke	♀	20	2	18	90.0%	9	9	0
	♂	5	2	3	60.0%	0	2	1
Fin	♀	35	12	23	65.7%	17	6	0
	♂	77	43	34	44.2%	17	17	0
Blue	♀	44	30	14	31.8%	11	3	0
	♂	50	34	16	32.0%	13	3	0
Humpback	♀	88	33	55	62.5%	12	38	5
	♂	81	26	55	67.9%	21	29	5

L = low-, M = moderate-, and S = strong-level responses.

females since frequencies of moderate-level responses were similar between sexes. Chi-square analyses were not conducted for female and male minke whales because the average expected frequency was smaller than 6.0.

Response categories—Submerging (15.0%), combinations of two reactions (11.0%), tail flicks (8.9%), and hard tail flicks (8.3%) were the most frequently observed responses (Table 5). Humpback whales mainly displayed hard tail flicks. Most blue and fin whales submerged after the biopsy attempt. Breaching, flipper slapping, lobtailing, tail slashes, tail waving, and trumpet blows were observed only in humpback whales, tail sweeps only in minke whales and defecation and flipper flicking only in fin whales. Two biopsied fin whales and seven biopsied humpback whales were identified as calves. Three of the humpback whales and all the fin whale calves did not react to biopsy sampling, and the other four humpback calves responded by either a slight acceleration, a hard tail flick, or a combination of an acceleration and a tail flick.

Minke and humpback whales often showed combined reactions to biopsy sampling, which accounted for 32.0% and 17.5%, respectively, of their reactions (Table 5). Response categories which made up combined responses were similar to behaviors observed individually, except that no breaching, defecation, flipper flicks, or lobtails were observed. However, flipper slapping and tail waving were observed only within combined responses in humpback whales. Combined responses observed in minke whales consisted mostly of hard tail flicks (27.8%), diving (22.2%), acceleration (16.7%), and submerging (11.1%). Behaviors displayed during combined responses in fin whales were mainly hard tail flicks (22.2%), rolling (19.4%), submerging (16.7%), and diving (13.9%). Blue whales displayed few combined responses and these comprised mostly submerging (35.7%), acceleration (28.6%), and diving (21.4%). Trumpeting was an important component of combined responses in humpback whales (20.0%), but hard tail flicks (22.4%), diving (16.5%), and submerging (11.8%) were also frequently observed.

Effect of Group Size and Geographical Region

Group size was recorded for 223 of the 447 biopsied whales and categorized as singles, small groups (two–four) or large groups (five or more) (Table 6). No statistical differences were found in response frequencies for different group sizes in fin, blue, and humpback whales (χ^2_2 = 0.08, 1.13, and 0.006, P = 0.962, 0.568, and 0.997, respectively). Chi-square analyses were not conducted for minke whales because the average expected frequency was smaller than 6.0.

Biopsy samples were obtained from whales in regions of Mingan (217 biopsies), Strait of Belle Isle (141), Godbout to Les Escoumins (56), Sept-Îles to Pointe des Monts (24) and Gaspé (9) in the St. Lawrence estuary and Gulf of St. Lawrence, Quebec (Fig. 1). Response frequencies to biopsy sampling of humpback whales sampled in the Mingan (70.3%, n = 64) and in the Strait of Belle Isle (63.1%, n = 141) regions were not statistically different (χ^2_1 = 1.01, P = 0.316). No differences were found between blue whales sampled

Table 5. Frequency of response categories displayed following biopsy sampling by species and sex. Sex determined for 400 of 443 biopsied whales. Sex unknown for 1 fin, 9 blue, and 37 humpback whales. Categories within combined responses are described in text.

in regions of Godbout to Les Escoumins (25.0%, n = 56), Sept-Îles to Pointe-des-Monts (50.0%, n = 18), Gaspé (25.0%, n = 8) and Mingan (38.1%, n = 21) ($\chi^2_3 = 4.48$, $P = 0.214$).

Effect of Biopsy Sample Size

Blubber portions of biopsy samples had a diameter of 6 mm and, for 42 measured biopsies, the blubber core length ranged from 5 to 30 mm and the sample weighed between 0.035 and 0.582 g (mean = 0.25 g). Core length was found to be a good predictor of sample weight ($P < 0.001$) according to the regression equation: weight = 0.0062 + 0.0139 length (r^2adj. = 54.3%). Therefore, core length was used as the criterion for comparing response frequency and intensity of response with biopsy sample size.

Mean core length ranged from 14.6 to 21.8 mm (Table 7). Blubber cores with a greater length than average taken from minke whales (mean = 21.8 mm) may have contributed to the high response frequency in this species. Humpback whales appear to be particularly sensitive to biopsy sampling, since

Table 7. Sample size, mean, range (in parentheses), and standard deviation about mean for length of total blubber portions of 42 biopsy samples and response frequency to biopsy sampling for each species.

		Length (mm)		
Species	n	Mean (range)	S.D.	Response Frequency*
Minke	13	21.8 (14–30)	6.2	100%
Fin	19	17.8 (5–27)	5.9	68.4%
Blue	3	17.3 (6–21)	0.5	33.3%
Humpback	9	14.6 (5–20)	3.7	88.9%
Total	42	17.6 (5–30)	6.3	67.1%

* Calculated only for whales for which data were available on biopsy blubber core depth.

relatively short blubber cores (mean = 14.6 mm) were associated with a high response frequency (88.9%). In all species, no significant differences were found in blubber core length for the different response levels (P = 0.367–0.456).

DISCUSSION

The biopsy sampling technique used in this study was an efficient method for obtaining skin and blubber samples from four species of balaenopterid whales. Success rate for first biopsy attempt in this study (91.2%) was similar to or higher than reported for humpback and killer (*Orcinus orca*) whales (57.0%–85.0%: Weinrich *et al.* 1991, 1992; Clapham and Mattila 1993; Brown *et al.* 1994; Lambertsen *et al.* 1994; Barrett-Lennard *et al.* 1996).

Response frequencies to biopsy sampling of blue, fin, humpback, and minke whales were 2- to 5-fold greater than for right whales, *Balaena glacialis* (17.6%, Brown *et al.* 1991). However, blue whales appeared to have a low response frequency compared to other balaenopterid species. Response frequencies of minke, fin, and humpback whales were within the range previously reported for humpback whales (41.4%–85.9%, Weinrich *et al.* 1991, 1992; Clapham and Mattila 1993; Brown *et al.* 1994). Intensity of response was lower in both blue and fin whales compared to minke and humpback whales, which reacted with intensity similar to that for humpback whales sampled by Weinrich *et al.* (1991, 1992) and Clapham and Mattila (1993).

Individual fin, blue, and humpback whales reacted with similar intensity when biopsied more than once during this study, which may indicate that response to biopsy has a large individual component. A response may reflect general sensitivity of an individual or species to an unknown stimulus, including biopsy sampling. Small mammals have higher relative metabolic rates and usually react more strongly to stress than large mammals (Peters 1983). The susceptibility of reaction to an unknown stimulus, such as biopsy sampling, may be inversely related to size. The smaller minke (~8 m, 7 tons) and humpback (~15 m, 30 tons) whales responded two–three times more frequently to biopsy sampling than did blue whales (~25 m, 100 tons). Other morphological factors such as thickness and innervation of skin and blubber thickness may play a role in the differential sensitivity of species or individuals, but no quantitative data are available.

Compared to interspecific differences, most intraspecific factors had little or no effect on the response to biopsy sampling. Frequencies and intensities of response to biopsy were similar in female and male blue and humpback whales, which is comparable to results for humpback whales sampled on their feeding grounds by Weinrich *et al.* (1991). Although female fin whales showed greater response frequencies to biopsy than males, this was due mostly to differences between frequencies of no-level and low-level responses. Group size was not a factor that determined response to biopsy sampling for fin, blue, and humpback whales. Similar results were obtained for humpback whales sampled from different group sizes by Weinrich *et al.* (1991) and Brown *et al.* (1994). Although different geographical regions could have reflected differences in familiarization of whales to close boat traffic, blue and humpback whales sampled in different regions showed similar response frequencies to biopsy sampling.

In general, whales in this study demonstrated a similar range of behavioral responses as previously recorded for sperm (*Physeter macrocephalus*), right, and humpback whales (Whitehead *et al.* 1990; Brown *et al.* 1991; Lambertsen *et al.* 1994; Weinrich *et al.* 1991, 1992). While humpback, right, and sperm whales typically responded with tail flicks or hard tail flicks, fin and blue whales responded most often by submerging. Tail flicks may be a reflex response to biopsy, but have also been observed in non-reflexive contexts (Weinrich *et al.* 1992, Lambertsen *et al.* 1994). Defecation was observed in one fin whale and this behavior may be typical of startled sperm whales (Whitehead *et al.* 1990, Watkins and Tyack 1991). The tail slashes and trumpet blows observed only in humpback whales are thought to be aggressive behaviors in response to harassment (Norris and Reeves 1977, Baker and Herman 1984, Watkins and Wartzok 1985). However, many of the behaviors observed after biopsy have also been displayed in the study area by whales that were not approached for biopsy or photoidentification. This was also reported by Weinrich *et al.* (1992) for humpback whales biopsied in the Gulf of Maine.

Whales that responded to biopsy sampling typically resumed their normal behavior immediately or a few minutes after the response. This has also reported by other authors (Winn *et al.* 1973; Whitehead *et al.* 1990; Brown *et al.* 1991, 1994; Weinrich *et al.* 1991, 1992; Lambertsen *et al.* 1994; Barrett-Lennard *et al.* 1996). Repetitive attempts to biopsy a whale usually resulted in a response of similar or decreased intensity. As indicated by the short duration of the response and the apparent acclimation by some whales to repeated biopsy attempts, reaction to the tip may be due more to the element of surprise to an unknown sensation, rather than to pain. Implantation of radio tags into the muscle layer have mostly elicited no response or mild reactions in large baleen whales, including fin and humpback (Watkins, 1981, Watkins and Tyack 1991). Moreover, the absence of changes in response intensity for fin, blue, and humpback whales inadvertently biopsied more than once during this study suggests the lack of long-term effects of biopsy sampling.

Nevertheless, only immediate surface responses were recorded, and it must be considered whether other undetected effects were caused by biopsy. Also, the presence of strong responses indicates that certain individuals may be very sensitive to biopsy sampling. Biopsy tips which remained lodged in the whale's blubber usually resulted in a strong response, which subsided only when the tip was dislodged from the whale's body. Similar findings were observed by Brown *et al.* (1991) and Weinrich *et al.* (1991, 1992). It is more likely that the tip will remain lodged in the whale's blubber if deep cores are taken. Although no significant relationship was found between intensity of whale response and sample core length, the high response frequency of minke whales may be due in part to the relatively long biopsy samples (14–30 mm) obtained from individuals of this species, but a greater sample size is needed to verify this. Very small blubber samples (5 mm) weighing as little as 0.035 g can be used to quantify low concentrations of lipophilic organochlorine contaminants found in balaenopterid whales (Gauthier *et al.* 1997). Blubber samples measuring 11–22 mm were shared for fatty acid analysis and contaminant analysis, indicating that such small samples can be used in cooperative research projects.

In conclusion, species was the most important factor governing response to biopsy sampling. Interspecific comparisons in response of balaenopterid whales biopsied using the same methodology showed that blue and fin whales may be less sensitive to biopsy than the smaller minke and humpback whales. Results from this study also show that the biopsy technique is a relatively non-invasive method for obtaining high quality samples from balaenopterid whales with limited behavioral disturbances, as has been previously shown for humpback whales.

Acknowledgments

Special thanks to the personnel at the Mingan Island Research Station who helped in collecting samples and information in the field, and in particular to Catherine Berchok who also helped in organizing and entry of the data. We are especially grateful to Chris Metcalfe for advice and suggestions on the manuscript. The map was done by Simon Labelle. Biopsy sampling was carried out under permit # 6350–3 issued by the Department of Fisheries and Oceans of Canada. This study was funded by a Canadian Fisheries and Oceans Grant to Chris Metcalfe. Graduate support for J. Gauthier was supplied by Fonds pour la Formation de Chercheuses et Chercheurs et l'Aide à la Recherche (FCAR), Québec.

GRAY WHALES ALONG THE OREGON COAST IN SUMMER, 1977-1980

JAMES L. SUMICH

ABSTRACT—Gray whale (*Eschrichtius robustus*) distribution and relative abundance along the Oregon coast were studied during the summers of 1977-1980. Shore-based observations along the entire Oregon coast were made in 1977. In 1978-1980, detailed studies of whale distribution, activities, and body size were made along the central coast only; they were supplemented with observations from aircraft.

Over 1200 summer sightings were made within 0.5 km of shore. Numbers of sightings varied considerably from day to day and from year to year, with whale abundance estimated at 0.2-0.3 whales/km of shoreline for a 100 km portion of the study area. Over one-half the whales were presumed to be feeding; the remainder were traveling, usually parallel to shore. Body length was determined for 42 whales photogrammetrically. The majority of these summer whales were evidently subadults; calves and yearlings accounted for approximately 50% of the total.

The annual migration of the gray whale, *Eschrichtius robustus*, along the western shores of North America links summer feeding grounds in the arctic with their winter breeding, calving, and assembling grounds along the coast of Baja California and nearby mainland Mexico. Gray whales occupy their principal feeding grounds north of 60° N latitude, especially the Bering Strait region, from late May into November when the southward migration begins. Commencing in late December, gray whales arrive in their winter lagoons and remain there for a few weeks to several months. The northward migration has been described by Poole (1984) and by Herzing and Mate (1984) as two separate migratory pulses, the second composed chiefly of lactating females and their calves.

Not all northward migrants leaving their winter grounds in Mexico proceed directly to the Bering Sea. Pike (1962) reported that a few gray whales remained as summer residents along the British Columbia coast. Rice and Wolman (1971) listed six summer sightings between Baja California and British Columbia. Additional published reports (Hatler and Darling 1974, Patten and Samaras 1977, Sprague et al. 1977, Sullivan et al. 1983, Darling 1984) and numerous unpublished reports indicate that summer occurrences of gray whales along much of the west coast of North America are more common than previously assumed. In 1976, gray whales were reported as sighted or stranded during summer in at least 24 coastal locations in California and Oregon (Sumich, unpubl. data). Subsequent studies of summer gray whales in 1977-1980 along the Oregon coast are the subject of this paper.

METHODS

Summer sightings are defined as those occurring between 1 June and 15 September in coastal waters. Beginning in June 1977, fortnightly ground-based searches for summer gray whales were conducted from elevated observation sites approximately 20 km apart between the Columbia River and the Oregon-California border (a distance of 450 km). Visual searches for whales (aided by 7 × 35 binoculars) were made from each site. The date, time, apparent activity, direction of travel, and number of whales seen were recorded. Body size estimates were made when possible. These observations were supplemented with opportunistic sightings made by Coast Guard personnel, park rangers, commercial and sports fishers, and other cooperators. The counts were adjusted to discount possible repeated sightings of the same whale(s) on the same day. No corrections for visibility or observer effort have been attempted.

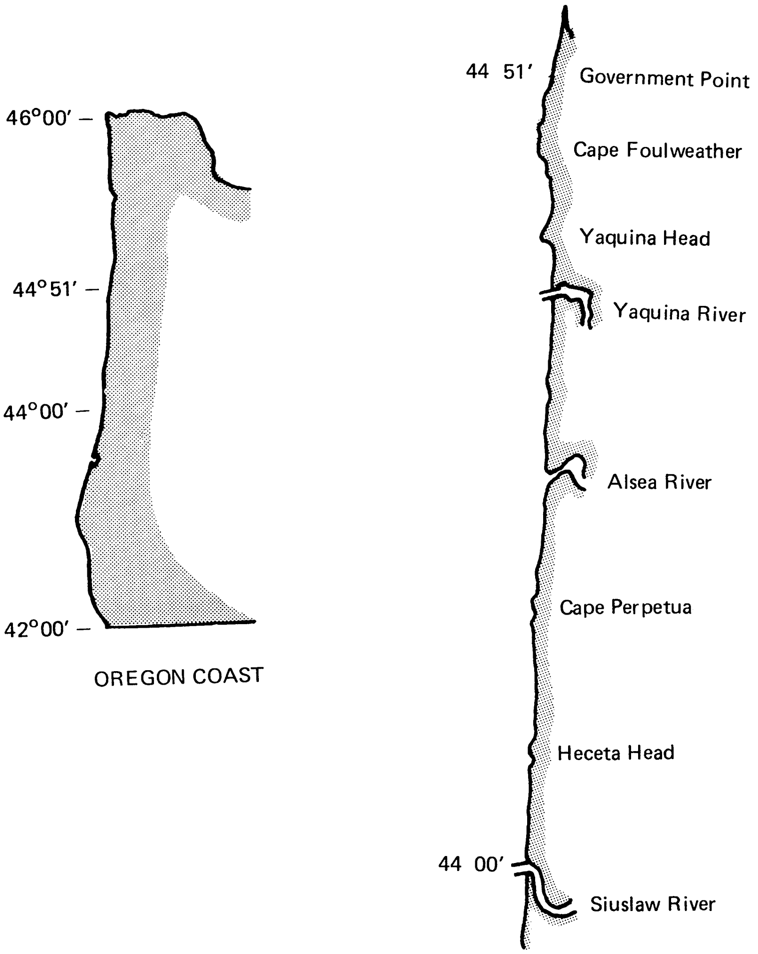

FIGURE 1. The 1977 (left) and 1978 (right) Oregon summer gray whale study areas.

The scope of the summer study area was narrowed in 1978 to 100 km of the Oregon coastline between the Siuslaw River (44°00' lat.) and Government Point (44°51' lat., Fig. 1) to obtain detailed information on site utilization, identification of individual whales, body length, and activities. Ground surveys in 1978 and 1979 were concentrated along the 25 km northern portion of the study area between Yaquina Bay (44°37' lat.) and Government Point, where several coastal bluffs and headlands (named in Fig. 1) provided elevated observation sites for complete visual coverage. Cape Foulweather (44°46' lat.) with an elevation of 140 m was especially suitable for monitoring behavior and for obtaining information on size and identification of individual whales. Ground surveys were discontinued in 1980.

During summer months of 1978, 1979, and 1980, aerial flights were made along portions of the Oregon coast. Helicopters of the U.S. Coast Guard (equipped with radar altimeters) or fixed wing aircraft were utilized as observation platforms. Determinations of body length were made from photographs taken from known distances with 35 mm high speed black and white film, 230 mm telephoto lens, and polarizing filter. Whales were usually photographed vertically from altitudes between 200 and 300 m when they surfaced to blow. For oblique photographs, the angle deviation from vertical was measured with a hand-held inclinometer and the correct camera-whale distance was calculated.

Additional photographs, using the same procedure, were taken from Cape Foulweather. Film

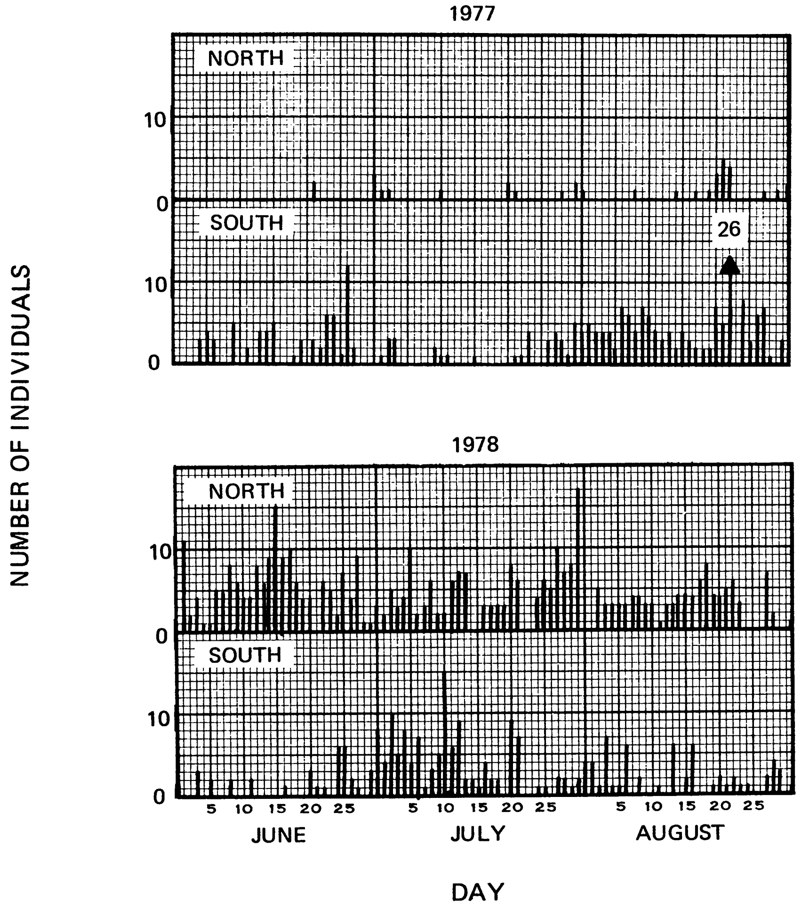

FIGURE 2. Daily numbers of summer gray whales reported from all sources in 1977 and 1978 for the northern (44°51′–44°25′ lat.) and southern (44°25′–44°00′ lat.) halves of the 100 km study area. Each small vertical division represents one whale.

negatives were examined under a 7× microscope. The standard length of the whale image was measured to the nearest 0.01 mm with an ocular micrometer. Body length was calculated with the following formula:

$$L = \frac{I \times D}{F}$$

where L = body length, m
I = whale image size on film, mm
D = whale to camera distance, m
F = camera lens' focal length, mm.

When a whale was photographed more than once, the lengths calculated from each photograph were averaged.

The relationship between body length and age of gray whales has been unresolved for some time (Zimushko 1970, Rice and Wolman 1971, Zimushko and Ivashin 1980), principally because most studies are of large, sexually mature whales. A re-examination of the age:body-length relationship of young gray whales (Sumich, unpubl. ms.) indicates that calves in their first summer are shorter than 8 m, and yearlings are between 8 and about 9.5 m.

TOTALS:	18 (32%)	39 (68%)	57 (100%)	

On 20 July 1978, a study was conducted to test the value of aerial surveys along more extensive reaches of coastline. Seven shore observers were positioned on vantage points along a 25 km long portion of the study zone (Yaquina River to Government Point). Concurrently with the observations from shore, seven sequential flights of approximately ten minutes duration each were made over the zone with a Cessna 180 carrying a pilot and an observer. Flight speed was 180 km/h at 500 m altitude. The observation strip was 1 km wide, established with calibrated marks on the wing strut. Four flights were made to the south over the shoreline (observed strip extending from shore seaward 1 km); and three flights were made to the north 1 km offshore (observed strip extending from the line of flight to shore).

RESULTS

Over 1200 sightings of summer gray whales were reported from all sources along the Oregon coast between 1 June 1977 and 15 September 1980. Sixty percent of the 460 summer whales reported in 1977 were along the 100 km of coastline from the Siuslaw River to Government Point just north of Depoe Bay (latitude 44°00′ to 44°51′, Fig. 1), suggesting that they were either more numerous or were more easily seen there than along other portions of the Oregon coastline. Therefore, the 1978 shore surveys were limited to that region. Figure 2 illustrates the daily number of gray whale sightings from all sources between 1 June and 31 August of 1977 and 1978 for the northern (44°51′-44°25′ lat.) and southern (44°25′-44°00′ lat.) halves of that 100 km study area.

Observer effort and weather conditions affecting whale visibility were not necessarily equivalent for 1977 and 1978, and statistical comparisons of the two summers cannot be made. However, the data in Fig. 2 do suggest that summer gray whales occurred more frequently in the northern half of the study area in 1978 than in 1977. The largest single-day count in 1977 (August 22) was 30 for the 100 km study area; in 1978, it was 19 (on July 30), yielding a maximum observed occurrence of 0.2-0.3 whales/km of coastline.

Ten complete shore surveys were made along the 25 km coastal section from Yaquina River to Government Point in 1978 and 1979 during half-day periods of acceptable visibility (at least 5 km) and sea state conditions (Beaufort 3 or less). All 10 surveys were conducted by the same observer. Whale counts for those surveys are listed in Table 1. During June and July, calves remained close to their mothers and were easily recognized. As summer progressed, calves wandered farther (often more than 200 m) from their inferred mothers, were seen alone more frequently, and thus were more difficult to identify as calves without independent estimates of their body lengths. Accordingly, the relative number of calves listed in Table 1 (32% of the whales sighted) is considered a conservative estimate, particularly for the latter part of the summer. The mean ob-

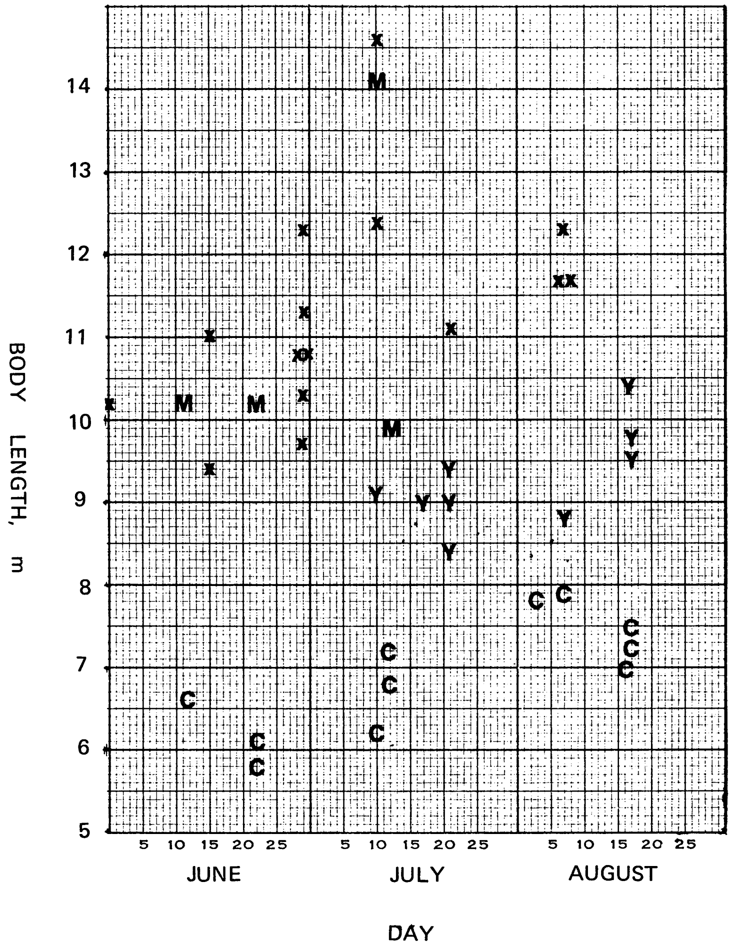

FIGURE 3. Body lengths of 42 summer gray whales photographed 1978–1980, plotted at dates of length determination. Age class assignment based on Sumich, unpubl. ms. (C = calf, Y = yearling, M = inferred mother with calf, x = other).

served occurrence of 0.23 whales/km compares well with the highest occurrences (0.2–0.3 whales/km) seen along the 100 km section of coastline in 1977 and 1978.

During the 20 July simultaneous ground/air study, the shore observers sighted 6 whales within the 25 km study zone during the aerial observation period. Four of the 6 whales were within 100 m of shore, and all 6 were located in surf or foam lines. No whales were seen from the air on any of the three flights 1 km offshore. Of the four flights over the shoreline, 0, 1, 3 and 1 whales were seen on successive passes ($\bar{x} = 1.25$ whales/pass; SD = 1.26).

In conditions of good visibility, 5 km was considered a practical maximum distance that gray whales could be reliably seen with binoculars under ideal conditions. Most of the sightings mentioned to this point were made within 500 m of shore. However, 14 reports of 27 whales 5 to 80 km offshore were received from Coast Guard personnel and fishing boat operators during 1977 and 1978. Water depths of these locations ranged from 50 to 2700 m. After 1978, efforts to contact these observers were discontinued.

Body lengths of 42 gray whales (Fig. 3) were determined using the photogrammetric technique. The precision of this technique was tested on a small whale photographed repeatedly from Cape Foulweather on 3 August 1979. Five film negatives showed the entire animal clearly. From these, body lengths were calculated ($\bar{x} = 7.78$ m; SD = 0.11 m). Twelve of the 42 whales (29%) measured were less than 8 m and were judged to be calves. This percentage is very close to the 32% calves observed in ground surveys (Table 1). Eight additional whales (19%) were considered yearlings (Fig. 3).

DISCUSSION

In the past decade, summer gray whale sightings have increased appreciably at several locations along the west coast of North America. The large variation in observed abundance along the Oregon coast described here may, in part, reflect varying observer effort. Sightings were never common north of Lincoln City (45°10′ lat.), where strategic headlands are fewer. Reliable estimates of whale numbers along inaccessible stretches of coastline could not be obtained from the air, because nearshore whales are extremely difficult to detect against their typical backdrop of surf and sea foam.

The numbers of summer whales at any one coastal site varied considerably from day to day and from one year to the next and showed no defined time of maximum occurrence to compare with other areas along the west coast. Due to the limitations of weather, sea state, and coastal terrain on the visibility of summer whales, the abundances reported in this study (0.2–0.3 whales/km) along the central Oregon coast are thought to represent fewer than the true number of whales in the study area. In another study of gray whales along a 40 km portion of the west coast of Vancouver Island, Darling (1984) found a maximum occurrence of 0.3 whales/km in July 1974 and 1976. In spite of the similar numbers of summer gray whales found for the Oregon and Vancouver Island locations situated over 500 km apart, it is premature to extrapolate these numbers to other west coast locations known to be frequented by summer whales. Consequently, it is not yet possible to indicate what fraction of the total whale population does not migrate to arctic waters in summer.

Although the principal activity of summer whales appears to be feeding, their prey is unknown. Gray whales in arctic feeding grounds forage on benthic infauna, particularly gammarid amphipods (Pike 1962, Rice and Wolman 1971). These organisms occur in the Bering and Chukchi Seas in densities to 24,000 animals/m^2 (Zimushko and Lenskaya 1970). The offshore sightings are intriguing in that eight of the 14 occurred at sites where water depths exceeded 100 m, and three were in depths of 400 m or more. Gray whales seldom feed in arctic waters deeper than 70 m (Nerini, pers. comm.). The presence of summer whales in deep water suggests that, if they are feeding, they are feeding on pelagic rather than benthic organisms, and thus they are exploiting a range of prey species broader than previously supposed.

Reilly (1984) estimated the annual gray whale birth rate to be no more than 14%, and the average annual mortality rate for all immature whales, 10%. However, it appears that mortality is much higher among calves (40%) and yearlings (27%) than for older immature animals (Sumich and Harvey, unpubl. ms.). Complications at birth, predation by sharks and killer whales, and severe storms may all contribute to high calf and yearling mortality (Morejohn 1968, Rice and Wolman 1971, Baldridge 1972). Thus, no more than 10% of the gray whale population during summer months would be expected to be calves, and 8%, yearlings. A Chi-square test indicated that the expected frequencies of calves (10%), yearlings (8%), and others (82%) were significantly different from those actually observed (29%, 19%, and 52%) ($\chi^2 = 57.30$, 2 df, $p < 0.001$).

Both calves and yearlings contribute significantly more to the counts of summer gray whales along the Oregon coast than would be expected from a random sample of the entire population. The numbers of calves suggest, by association, the presence of comparable numbers of lactating females, at least prior to weaning in late summer (Rice and

Wolman 1971). Moreover, approximately one-half of the whales in Fig. 3 larger than yearlings, including 3 of the 4 inferred females in the company of calves, are smaller than the mean length at sexual maturity (slightly over 11 m; Rice and Wolman 1971). Thus, Oregon summer whales are predominantly immature or atypically small mature animals.

Summer whales may gain energetic benefit by cutting short their northward migration and foraging in Oregon rather than colder arctic waters. Also, summer feeding can commence earlier and continue later prior to the southward autumn migration. These benefits may be particularly crucial for calves and their mothers, as pregnant females are the first to leave the arctic feeding grounds at the end of summer (Rice and Wolman 1971). Moreover, with their calves, they are the last to migrate north in spring (Sullivan et al. 1983, Poole 1984, Herzing and Mate 1984).

The benefits of a shortened northward migration hinge on the availability of adequate sources of prey in temperate southern waters. Where food resources are available well south of their principal feeding grounds, some whales can be expected to exploit them for energetic advantage. Thus, the shallow inshore portions of the Oregon coast, at least, should be considered as supplementary summer feeding grounds of the gray whale.

ACKNOWLEDGMENTS

I thank the many observers who volunteered for this project. The helicopter crews of the North Bend Coast Guard Air Station and Neal Langbehn, National Marine Fisheries Service, provided opportunities to photograph whales from the air. Denise Herzing and Marcia Frost deserve special thanks for assisting in the ground surveys. Jim Harvey, Dr. Victor Scheffer and an anonymous reviewer critically read the manuscript. Dr. Bruce Mate and the late Dr. Ray Gilmore provided valued assistance and encouragement throughout this project. Some financial support was provided by NSF Award #PRM-8109087.

Behaviour of gray whales (*Eschrichtius robustus*) summering off the northern California coast, from Patrick's Point to Crescent City

JAY S. MALLONÉE
187 Raft Islands, Gig Harbor, WA 98335, U.S.A.

Received November 20, 1989

MALLONÉE, J. S. 1991. Behaviour of gray whales (*Eschrichtius robustus*) summering off the northern California coast, from Patrick's Point to Crescent City. Can. J. Zool. **69**: 681–690.

This study quantifies basic dive characteristics and behaviour patterns of undisturbed gray whales (*Eschrichtius robustus*) observed summering at four northern California locations: the Big Lagoon – Patrick's Point area, Orick, Klamath River mouth, and Crescent City. Observable behaviours were limited to several locomotions (swim slow, swim moderate, swim fast, and floating) seen in different behavioural contexts (milling, circling, pluming, and transit). Sixteen behaviours were observed and they fit naturally into locomotive–context categories (i.e., swim-milling, swim slow – circling, etc.). Each behaviour was described using behavioural observations and dive characteristics. Behaviours that did not appear goal oriented or directed, i.e., milling and floating, had highly variable dive characteristics. More specific behaviours, such as circling and pluming, were less variable. Some specific and less directed behaviours appeared functionally related and usually occurred together. Apparent bottom feeding was observed and the Big Lagoon – Patrick's Point area appeared to be a favoured feeding site, as evidenced by mud plumes and repetitive circling of surfacing animals. Feeding was composed of at least three observable behaviours: circling, circling with pluming, and milling with pluming. Locomotive–context categories are useful in refining broad behavioural definitions and quantifying basic behaviour patterns. This approach can enhance the interpretation of observable surface behaviours.

MALLONÉE, J. S. 1991. Behaviour of gray whales (*Eschrichtius robustus*) summering off the northern California coast, from Patrick's Point to Crescent City. Can. J. Zool. **69** : 681–690.

Les caractéristiques de base de la plongée et les variations du comportement ont été étudiées chez des Baleines grises (*Eschrichtius robustus*) de Californie dans leurs territoires d'été au large de quatre points sur la côte, dans le nord de la Californie : site de Big Lagoon – Patrick's Point, Orick, embouchure de la rivière Klamath et Crescent City. Les comportements observés semblent restreints à divers types de mouvements (nage lente, nage modérée, nage rapide et flottement) reliés à des situations diverses (déplacements erratiques, déplacements circulaires, rejets de boue et déplacements d'un endroit à un autre). Seize comportements ont été observés et ils correspondent tout naturellement à des catégories de contextes de locomotion (i.e., nage lors de déplacements erratiques, nage lente lors de déplacements circulaires, etc.). Chaque comportement est décrit, tenant compte à la fois des observations du comportement lui-même et des caractéristiques des plongées. Les comportements qui ne semblent pas avoir de direction ou de but précis, par exemple les déplacements erratiques et les flottements, sont reliés à des caractéristiques de plongée extrèmement variables. Les comportements plus spécifiques, tels les déplacements circulaires et le rejet de boue, sont moins variables. Certains comportements spécifiques moins orientés semblent avoir une relation fonctionnelle et se produisent ordinairement en même temps. Les baleines semblent se nourrir sur le fond de l'eau et le site de Big Lagoon – Patrick's Point est apparemment un site d'alimentation de prédilection, du moins à en juger par le rejet de boue et les déplacements circulaires répétés des animaux qui refont surface. L'alimentation suppose au moins trois comportements différents : déplacements circulaires, déplacements circulaires avec rejet de boue et déplacements erratiques avec rejet de boue. Les catégories de contextes de locomotion sont des outils commodes pour raffiner les définitions trop vagues de certaines comportements et pour quantifier les comportements de base. Cette approche offre la possibilité d'une interprétation plus juste des comportements de surface observés.

[Traduit par la rédaction]

Introduction

The migratory pathway of gray whales (*Eschrichtius robustus*) extends from calving lagoons in Baja California, Mexico, along the west coast of North America to feeding areas in the Bering, Chukchi, and (occasionally) Beaufort seas (Rice and Wolman 1971; Rugh and Fraker 1981). However, detailed information about individual migratory patterns, coastline utilization, and summertime distributions is usually not available (Pike 1962; Rice and Wolman 1971; Wilke and Fiscus 1961). Censuses conducted at Unimak Pass, Alaska (Hall et al. 1977; Rugh and Braham 1979; Rugh 1984), indicate that by summer, the majority of gray whales end their migration at these northern feeding grounds. Groups of summering whales, however, have been observed in many coastal areas along the migratory pathway. Summertime sightings have occurred off British Columbia, Washington, Oregon, and California (Darling 1978, 1979, 1984; Dohl et al. 1981; Gilmore 1960; Pike 1962; Rice and Wolman 1971). Small groups of whales (six to eight per group) reside in at least four northern California locations during the summer months: the St. George Reef offshore from Crescent City, at the Klamath River mouth, in the Big Lagoon – Patrick's Point area, and in waters adjacent to the Farallon Islands (Dohl et al. 1983). The presence of summering whales in these areas offers an opportunity to observe identified individuals (using natural markings as described in Darling 1984) over extended time periods. Such observations are usually not possible for animals in the inaccessible northern seas or migrating far offshore.

Few detailed behavioural observations and dive characteristics have been reported for summering gray whales and the available literature deals mainly with feeding activity. Thus, behaviours such as bottom feeding by summering whales (Hatler and Darling 1974; Oliver et al. 1983; Oliver and Kvitek 1984) must usually be inferred from the muddy plumes of surfacing animals or resultant bottom depressions (Nerini 1984). Using indirect evidence of feeding, Guerrero (1989) reported that significantly different patterns in the apparent feeding behaviour of summering gray whales were related to the patchiness and mobility of two different benthic prey items.

Some gray whale behaviours are defined broadly and could

Printed in Canada / Imprimé au Canada

reflect behavioural contexts rather than specific actions. For example, several specific behaviours may occur during "feeding," each having different dive characteristics. Taken together, these behaviours represent a feeding context rather than a specific feeding behaviour. Noting only that an animal is "feeding," therefore, may not accurately reflect the actions of that animal. Dive characteristics can be obtained by monitoring respiratory blows of surfaced whales (Sumich 1983; Würsig et al. 1986) and have been described by Harvey and Mate (1984) using radio-tagged animals. Combining visual observations of gray whales with their corresponding dive patterns can enhance the interpretation of many broadly defined behaviours, but this practice has been limited to only a few studies (Guerrero 1989; Harvey and Mate 1984; Murison et al. 1984; Oliver et al. 1984; Würsig et al. 1986). Admittedly, individual variability exists among whales exhibiting these behaviour patterns. This study, however, attempts only to describe observable behaviours common to most of the study animals rather than specify the behaviours of each individual.

Before this study, I observed undisturbed (from boat traffic, planes, divers, fishing operations, etc.) summering gray whales in the Big Lagoon – Patrick's Point area, California, during 1979 and 1980. These whales exhibited different behavioural contexts such as transit between areas, milling, and apparent feeding. Locomotions, ranging from floating to fast swimming, were noted throughout the observations and they did not occur with equal frequency in each behavioural context. All observable behaviours could be naturally grouped into locomotive–context categories (i.e., swim slow – milling, swim fast – transit, etc.). These categories showed that it was possible for many of the swimming movements to have different meanings or functions dependent upon the context in which they occurred. The meaning of some animal behaviours is known to change in different contexts (i.e., Smith 1965). Noting the context in which specific behaviours occur can improve the interpretation of those behaviours.

Locomotive–context categories offer a new approach to understanding gray whale behaviour by refining broad behavioural definitions. Much informal knowledge of gray whale behaviour exists, but little of it has been quantified. Swartz and Jones (1980) stated that in their study, much of the gray whale behaviour was anecdotal and requires additional study for quantification. This indicates that in general, gray whale behaviour needs additional quantification and a need exists for additional descriptions of base-line behaviours. Using the locomotive–context approach, this study will quantify some basic dive characteristics and base-line behaviour patterns of undisturbed gray whales that spend the summer off the northern California coast.

Methods

Four northern California locations served as observation sites: the Big Lagoon – Patrick's Point area, Orick, the Klamath River mouth, and Point St. George in Crescent City (Fig. 1). These sites afforded unobstructed views of the coastline and ranged from 6 to 50 m above the water surface. Observations were made 2 days each week from September 1986 through October 1987, and May 1988 through August 1988. The 1st year of observations provided information as to whether the summering whales migrated, and if so, their approximate departure and arrival times. Beginning in May 1987, observation time at each site was distributed approximately equally through the daylight hours so that daily behavioural changes could be observed. Each site was visited once or twice daily, 2 days a week, in the morning, afternoon, or evening. My previous sightings in 1979, 1980, and 1986 indicated that approximately 70% of sightings occur within the 1st hour of observation time. A 60-min minimum waiting period was therefore established before abandoning the site. When a sighting occurred, observations continued until the whale left the area. The remaining sites were then sampled as time permitted.

During a sighting, data used for calculating dive characteristics were recorded on respiration, location, locomotion, and general behaviour of each visible whale. A time, direction, compass bearing, and distance were noted for every surfacing. Because the whales were close to the shoreline, their distance offshore was estimated subjectively using offshore landmarks where distances were predetermined using a topography map. A similar technique of estimating distance subjectively has been used successfully by Poole (1984). Instead of a topography map, Poole used a surveyor's transit to determine the distance of offshore landmarks. He then estimated subjectively the distance offshore of migrating gray whales.

Observations were limited to behaviours at or above the water surface. Changes of direction in successive surfacings, however, were assumed to occur underwater. Surfacings with visibly exhaled water vapour were noted as blows. Remaining surfacings were noted as no-blows. When the animals dove after a surfacing, it was noted if the flukes were raised completely or partially above the water surface, or not at all. Visible flukes may indicate when the whales begin a long dive (sounding) and could be useful in determining their next surfacing. Whales were generally 100–500 m from shore and could be individually identified from scars and pigmentation patterns on the back, head, and sides (i.e., Darling 1984).

Previous observations determined that dive durations could be naturally grouped into surface–dive sequences of long and short dives. A surface–dive sequence was defined as one long dive (≥60 s) followed by a variable number of shorter surface respirations. A locomotive pattern and the context in which it occurred were assigned to all the observed surface–dive sequences. The surface–dive sequences were placed in locomotive-context categories and divided into duration of long dive, blow interval, number of blows per surfacing, and duration of surfacing. Dive characteristics were obtained for each categorical division by calculating the mean and standard deviation. Significant differences between categories were determined by using analysis of variance and *t*-tests.

When observing the summering whales prior to this study, I noted that at least three distinct swimming speeds could be observed. Approximate swimming speeds, therefore, were calculated in an attempt to quantify observable changes in speed. Because offshore distance was estimated subjectively, calculated swimming speeds were never intended to be extremely accurate. Instead, these swimming speeds were grouped into six gross categories of locomotion (Table 1).

Swimming speeds were determined by plotting the compass bearings onto topography maps and calculating the time and distance between surfacings. Based on the topography map scale, with 100 m as the smallest division, accuracy could have been within ±10 m for the distance between surfacings. Offshore distances, however, were estimated subjectively, which probably reduced accuracy by an unknown amount. Accuracy, therefore, was greater than ±10 m, but in my estimation, probably less than ±50 m (one-half of the smallest division). The whales were always observed within one of the following contexts: transit, milling, circling, and pluming. Contexts and locomotions are defined in Table 1.

Results

Summering whales were observed during 29 sightings at all observation sites between the dates of September 1 and October 31, 1986; May 1 and October 31, 1987; and May 1 and August 31, 1988. Whales sighted between the beginning of May and the end of October were considered summering whales. These animals remained close to shore and never appeared to be migrating. A total of 50 summering whales (representing a smaller number of resighted individuals) were observed. Thirty-one animals were observed at the Big Lagoon – Patrick's Point

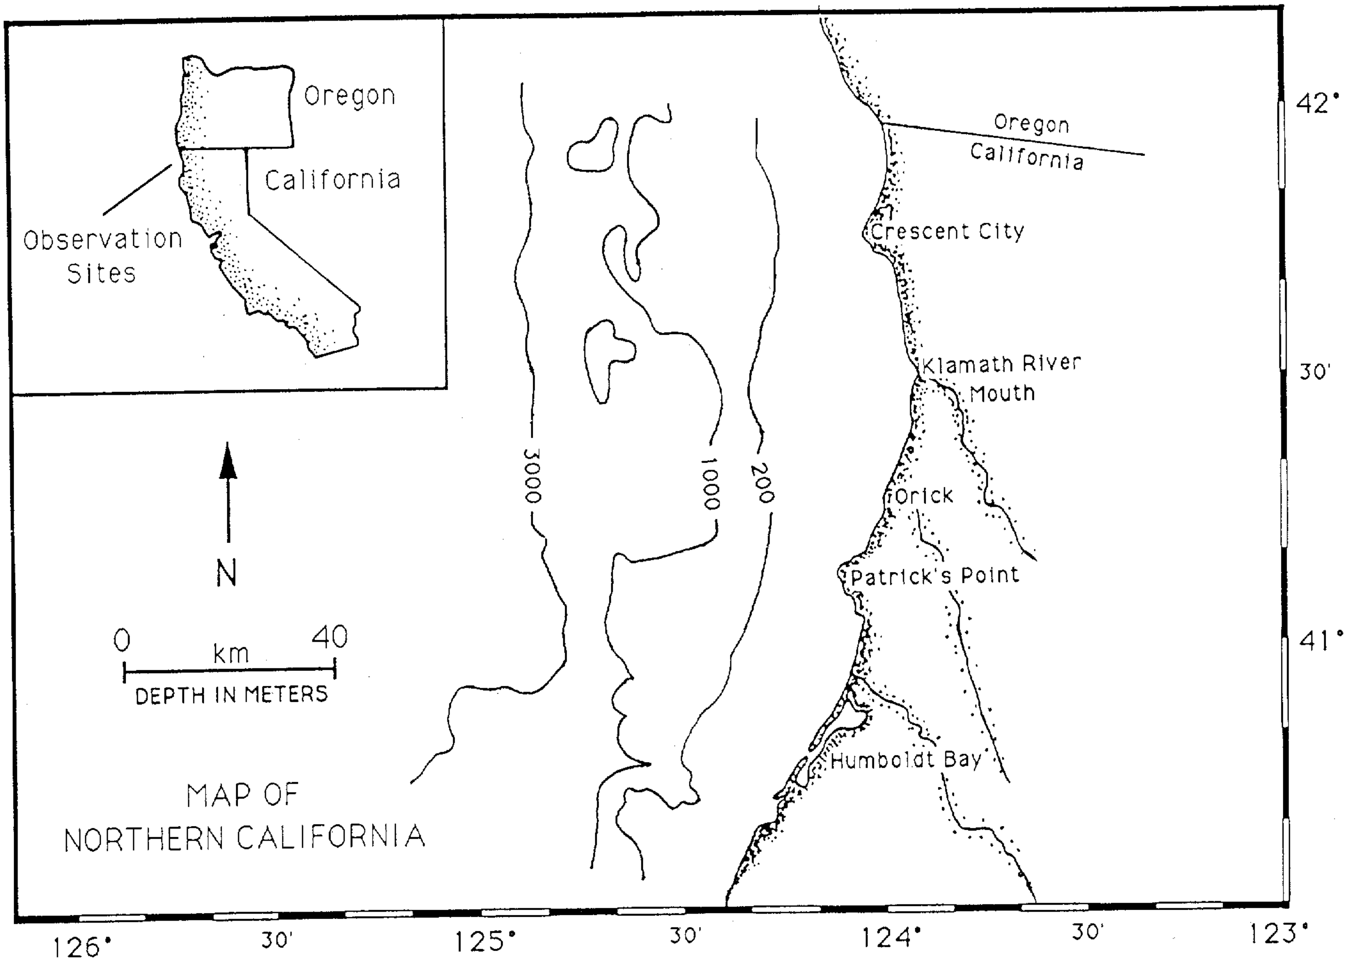

FIG. 1. The four observation sites used to observe gray whales summering off the northern California coast: Crescent City, Klamath River mouth, Orick, and Patrick's Point.

TABLE 1. Definition and probable function of the four behavioural contexts and six locomotions observed in gray whales summering off the coast of northern California

Term	Definition	Probable function
Context		
Transit	Forward movement from area to area	Travel
Milling	Forward and numerous directional changes in movement within a restricted area	Searching
Circling	Constant directional changes in movement within a restricted area	Bottom feeding
Pluming	Sea floor disturbance resulting in surface mud patches and plumes	Bottom feeding
Locomotion		
Swim slow	Minimal forward progress (0.5–1.0 km·h^{-1})	Bottom feeding
Swim moderate	Constant forward progress (3.0–4.0 km·h^{-1})	Travel
Swim fast	Rapid forward progress with occasional white water (7.0–8.0 km·h^{-1})	Unknown
Float	No forward movement	Resting/orientation
Float then swim slow	—	Searching
Float then swim fast	—	Searching

area. Three to five whales were observed at each of the remaining observation sites, including opportunistic sightings at Crescent Beach (three whales) and Dry Lagoon (three whales). The majority of whales were seen at the Big Lagoon – Patrick's Point area because fog and rain severely reduced observation time at Point St. George and the Klamath River mouth. All observed summering whales were judged to be "adults" and usually were sighted as individuals with occasional groups of two or three animals.

Because many whales were in transit and swam out of view before specific behaviours could be noted, behavioural analysis was limited to 13 sightings and a total of 12 different whales. One whale (identified by distinct natural markings) was observed in 3 of the 13 sightings, once with another whale and

TABLE 2. Number of observed surface–dive sequences per behaviour (locomotive–context category) seen during the 13 sightings

	Context					
Observed locomotion	Circling	Circling with pluming	Transit	Milling	Milling with pluming	None
Swim slow	38 (2)	9	2 (1)	92	15	*
Swim moderate	4 (4)	0	41 (11)	16 (16)	0	*
Swim fast	1 (1)	0	2	1 (1)	0	*
Float	5 (4)	*	*	*	*	14 (6)
Float then swim slow	6	*	*	*	*	2
Float then swim fast	1	*	*	*	*	0

NOTE: The numbers in parentheses represent the contribution made by one whale in the two sightings not used in statistical analysis.

*Behaviours that cannot take place. For example, a whale cannot simultaneously float and transit.

twice alone. To avoid repeated observations of the same whale (which would bias statistical analysis), two of these sightings were not included in the statistical analysis, which was limited to 11 sightings and 12 different whales. Six locomotive behaviours were seen across five behavioural contexts resulting in 16 observable behaviours (locomotive–context categories) (Table 2). The division of long and short dives was determined by inspecting the frequency distribution of all observed dive durations. An apparent break in dive duration occurred at 60 s and correlated well with the observed behaviours.

Locomotive behaviours

These behaviours ranged from variable speeds of forward movement to floating at the water surface (Tables 1 and 2). Swim slow was minimal forward movement seen in animals milling and apparently feeding. Slow swimming comprised 62.7% ($n = 156$) of observed surface–dive sequences. The swim moderate behaviour was also used while milling but rarely seen during apparent feeding. The majority of swim moderate surface–dive sequences were observed during transit when an animal would move from one area to another. Of observed surface–dive sequences, 24.5% ($n = 61$) were during swim moderate. Swim fast was observed rarely and never during apparent feeding (i.e., circling and pluming). Only 1.6% ($n = 4$) of observed surface–dive sequences were swim fast.

Floating was also observed, in which the animals remained just below the water surface. Because floating required no forward movement, it was seen rarely during the observed behavioural contexts. Instead, floating was observed by itself or in combination with another locomotive behaviour during apparent feeding. These feeding surface–dive sequences began with the animal floating near the surface and ended with the whale swimming slowly in a semicircle. Floating was seen in 11.2% ($n = 28$) of observed surface–dive sequences.

Behavioural contexts

Throughout each sighting, the whales were always observed to be in one of four behavioural contexts: transit, milling, circling, and pluming. Transit involved forward movement from one area to another, usually in a straight line. A beeline course was altered only when the animals were rounding a headland or avoiding an obstacle. Otherwise, the shortest distance was taken between two areas. Of observed surface–dive sequences, 18.1% ($n = 45$) were transit. When the new area was reached and transit ended, either the milling or the circling context would begin. Pluming was never observed immediately after transit.

Milling occurred in 43.8% ($n = 109$) of observed surface–dive sequences and involved swimming back and forth within a restricted area, usually a few 100 m in diameter. These areas were located approximately 50–500 m from rocky headlands, in the middle of bays, and occasionally at the Klamath River mouth. Milling usually involved only one or two animals. Six whales, however, were observed for 2 consecutive days at Patrick's Point milling near shore. During milling, the whales would swim throughout the area making many directional changes both above and below the water surface. Since individual whales would sometimes dive in one direction and surface in another, it was clear that directional changes occasionally took place underwater.

Some surface swimming patterns were repeated before diving. Within this context, the whales would swim in a semicircle before diving and then surface where the semicircle began, completing a circular route. The pattern would then be repeated numerous times with half the circle occurring at the surface and the other half apparently underwater. The majority of these circular patterns were in a clockwise direction (61.4%, $n = 35$) and never more than approximately 100 m in diameter. Circling comprised 22.1% ($n = 55$) of observed surface–dive sequences.

Occasionally, surface mud patches and plumes were seen during milling and circling. Mud patches about 20–25 m in diameter were present before the animals surfaced during milling. While at the surface, the whales never swam back or dove through the mud patches. If new mud patches were formed in succeeding dives, they would form near previous patches but never in the same location. During circling, mud patches formed semicircles before the animals surfaced and occasionally a whale surfaced with mud streaming from its mouth, forming mud plumes. Mud patches and plumes occurred in 6.0% ($n = 15$) of observed surface–dive sequences during milling and 3.6% ($n = 9$) during circling. Most sightings of mud patches and plumes involved one whale. If two animals were present, each formed mud patches or plumes independently of the other in different but nearby locations (approximately 100–300 m apart).

Behaviours (locomotive–context categories)

Table 3 provides descriptions of the most frequently observed behaviours. A frequent behaviour was defined to be a loco-

TABLE 3. Description of the most frequently observed behaviours (locomotive–context categories)

Behaviour (locomotive–context category)	Description	%*	*n*
Swim slow – milling	Most frequent behaviour. Tendency to surface facing the same direction. Constant positional changes for individual whales, ranging from 0 to 60°. Positional changes did not occur in a straight line, therefore constant directional changes occurred.	36.9	92
Swim slow – milling with pluming	Similar to swim slow – milling but involved the formation of mud patches and plumes. Tendency to surface facing the same direction. Occurred within smaller areas (0–14°) than swim slow – milling.	6.0	15
Swim slow – circling	Tendency for clockwise circling (63.2%, $n = 24$, of these observed surface–dive sequences). Surfaced facing different directions. Small positional changes (<10°). Occasional no-blows.	15.3	38
Swim slow – circling with pluming	Similar to swim slow – circling but involved the formation of mud patches and plumes. Clockwise circling in 57.1% ($n = 4$) of these observed surface–dive sequences.	3.6	9
Swim moderate – transit	Constant positional and distance changes. Always visible blows and surfaced facing the same direction.	16.5	41
Swim moderate – milling	Observed only in one whale. Similar to swim slow – milling but positional changes were smaller (0–15°). Occasional no-blows. Tendency to surface facing the same direction.	6.4	16
Swim moderate – circling	Observed only in one whale. Position never changed and surfaced facing the same direction. Occasional no-blows.	1.6	4
Float	Occurred at or near the water surface. Animals always faced the same direction. Numerous no-blows.	5.6	14
Float–circling	Same as float but whales' direction changed gradually with each succeeding respiration. They rotated (clockwise and counterclockwise) between 45 and 180° by the end of each surface–dive sequence. Numerous no-blows.	2.0	5
Float then swim slow – circling	Occasionally, floating preceded swim slow – circling within a surface–dive sequence. Respirations were visible and surfacing directions were always different.	2.4	6

Float then swim slow – circling	50.0	3	—	0	50.0

motive–context category that was observed in a total of four or more surface–dive sequences. These behaviours occurred during swim slow, swim, float, and across most behavioural contexts. The majority of frequently observed behaviours were seen when the animals were swimming slowly within a restricted area.

When the animals completed a dive or surface respiration during swim slow – milling or swim slow – milling with pluming, they had a tendency to surface facing the same direction. For example, a whale that surfaced facing north did so during all of its swim slow – milling surface–dive sequences. The surfacing direction was different for each animal but usually remained constant throughout that animal's surface–dive sequences. The position or compass bearing, however, changed throughout the surface–dive sequences, indicating that directional changes occurred during swim slow – milling. Because a whale surfaced facing the same direction, changes in direction occurred underwater during the dive.

Occasionally, when the animals sounded (beginning of a long dive) at the end of a surface–dive sequence, the peduncle area became arched severely or the flukes were lifted entirely out of the water. The percentage of surface–dive sequences in which this occurred is listed in Table 4 for each frequently observed behaviour.

The majority of observed surface–dive sequences were of whales swimming slowly. Fewer surface–dive sequences and behaviours were observed when the locomotion was swim moderate. Most of the swim moderate surface–dive sequences

*Behaviours seen in repeated observations of only one whale. To avoid data bias, the remaining behaviours displayed by this animal were not incorporated into the other summary statistics.

were seen during transit in which the animals were usually passing through the immediate area. Less time, therefore, was spent observing animals in the swim moderate locomotion. Swim moderate was never seen during pluming and was observed only in transit, circling, and milling.

Floating, in one form or another, was seen in 11.2% ($n = 28$) of observed surface–dive sequences. Five variations of floating were observed, three of which were considered frequent behaviours. It was obvious when the animals were floating because the distance from shore and position never changed. The animals remained just under or at the water surface. They always remained low in the water and little of their bodies could be seen. During floating, many surfacings occurred with no visible blow and were therefore recorded as no-blows. When no-blows occurred, they were lumped together in particular surface–dive sequences. The remaining surface–dive sequences consisted mostly of visible respirations with occasional no-blows.

Surfacing and respiration characteristics

Although the aim of this study was to describe whale behaviour that occurred near or at the water surface, it was also possible to quantify these activities (Table 5). Surface–dive sequences for locomotion, context, and locomotive-context categories were analyzed for duration of dive, blow interval, number of blows per surfacing, and duration of surfacing. Frequency distributions of these four divisions are presented in Fig. 2. The distributions were skewed positively but when transformed into logarithms, they became approximately normal. The use of parametric statistics, therefore, was appropriate.

Using ANOVA (99% confidence intervals), significant differences were found between contexts for duration of dive ($F = 5.67$, $p = 0.001$), blow interval ($F = 24.71$, $p = 0.0001$), and number of blows per surfacing ($F = 8.28$, $p = 0.0001$). No significant differences were found among contexts for duration of surfacing. Duration of dives was significantly longer during milling ($t = 3.52$, df = 121, $p < 0.001$), circling ($t = -3.65$, df = 65, $p < 0.001$), and pluming ($t = -3.33$, df = 49, $p < 0.002$) than during transit. When transit occurred, the blow interval was significantly longer than that seen during milling ($t = -8.01$, df = 242, $p = 0.0001$), circling ($t = 6.54$, df = 181, $p = 0.0001$), and pluming ($t = 6.39$, df = 139, $p = 0.0001$). During apparent feeding (circling and pluming), the number of blows per surfacing was significantly higher than during nonfeeding activities (milling and transit). Circling had more blows per surfacing than did milling ($t = -3.86$, df = 120, $p < 0.001$) and transit ($t = -2.83$, df = 63, $p < 0.007$). Pluming also showed an increase in the number of blows per surfacing over milling ($t = -3.48$, df = 104, $p < 0.001$) and transit ($t = -2.79$, df = 47, $p < 0.008$).

Significant differences were also observed among locomotions (at the 99% confidence interval) for duration of dive ($F = 8.32$, $p = 0.0001$) and blow interval ($F = 28.00$, $p = 0.0001$). Dive duration was significantly longer when the whales swam

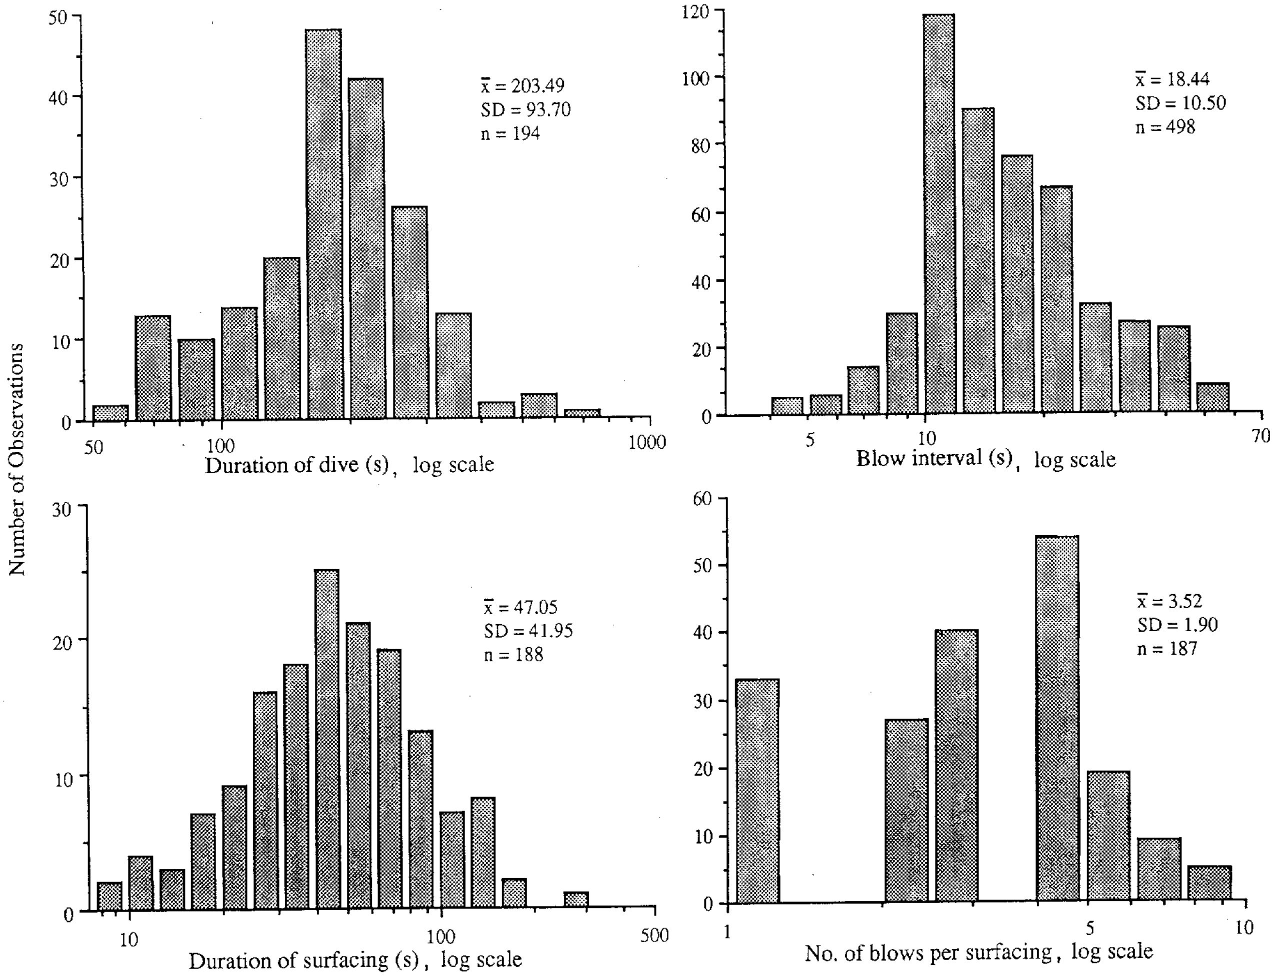

FIG. 2. Frequency distributions of the dive, respiration, and surfacing divisions. The $\bar{x}$ and SD are the observed measurements and are not log transformed numbers.

slowly rather than moderately ($t = 3.91$, df = 173, $p = 0.0001$). During float, dive duration was longer than that of swim moderate ($t = -4.81$, df = 44, $p = 0.0001$) and swim slow ($t = -2.47$, df = 161, $p < 0.02$). The blow interval during swim moderate was longer than the blow intervals in float ($t = 2.91$, df = 81, $p < 0.005$) and swim slow ($t = -8.77$, df = 427, $p = 0.0001$). While floating, however, the whales had longer blow intervals than they did during swim slow ($t = -2.95$, df = 396, $p < 0.004$). Sample sizes for swim fast were too small for statistical analysis in all four divisions. For duration of surfacing, float sample sizes were also too small for analysis and there was no significant difference between swim slow and moderate. No significant differences were found among locomotions for number of blows per surfacing.

Discussion

A dive pattern of one long dive followed by a surfacing sequence of one or more shorter dives (blow intervals) was constant throughout all the observed behaviours. There was undoubtedly a real distinction between long and short dives. This distinction becomes apparent by inspecting the frequency distribution of all observed dive durations. An apparent break in dive duration occurred at 60 s. This break could have been a chance sampling effect, but it correlated well with the observed behaviours. This study, therefore, used 60 s as the division between long and short dives. In Harvey and Mate's (1984) study of gray whale diving patterns, they also used 60 s as the division between long and short dives. After a long dive, the whales produced a sequence of blows separated by short, and doubtless, shallow dives. It is the overall duration of this surface sequence that is summarized in the duration of surfacing column in Table 5. It appears that gray whales must conform to a respiratory pattern of one long dive followed by one or more shorter dives and that the observed variability in respiration patterns can be correlated with the behaviours. Although the respiratory patterns observed in this study were those of summering gray whales, they appear to correspond with the "clumped" dive patterns observed by Harvey and Mate (1984) in gray whales wintering in Mexican lagoons, between southward and northward migrations.

For most frequent behaviours, locomotions, and contexts, coefficients of variation indicated that behavioural variability was high. This may reflect individual variability in behaviour patterns; nevertheless, some behaviours and contexts appeared more variable than others. For example, milling and floating did not appear goal oriented or directed and had the highest overall variability in respiration patterns. The more specific and directed behaviours like circling and pluming were less variable. Circling and pluming had extremely similar numbers in all four dive characteristic divisions. Both had the lowest overall behavioural variability of any locomotion or context. Their similarity reflects that these observations are probably the same and were only separated into different contexts because mud was not always visible.

While observing the whales, distinguishing between the different contexts and locomotions was not difficult. It was obvious when the whales were in transit, since they swam in a straight line and out of view. Circling and milling also appeared different from one another. Aside from significant differences in the number of blows per surfacing, it was obvious when the whales were circling as opposed to milling. During milling, the whales surfaced facing numerous directions, which they did not do during circling, and they also utilized a much wider area. Floating was also obvious because the whales did not move forward. In addition, significant differences in dive duration and blow interval were observed between swimming slowly and moderately.

My observations indicated that behaviours could be split naturally into two different groupings: context and locomotion (locomotive–context categories). Statistically significant differences between contexts were found for measures of dive duration, blow interval, and number of blows per surfacing; significant differences among locomotions were found for duration of dive and blow interval. Since I was unable to compare my observations with those of a second observer working independently, the reliability of the behavioural groupings needs to be established. Nevertheless, I believe that the differences between the various context and locomotive categories are real and provide a more refined and biologically meaningful view of previously defined behaviours (i.e., feeding).

Some specific behaviours and less goal-oriented behaviours appeared to be functionally related and usually occurred together. The best example was swim moderate – milling and swim moderate – circling. These two behaviours were seen numerous times as shown by one whale (Table 5). Although swim moderate – milling could happen alone, swim moderate – circling always occurred during swim moderate – milling. Swim moderate – milling had the highest variability in dive duration times of any behaviour. Swim moderate – circling had the second lowest dive duration variability. Duration of surfacing was also more variable during swim moderate – milling than during swim moderate – circling. When these behaviours occurred together, the whale would mill for five or six sets within a restricted area and then spend one or two sets circling at a specific location. This pattern of highly variable milling sets followed by a short series of less variable circling behaviours was repeated by this whale, sometimes for hours. Five other whales exhibited the same behaviour pattern using similar paired behaviours. Three of these whales used swim slow – milling with swim slow – circling and the remaining two used swim slow – milling (occasionally with pluming) with swim slow – circling with pluming. In all cases, the duration of dives and surfacings were more variable during milling than circling. From this behaviour pattern, it can be hypothesized that during milling, the whales appeared to be searching for a specific feeding site or object. When the feeding site was located, the whales began to circle and dive at this location. When pluming was observed, the whales were probably feeding. Even if mud was not observable, the whales still could have been feeding or perhaps verifying that this was an appropriate feeding site.

During circling, circling with pluming, and milling with pluming, the whales were apparently feeding. True feeding could not be verified and instead apparent feeding was divided into the three observable contexts. Pluming is a strong indication that the whales were bottom feeding and is associated with two of the feeding contexts. Mud patches and plumes have been reported during apparent feeding activity (Dohl et al. 1983; Harrison 1979; Hatler and Darling 1974; Norris et al. 1977; Wilke and Fiscus 1961), but most behavioural descriptions are general and do not include dive times. Two exceptions are Oliver et al. (1984) and Würsig et al. (1986), both of whom observed summering gray whales producing mud plumes and apparently feeding. The number of blows per surfacing, duration of surfacing, and dive duration were recorded. The locomotion and swim patterns were described as milling; circling was never mentioned. The dive times for these animals, therefore, could have reflected both milling and circling. Nerini (1984), in a review of gray whale feeding activities, concluded that whales feeding during migration or summering usually consume benthic resources, such as several species of amphipods and isopods. Because pluming has been associated with bottom feeding, the apparent feeding observations in this study support Nerini's conclusions and the summering gray whales observed pluming were probably bottom feeding. Feeding, however, may also take place without obvious pluming.

Circling (without pluming) was also associated with feeding. Although the whales appeared to be feeding exclusively on benthic organisms, it is possible that during circling they may have been feeding near the surface or thoughout the water column. Guerrero (1989) described the significantly different surface behaviours observed in gray whales feeding on benthic amphipods (*Ampelisca agassizi*) and free-swimming mysids (*Neomysis rayii*). The whales feeding on benthic amphipods dove and surfaced for longer periods and respired more times during surfacings than the whales feeding on swarms of mysids. In addition, respiratory patterns of mysid-feeding whales did not differ greatly from those engaged in nonfeeding activities, i.e., travel. The whales in this study exhibited similar respiratory patterns during apparent feeding activities, including circling (without pluming). There was a tendency for their dives and surfacings to be longer, with an increased number of blows per surfacing during apparent feeding activities than during nonfeeding activities. Guerrero also reports that during feeding on mysids, the whales she observed would initiate dives by rolling onto the side and exposing only one fluke. This did not occur with the whales feeding on benthic amphipods nor with the whales in this study. The feeding activities of the whales in this study, therefore, were probably oriented towards the sea floor rather than throughout the water column.

Although swim moderate – circling was observed only four times in one whale, on average this whale spent three times longer at the surface during swim moderate – circling than other whales did during swim slow – milling. Circling was observed to be associated with sea floor disturbances (swim slow – circling with pluming) and has been observed during feeding in other gray whales (Nerini 1984; Pike 1962; Sund 1975). The increased time spent at the surface during this behaviour may reflect the need to manipulate (i.e., swallow, spit out, sort out, etc.) the material obtained from the seabed. (It may also reflect individual variability in behaviour.) Although pluming was not associated with swim moderate – circling, the ingestion of food was still possible. A more likely possibility is that dives during swim moderate – circling may be more strenuous than those of swim slow – milling. A longer recovery period could be needed at the surface before another attempt is made at circling. Würsig et al. (1986) reported similar findings in feeding gray whales, which had longer dive and surface durations and more blows per surfacing than nonfeeding whales. Duration of surfacings and dives and the number of blows per surfacing have also been found to be correlated positively with water depth not only in gray whales (Würsig et al. 1986) but also in bowheads (*Balaena mysticetus*) (Würsig et al. 1984) and humpbacks (*Megaptera novaeangliae*) (Dolphin 1987*a*, 1987*b*). In this study, however, water depth was not measured and the whales did not show an increase in dive duration or number of blows per surfacing during apparent feeding.

Except for apparent feeding behaviours, almost all the remaining behaviours were seen at each observation site. Circling and pluming, however, were seen only in the Big Lagoon – Patrick's Point area. Hatler and Darling (1974) suggest that significant feeding grounds for gray whales may not exist south of Vancouver Island. Milling and apparent feeding, however, were the majority of behaviours observed at Patrick's Point, and of the four observation sites, Patrick's Point appeared to be a bottom feeding area for the summering gray whales.

The areas chosen as observation sites for this study were reported by Dohl et al. (1983) to be occupied by small groups of summering gray whales. The groups were indeed small and only once did I see more than two to three individuals during a sighting. This resulted in a low but adequate sample size. Opportunistic sightings between observation sites indicated that the whales transit between these areas and may utilize a large portion of the coastline rather than only a specific area. I am currently photographically identifying the summering whales to see if they utilize more than one area and if the same individuals return each year. One individual whale was sighted during each of the three summers I collected data and at different observation sites (twice at Patrick's Point – Big Lagoon area and once near Point St. George). This indicates that some whales may not only return to their previous summering grounds but also utilize a large portion of the coastline.

During transit, surface time was highly variable (Table 5). The whales were observed making a consistent forward progression and a high surface time variation was not expected for such a steady pace. The dive characteristics indicated that transit was not as directed as it appeared during observation. Transit may be undirected because all that is required is travelling from point A to point B. How the whales accomplish this may not be a specific process. Transit was associated with near-shore travel along the coastline and occasional observation of terrestrial landmarks may aid the animals in navigation. An increase in surface time variability would be expected under these circumstances, but behaviours such as spy hopping, which may increase long distance viewing of terrestrial reference points (Daugherty 1972; Pike 1962; Walker 1971), were never observed. The observation sites, however, were high bluffs and headlands that could be seen easily if the whales were looking for landmarks.

All calculated swimming speeds were grouped into three gross categories: swim slow ($0.5–1.0\,\mathrm{km \cdot h^{-1}}$), swim moderate ($3.0–4.0\,\mathrm{km \cdot h^{-1}}$), and swim fast ($7.0–8.0\,\mathrm{km \cdot h^{-1}}$). (Floating and its variations have been omitted here; see Table 1.) During observations, the different speed categories were easily distinguishable. Because distance from shore was estimated subjectively, the calculated swimming speeds are only estimates. They indicate, however, that the speeds of each category are different from one another, a difference that could be appreciated visually. Although many gray whales probably do not limit their swimming speeds to these categories, a tendency may exist for gray whales to utilize only certain ranges of speed. Mate and Harvey (1984) reported that gray whales average $127\,\mathrm{km \cdot day^{-1}}$ ($5.3\,\mathrm{km \cdot h^{-1}}$) during the last 29 days of the northward migration. During most of the migration, however, the whales average $85\,\mathrm{km \cdot day^{-1}}$ ($3.5\,\mathrm{km \cdot h^{-1}}$), which is within the swim moderate category range. Gray whales appear to swim faster during the southward migration at an average speed of $2.0\,\mathrm{m \cdot s^{-1}}$ ($7.2\,\mathrm{km \cdot h^{-1}}$) (Sumich 1983). The summering whales in this study displayed behaviours not usually associated with migration, but their swimming speeds could be categorized into distinct groups with swimming speeds similar to those observed in migrating animals. Why gray whales would swim within certain speed ranges is unknown. Perhaps swimming metabolism is more efficient at certain speed ranges and the whales tend to stay within them.

During the past observations of summering gray whales, I observed that their flukes would occasionally be lifted above the water surface as the animals began a long dive. This behaviour is common in migrating gray whales (Leatherwood et al. 1982). Observations of flukes raised above the water surface were recorded and found to be a reliable indication of when a surface–dive sequence ended (the beginning of a long dive). When raised flukes occurred, they were always at the end of a surface–dive sequence. The whales, however, did not always lift their flukes before a long dive. Occasionally, the flukes did not come out of the water completely and instead a severely arched peduncle was observed at the end of a surface–dive sequence.

Flukes were seen most frequently during apparent feeding and floating behaviours but almost never during transit. When the flukes were lifted above the water, the animals appeared to be entering a steep dive in which their bodies became almost perpendicular to the sea floor. W. J. Richardson (personal communication), however, observed similar behaviour in bowheads where raised flukes were seen when they dove in water only 4–5 m deep, less than half their body length. Raised flukes, therefore, may not be indicative of deep and near vertical dives in gray whales. Raised flukes, however, seem appropriate during feeding but unusual for floating animals. Float surface – dive sequences occurred independent of apparent feeding and tended to occur in a series. Flukes were seen rarely, indicating that the animals were actually resting. The frequency of flukes observed in float–circling and float then swim slow – circling, however, was the same as in apparent feeding behaviours. These two floating behaviours occurred occasionally during apparent feeding and never in a series. Under these conditions, the whales appeared inactive but were probably engaged in apparent feeding activities. Because transiting animals rarely show their flukes, they probably take shallower and most certainly less inclined long dives than during apparent feeding. Making shallow dives is consistent with whales that seem intent on travelling from one area to another.

In summary, locomotive–context categories, in conjunction with dive characteristics, has helped refine broad behavioural definitions and quantify several basic gray whale behaviour patterns not reported before this study. (*i*) Behaviours that did not appear goal oriented or directed, i.e., milling and floating, had highly variable dive characteristics. More specific behaviours, such as circling and pluming, were less variable. (*ii*) Some specific and less goal-oriented behaviours appeared functionally related and usually occurred together, i.e., swim slow – milling and swim slow – circling. (*iii*) Feeding was composed of at least three observable behaviours: circling, circling with pluming, and milling with pluming. Even an obvious behaviour such as floating had several variations. (*iv*) The Big Lagoon – Patrick's Point area appeared to be a main feeding site for many gray whales summering off the northern California coast.

Acknowledgments

I thank Dr. Nick Lerche and Dr. Mari Golub for their statistical suggestions and support, and thanks to Dr. Bill Mason, Dr. Michael Owren, Dr. Karen Ebeling, and Dr. Jim Donald for constructive criticism of earlier drafts of this paper.

---

ABSTRACT: Gray whales *Eschrichtius robustus* forage in parts of Clayoquot Sound on several prey species in different habitats. Between June and September in 1996 and 1997 we carried out analyses of the density, biomass, and other measures of their primary prey species, and of whales' movement patterns in response to prey characteristics. The prey base consists of hyper-benthic mysids (family Mysidae), pelagic porcelain crab larvae (4 spp. of family Porcellanidae), benthic amphipods (family Ampeliscidae) and benthic ghost shrimp *Callianassa californiensis*. Whales foraged primarily for mysids, switching to porcelain crab larvae in August, and then to amphipods even later in the season when these organisms increased in body size. In 1997, whales rapidly switched from feeding on planktonic to benthic prey during mid-August. Sampling indicated low numbers of mysids and crab larvae at that time. Selection of amphipod prey was based on high biomass and a high proportion of individuals ≥6 mm in length. In parts of the study area gray whales did not return to forage on benthic amphipods when this size criteria was not met. A single whale departed from a ghost shrimp feeding ground because its search time for food was long, it achieved only a low biomass removal rate, and it was not able to find sufficient food each day. We show that gray whales are dynamic and selective foragers that switch prey and foraging tactics rapidly to take advantage of short-term availability of energy.

KEY WORDS: Gray whale · *Eschrichtius robustus* · Prey selection · Prey-switching · Plankton · Benthos · Clayoquot Sound

INTRODUCTION

The primary foraging strategy of baleen whales is to locate dense concentrations of prey, since they cannot obtain their daily caloric requirements by feeding in areas of average food abundance (Nemoto 1970, Brodie 1977, Murison & Gaskin 1989). The foraging strategy of gray whales *Eschrichtius robustus* is similar. This species is predominantly a high-Arctic migrant which takes advantage of rich benthic amphipod beds. Numerous observations of gray whales along their migration route between Baja, Mexico and the western Arctic seas report opportunistic foraging along the west coast of North America (Howell & Huey 1930, Walker 1949, Pike 1962, Pike & MacAskie 1969, Rice & Wolman 1971, Hudnall 1983, Norris et al. 1983, Oliver et al. 1983, Murison et al. 1984, Nerini 1984, Sumich 1984, Guerrero 1989, Calambokidis et al. 1991, Weitkamp et al. 1992, Duffus 1996).

Apart from the more recent reports, these studies considered such opportunistic foraging events to be sporadic and transitory. However, as the total population of gray whales reaches estimated historic levels, more whales are at least temporarily abandoning their migratory habit and foraging in habitats along their migration route, taking advantage of whatever prey they encounter that is energetically 'profitable'. When feeding aggregations of whales become large stable associations with many individuals returning to spe-

cific sites, these groups are equivalent to populations, but not with the same demographic status as biological populations, since they are unlikely to comprise distinct breeding entities. Short-term spatio-temporal grouping may be the most important focus for management. Human activities that affect gray whales, such as whale-watching, hunting by aboriginals and contamination, occur on scales much more applicable to the summer aggregation of whales described in this paper than to the larger Baja to Bering unit typically considered.

The consideration of smaller spatial units in the management of gray whales requires more detailed understanding of their ecology on the same scale. Thus, our objective was to document and analyze at least a part of the 'normal' ecology of gray whales *Eschrichtius robustus* on the west coast of Vancouver Island, Canada. In this region, aggregations of gray whales spend the boreal summer months feeding on an assemblage of invertebrate prey throughout central Clayoquot Sound. Since gray whales feed on a wide variety of prey items, important aspects of gray whale foraging behavior include prey choice, prey-switching, and the resulting habitat use patterns. While certain aspects of gray whale prey are known, such as abundance (Pike 1962, Moore et al. 1986), patchiness (Clarke et al. 1989) and availability (Gill & Hall 1983, Moore & Ljungblad 1984, Clarke et al. 1989), there is little information on prey-switching behavior or habitat use of gray whales feeding in Clayoquot Sound (Duffus 1996).

In this paper, we document those characteristics of their prey that affect whales' prey choices, their subsequent switching between prey items, and their use of prey habitats. We describe whale use of 5 prey habitats located in central Clayoquot Sound. The predominant prey types are hyper-benthic mysids (family Mysidae), pelagic porcelain crab larvae (family Porcellanidae), benthic amphipods (family Ampeliscidae) and benthic ghost shrimp *Callianassa californiensis*. We employed a quantitative sampling regime to estimate prey density, biomass and size in the various prey habitats. Estimates of these characteristics are linked to observations of whales' foraging patterns in the different prey habitats. By quantifying prey characteristics and whale observations simultaneously, we identified which specific characteristics of the prey caused whales to actively select them.

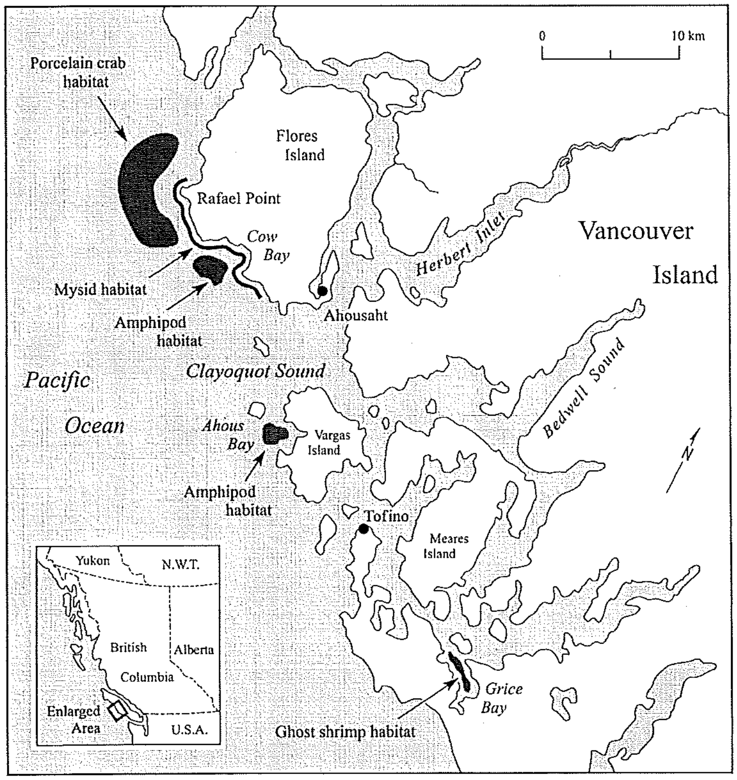

Fig. 1. Habitat of the gray whale *Eschrichtius robustus* and its prey in central Clayoquot Sound

METHODS

Study area. We classified 5 gray whale prey habitats in central Clayoquot Sound, British Columbia, based on observations from 1987 to 2000. The study area is a discrete unit bounded on each side by open deeper water and non-productive areas that are rarely, if ever, used by foraging gray whales. Prey habitats are distinguished according to distance from shore, type of substrate, and depth. Free-swimming porcelain crab larvae were collected >1 km from shore, over boulder substrate around Rafael Point (Fig. 1), in water depths between 10 and 30 m. Mysids were collected <1 km from shore near kelp beds and rock reefs on the south-southwest side of Flores Island, in water 0 to 15 m deep. Amphipods were collected from the sandy substrate that covers about 10 km^2 of the bottom of Cow Bay, in water 0 to 35 m deep. Amphipods were also collected from the fine-sandy substrate that covers about 8 km^2 of the bottom of Ahous Bay, in water 0 to 25 m deep. Ghost shrimp *Callianassa californiensis* were collected from littoral sand/mud flats in Grice Bay, in water <3 m deep.

Whale distributions. The number of gray whales observed foraging in the study area was recorded daily, and individual whales were identified in order to minimize the possibility of individuals being counted twice. In 1996, prey habitats were visited when sampling was conducted, when detailed whale respiration data were recorded, or when we were in transit between sampling sites. In 1997, a transect route was established along the southern and western shorelines of Flores Island. The transect passed through the mysid habitat along the shoreline of Flores Island, the amphipod habitat in Cow Bay, and the porcelain crab larvae habitat near Rafael Point. Vessel speed was constant (15 to 20 km h^{-1}) along the transect route. A minimum of 4 observers covered the 360° viewing area. In both years, we covered the entire study area daily, weather permitting, with the exception of the amphipod habitat in Ahous Bay and the ghost shrimp habitat in Grice Bay, which were not included in the transect route. We relied on periodic checks in both these bays and information collected by the local research coordinator Rod Palm (Strawberry Isle Research, Tofino) for dates of entry and departure of whales from the bays. Whale observations are standardized by the number of observation days.

Grice Bay is a shallow bay that enabled us to make detailed observations of whale foraging tactics and link them to prey characteristics. Feeding pits (n = 36) in Grice Bay were measured when they were exposed at low tide; only well defined pits with distinct edges were measured. Pit length (l) and width (w) were measured to the nearest 5 cm. Pit area was calculated as the area (a) of an ellipse, given by; $a = \pi\,[0.5\,(l) \times 0.5\,(w)]$. Foraging behavior was recorded as follows. The time from emergence of the pectoral fin as the whale rolled onto its side until the fin dropped down again as the whale righted itself was recorded as the time required to excavate a feeding pit. After the whale respired, it normally swam around for a short period of time until it again rolled onto its side to excavate another feeding pit. The time spent swimming after each ventilation until the whale stopped and rolled onto its side was defined as searching behavior.

Gray whales observed foraging in a particular habitat were assumed to be utilizing the prey type characteristic of that habitat. This assumption was based on analyses of whale feces, opportunistic and systematic plankton tows, core samples, SCUBA surveys, and underwater video records collected between 1993 and 2000. Crab larvae carapaces were collected in fecal samples. Both plankton samples taken near foraging whales and visual observation confirmed prey identity. Amphipods were the dominant organisms collected in benthic samples. Small amphipods were also collected in the sediment plumes of whales foraging in the amphipod habitat. Tows in the water column over these sandy bottom bays collected very little plankton. Clams and ghost shrimp constituted ≥98 % of the benthic biomass in Grice Bay, where there is little else upon which whales can forage.

Prey sampling. Prey sampling coordinates were determined using the Canadian Hydrographic Service Field Sheet No. 3603 (1996). Each prey habitat was divided by lines whose intersections created a minimum of 100 possible sampling coordinates. From these coordinates, 6 to 8 sampling sites were randomly chosen before each sampling period. In the field, a GPS was used to navigate the research vessel to each sampling site. During the 2 field seasons, each prey habitat was sampled at consistent time intervals between mid-June and early September. In 1996 samples were obtained semi-monthly, resulting in 5 sampling periods during the field season; in 1997 samples were obtained every 4 to 6 wk, resulting in 3 sampling periods. We collected samples adjacent to foraging whales in an opportunistic fashion. Foraging whales were defined as whales which remained within a restricted area of a particular habitat and exhibited constant directional changes in movement (Mallonée 1991).

We collected plankton samples with a 2 × 20 cm diameter bongo-style plankton net, 80 cm long, with 500 µm mesh size. A mechanical flowmeter (General Oceanics, Miami, FL, Model 2030R) determined the volume of water (m^3) to calculate standardized density and biomass estimates for the invertebrates. We collected porcelain crab larvae by towing the plankton net from the sea floor to the surface (max. depth = 30 m) in oblique tows through the water column. We collected mysids by towing the net horizontally along the bottom. Large samples were subdivided using a Folsom plankton splitter.

We used a 0.06 m^2 core sampler (WILDCO Ogeechee Sand Pounder) to collect benthic amphipods in Cow Bay and Ahous Bay. Sediment from each sample was rinsed through a 1 mm mesh screen to remove amphipods and other invertebrates. Amphipods were categorized into one of 2 size classes: individuals 0 to 5.9 mm in length were designated 'small' and individuals 6 to 11 mm 'large'. This classification follows with Rice & Wolman's (1971) analysis of the stomach contents of gray whales, where prey items measured >6 mm in length.

On July 15, 1996, we sampled 5 well-defined excavations created by 1 gray whale foraging in Grice Bay in order to quantify the density and biomass of ghost shrimp inside and outside feeding pits. We collected ghost shrimp with a section of PVC tubing 17 cm long and 10 cm in diameter. The tubing was pushed into the sediment and the core and sampler removed with a shovel. We removed 2 samples from inside and outside each feeding depression. Sediment removed from the depressions was rinsed through a 1 mm mesh screen on site, and ghost shrimp were retained. Two samples of sediment were retained to estimate the volume of sediment sampled.

We fixed all invertebrates in formaldehyde and stored them in 70% ethanol. Small individuals and species that were not known to be potential gray whale prey and that contributed very little to the overall biomass were not identified or counted. Biomass was measured to 0.001 g blotted wet weight.

We use both parametric and non-parametric tests to analyze our data. Significantly skewed data sets (Kolmogorov-Smirnov test, $\propto = 0.05$) were analyzed with non-parametric statistical tests.

RESULTS

Significantly fewer *Eschrichtius robustus* observations were made in the study area in 1996 (n = 171) than in 1997 (n = 363) ($\chi^2 = 69.03$, df = 1, $p < 0.05$; Fig. 2). In 1996, there were 2 d (August 10 and 11) on which no whales were observed and 19 d in which only 1 whale was observed (Fig. 2a). In 1997, whales were observed each day throughout the field season; on 2 d (July 28 and 29) only 1 whale was observed (Fig. 2b). Whales foraging on each specific prey type are discussed below.

Mysids

Mysids were the most consistently eaten prey during the 2 field seasons (Figs. 3a & 4a). In 1996, whales generally foraged for mysids between Cow Bay and Dagger Point on the northwestern margins of the study area; only on July 4 were 2 whales observed feeding near Fitzpatrick Rocks on the eastern margin of the study area. In contrast, in 1997, whales were consistently observed at Fitzpatrick Rocks between June 15 and July 19. Whales also foraged at Kutcous Point on the extreme eastern end of the study area between July 10 and 18; no whales were observed there in 1996. After July 19, whales suddenly abandoned the eastern sectors and moved to forage for mysids near Rafael Point.

The mean number of whales observed feeding in the mysid habitat at any one time was 2.6 in 1996 and 4.3 in

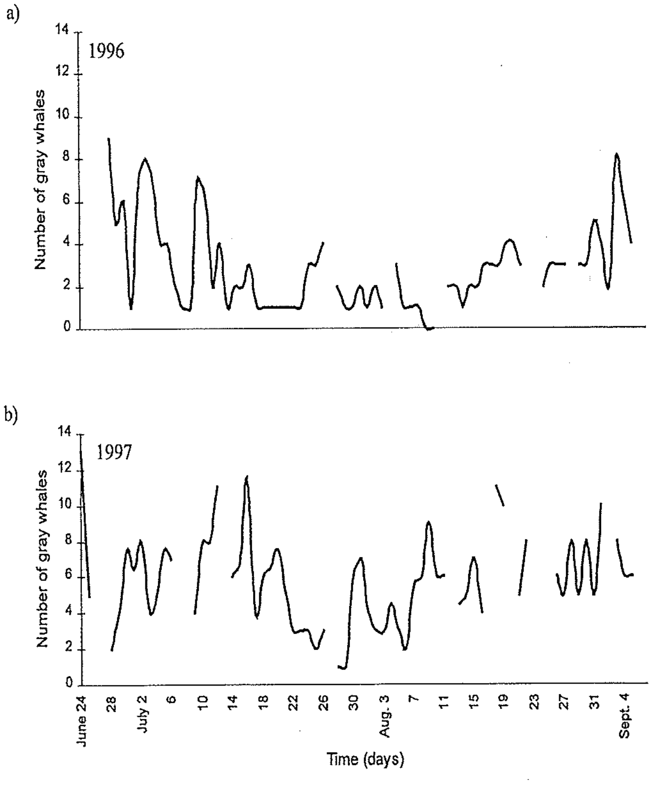

Fig. 2. *Eschrichtius robustus.* Daily numbers of gray whales observed throughout the study area in central Clayoquot Sound in 1996 and 1997. Breaks in lines are days on which no observations were made due to poor weather conditions

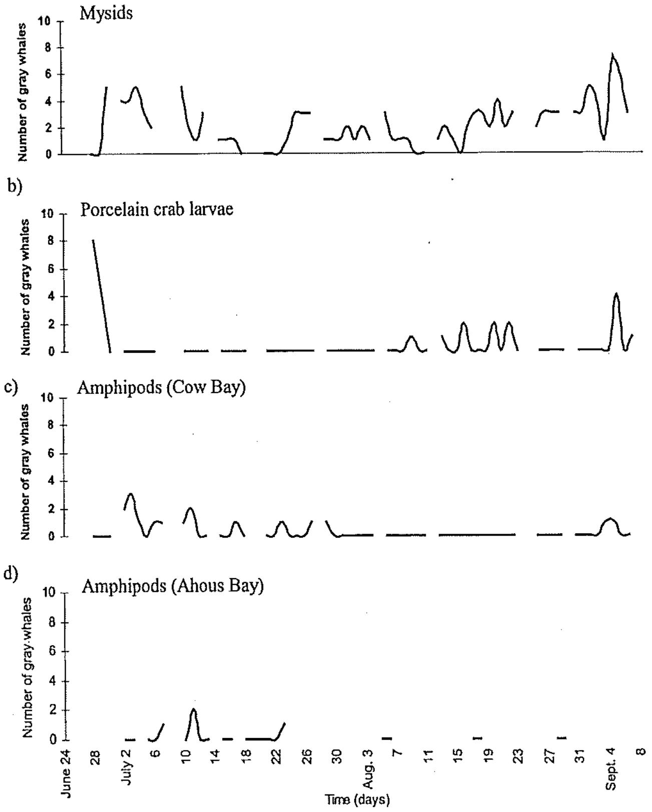

Fig. 3. *Eschrichtius robustus.* Daily observations of gray whales foraging in each of the 4 prey habitats in central Clayoquot Sound in 1996

1997 (Table 1). Results of our sampling tows suggest that mysid swarms were not as widely distributed along the shoreline of Flores Island in 1996 as in 1997. Mysid density was significantly lower in 1996 than in 1997 (Mann-Whitney *U*-test, $Z = -3.32$, $n = 59$, $p = 0.00$; Table 2).

When mysids were abundant, whales were present in larger numbers. The largest biomass of mysids (22.6 g m^{-3}) collected in the 2 field seasons was obtained on July 4, 1997. A larger number of whale observations ($n = 151$) were recorded around this date (between June 24 and July 23) than during the entire 1996 field season ($n = 131$) or after July 23 in 1997 ($n = 109$). Between June 24 and July 23, 5 to 6 whales (up to 10 individuals in 1 d) were observed each day foraging for mysids. The larger numbers of whales observed in the study area in 1997 foraged primarily for mysids (Fig. 4a).

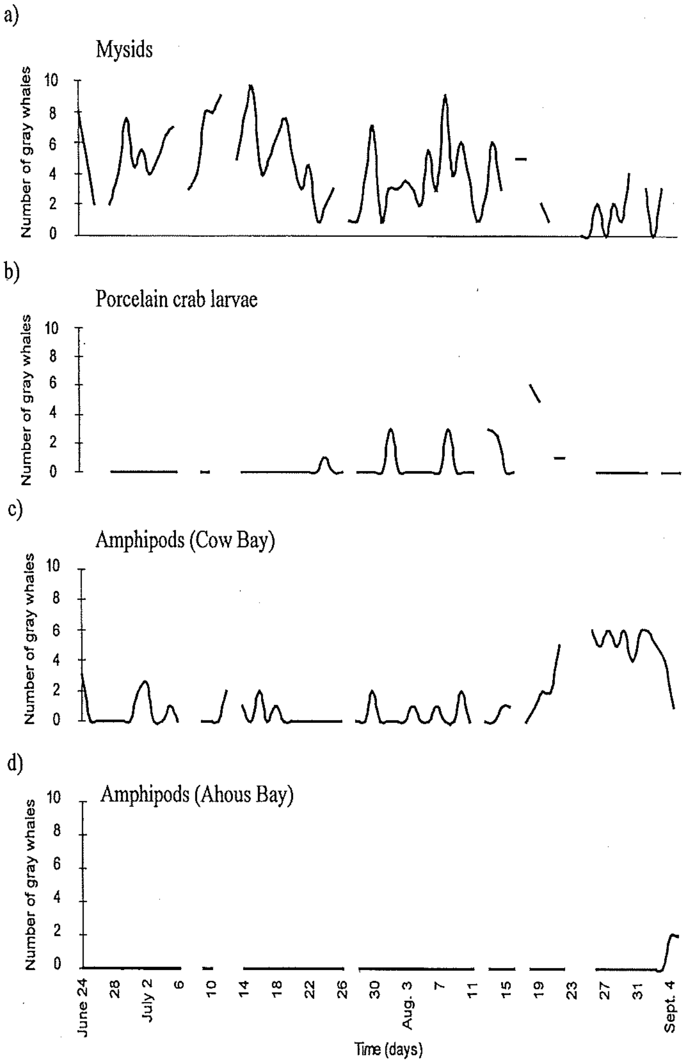

Fig. 4. *Eschrichtius robustus*. Daily observations of gray whales foraging in each of the 4 prey habitats in central Clayoquot Sound in 1997

Porcelain crab larvae

Gray whale presence in the porcelain crab larvae habitat was similar during the 2 field seasons. The proportions of whales foraging for crab larvae were similar in 1996 (17%) and 1997 (15%: Table 1) and the total number of whale observations ($n = 28$) made in crab larvae habitat in 1996 was similar to the number ($n = 26$) made in 1997 ($\chi^2 = 0.12$, $df = 1$, $p > 0.05$). The mean number of whales observed in the crab larvae habitat during each foraging episode in both years was identical (2.8 whales: Table 1). Crab larvae biomass was similar in 1996 and 1997 ($Z = -1.52$, $n = 25$, $p = 0.13$; Table 2), although density was significantly higher in 1997 ($Z = -2.16$, $n = 25$, $p = 0.03$; Table 2).

In 1996, 7 whale/crab larvae foraging episodes were recorded (Fig. 3b). Eight whales were observed foraging for crab larvae on June 28, falling to 4 individuals on June 29. On June 29 we obtained the highest density (10520 m^3) and biomass (16.7 g m^{-3}) of crab larvae collected in 1996. No whales were observed foraging for crab larvae between June 30 and August 8. During this period, crab biomass estimates ranged from 0 to 0.59 g m^{-3}.

In 1997, 6 whale/crab larvae foraging episodes were recorded (Fig. 4b). The maximum number of whales that foraged in the crab larvae habitat was 6 whales on August 18. On this date, the highest density (13198 m^3) and biomass (20.6 g m^{-3}) of crab larvae were obtained. No whales were observed foraging for crab larvae between June 24 and July 23 and after August 25. During these periods porcelain crab larvae biomass estimates ranged from 0 to 0.07 g m^{-3}.

Table 1. *Eschrichtius robustus*. Observations of gray whales foraging in each prey habitat in central Clayoquot Sound in 1996 and 1997. % of days: % of days whale(s) observed foraging in each prey habitat; no. observed: mean (±SD) no. of whale(s) observed foraging simultaneously

Prey	1996 (Jun 28–Sep 9)		1997 (Jun 24–Sep 7)	
	% of days	No. observed	% of days	No. observed
Mysids	85	2.6 ± 1.5	94	4.3 ± 2.3
Porcelain crab larvae	17	2.8 ± 2.1	15	2.8 ± 1.8
Amphipods in Cow Bay	18	1.4 ± 0.7	47	2.9 ± 1.9
Amphipods in Ahous Bay	13	1.3 ± 0.6	3	2.0 ± 0.0
Ghost shrimp	34	1.0 ± 0.0	0	0.0 ± 0.0

Table 2. Planktonic prey density and biomass near feeding *Eschrichtius robustus*. Data are means ± SD, and median inter quartile range [IQR] for 1996 and 1997

Prey	1996		1997	
	Density (m^3)	Biomass (g m^{-3})	Density (m^3)	Biomass (g m^{-3})
Mysids	10 [53] (n = 25)	0.32 [1.56] (n = 12)	175 [746] (n = 34)	1.43 [6.00] (n = 36)
Porcelain crab larvae	3006 ± 3718 (n = 17)	4.61 ± 6.09 (n = 17)	4726 ± 4598 (n = 8)	6.16 ± 7.54 (n = 8)

In general, whales foraged sporadically and for short periods of time on crab larvae. Observations of feeding whales indicated that crab larvae swarm in densities sufficient to attract whales for 2 to 3 d at a time. Gray whales generally foraged for crab larvae during August in both years (Figs 3b & 4b).

Proportions of the Zoea I and II larval stages determined for each sampling date in both years indicated that reproductive events for porcelain crabs occurred in August, at least in 1997. There was a large increase in the number of crab larvae in the Zoea I larval stage at the end of July, and a concomitant increase in the number of individuals in the Zoea II larval stage during the last 2 wk of August (Fig. 5). Reproductive events of *Pachycheles* spp. and *Petrolisthes* spp. at the beginning of August may have provided sufficient biomass to have attracted foraging gray whales throughout the month.

At particular times, gray whales were observed foraging in mysid and crab larvae habitats concurrently. In every case but one, not all whales left the mysid habitat to feed in the crab larvae habitat when crab larvae were sufficiently concentrated: whales normally spread out among the 2 food sources to forage. Mysid biomass (n = 36) in 1997 was similar to porcelain crab larvae biomass (n = 25) in 1996 and 1997 near foraging whales ($Z = -1.25$, $p = 0.21$; Table 2). In addition, maximum biomass estimates for mysids and crab larvae in both years were similar (22.6 and 20.6 g m^{-3} respectively). This suggests that when crab larvae were concentrated in patches a comparable amount of food was available for whales from the 2 prey types.

Only on June 28, 1996 did all 8 gray whales in the study area forage exclusively on crab larvae. The largest biomass estimate we collected during the 2 yr study was obtained on June 29, so there may have been an unusually large food source available during those 2 d.

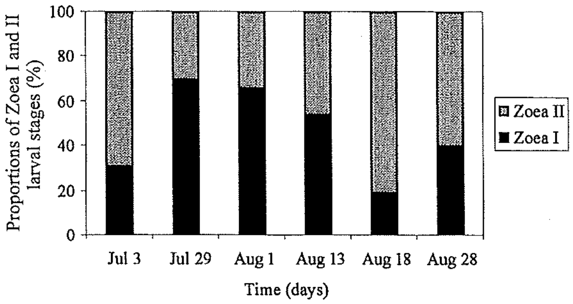

Fig. 5. Seasonal occurrence of Zoea I and II stage porcelain crab larvae, in central Clayoquot Sound, in 1997

Although quantitative sampling of the 2 types of planktonic prey indicate that there were comparable amounts of prey available to the whales, observations of the number and locations of feeding whales suggest that mysids were generally a more prevalent and consistent prey source than porcelain crab larvae (Table 1, Figs 3 & 4a,b).

Benthic amphipods

Between June 28 and September 9, 1996, we only occasionally observed gray whales foraging on the bottom in Cow Bay and Ahous Bay (Fig. 3c,d). In Cow Bay, no whales were observed foraging benthically between July 30 and September 3 (Fig. 3c). Whales that were observed in the bay did not remain for long periods of time; only on 2 occasions (July 2 and 3 and September 4 and 5) were whales observed foraging benthically for 2 consecutive days. In Ahous Bay, 1 or 2 whales were observed on July 7, 11 and 23, but these whales did not remain for more than 1 d in the bay (Fig. 3d).

In 1996, amphipod populations in Cow Bay and Ahous Bay were similar in terms of density ($Z = -0.79$,

Table 3. Characteristics of amphipods at sites where no *Eschrichtius robustus* were observed in 1996. Data are means ± SD

Characteristics	Cow Bay (n = 47)	Ahous Bay (n = 54)
Density (m^2)	16121 ± 20187	10654 ± 11741
Biomass (g m^{-2})	48 ± 54	36 ± 46
Length		
0–5.9 mm	3.4 ± 0.7 (n = 1257)	3.5 ± 0.8 (n = 870)
6–11 mm	7.9 ± 1.2 (n = 83)	7.7 ± 1.2 (n = 119)
Proportion		
0–5.9 mm	94	88
6–11 mm	6	12

n = 68, p = 0.43) and biomass ($Z = -1.04$, n = 67, p = 0.30; Table 3). 'Small' (0 to 5.9 mm) amphipods had similar mean lengths in both bays ($Z = -1.63$, n = 2127, p = 0.10), as did 'large' (6 to 11 mm) amphipods (Student's t-test, t = 1.17, df = 180, p = 0.24). Both bays had a high proportion of small amphipods and a corresponding low proportion of large amphipods (Table 3).

Table 4. *Eschrichtius robustus.* Gray whales observed foraging in each prey habitat before and after August 22, 1997. Total observation period was from June 24 to September 7. % of days: % of days whale(s) observed foraging in each prey habitat; no. observed: mean (±SD) no. of whale(s) observed foraging simultaneously

Prey	% of days		No. observed	
	Before Aug 22	After Aug 22	Before Aug 22	After Aug 22
Mysids	100	67	4.6 ± 2.3	2.3 ± 1.0
Porcelain crab larvae	17	8	3.1 ± 1.7	1.0 ± 0.0
Amphipods in Cow Bay	33	100	1.6 ± 0.7	4.8 ± 1.4
Amphipods in Ahous Bay	0	?	0.0 ± 0.0	2.0 ± 0.0
Ghost shrimp	0	0	0.0 ± 0.0	0.0 ± 0.0

Consistent bottom-foraging behavior by gray whales was only observed in Cow Bay in 1997. From June 24 to August 21 (49 observation days), between 1 and 3 whales were observed on 17 different days (approximately 1 in every 4 d) bottom-feeding in Cow Bay (Fig. 4c). However, on August 22 and 23, there was a rapid increase in the number of whales foraging on benthic prey in the bay. Between August 22 and September 4, 4 to 6 whales foraged continuously in Cow Bay on amphipods (Fig. 4c, Table 4). The maximum number of whales observed simultaneously feeding on benthic prey was 6.

Amphipod density (26 260 ± 23 716 m^{-2}) and biomass (73 ± 51 g m^{-2}) estimates (n = 34) obtained in 1996 from water depths ranging between 16 and 25 m were compared to density (11 054 ± 4151 m^{-2}) and biomass (113 ± 28 g m^{-2}) estimates (n = 21) obtained in 1997 from similar depths (between 18 and 24 m) near feeding whales. Although amphipod density was significantly higher in 1996 ($Z = -2.91$, n = 55, p = 0.00), biomass was higher in 1997 ($t = -3.28$, df = 53, p = 0.00).

Amphipod size changed as summer progressed. In 1996 in Cow Bay, amphipod density (ANOVA, F = 1.75, df = 31, p = 0.17), as well as biomass (F = 1.05, df = 31, p = 0.40), was similar between June 29 and September 2 (Table 5). 'Small' amphipods increased in length by 1 mm as the summer progressed (Kruskal-Wallis, χ^2 = 400.63, n = 1257, df = 4, p = 0.00; Table 5), but 'large' amphipods were not significantly larger over time (F = 1.47, df = 73, p = 0.22; Table 5). During the 2 field seasons in Cow Bay, amphipod density and biomass did not change between late June/early July and late August/early September. However, amphipod size did increase as summer progressed in both years: 'small' amphipods increased in size in 1996, whereas 'large' amphipods increased in size in 1997.

Amphipods also displayed size changes over time in Ahous Bay. In 1996, amphipod density was similar (F = 0.63, df = 35, p = 0.65), as well as biomass (F = 0.52, df = 34, p = 0.72), between July 2 and August 29 (Table 6). 'Small' amphipods increased in length by 1 mm as the summer progressed (χ^2 = 219.70, n = 870, df = 4, p = 0.00). In contrast, 'large' amphipods were not significantly larger (F = 0.41, df = 107, p = 0.80). In 1997, amphipod density (t = 2.02, df = 8.58, p = 0.08) and bio-

mass (t = 1.07, df = 12, p = 0.31) remained similar between July and September (Table 6). 'Small' amphipods were larger by 0.4 mm in September (Z = −4.56, n = 561, p = 0.00). In contrast, 'large' amphipods were not significantly bigger between the 2 sampling periods (Z = −0.42, n = 218, p = 0.68; Table 6). Therefore, during the 2 field seasons in Ahous Bay, amphipod density and biomass did not change significantly between early July and September. However, 'small' amphipods were larger later in the summer of both years.

Amphipod size may be important in determining gray whales' choices of benthic foraging grounds. Amphipod density (F = 0.20, df = 37, p = 0.82) and biomass (F = 1.78, df = 37, p = 0.18) at sites where whales were present in Cow Bay were similar to those at sites where whales were absent in Cow Bay and Ahous Bay (Table 7). However, amphipod sizes were significantly different between areas in which whales did and did not forage. 'Small' amphipods were significantly larger in Cow Bay, especially where whales foraged, than in Ahous Bay (χ^2 = 105.74, n = 879, df = 2, p = 0.00), and also 'large' amphipods were significantly larger in Cow Bay than in Ahous Bay, particularly in areas of Cow Bay where no whales were initially observed (χ^2 = 25.68, n = 671, df = 2, p = 0.00). Where gray whales foraged in Cow Bay, there was a higher proportion (61%) of large amphipods compared to similar-sized amphipods in Ahous Bay (29%; Table 7).

No gray whales were observed bottom feeding in Ahous Bay until September 4 (Fig. 4d). Two whales remained in the bay for at least 2 d, but we do not know whether they remained there for a longer period of time. Amphipods were, on average, smaller in Ahous Bay than in Cow Bay in July (Z = −8.99, n = 874, p = 0.00) and near the end of August/beginning of September (Z = −7.06, n = 266, p = 0.00). Not until September did amphipods in Ahous Bay attain the sizes that amphipods in Cow Bay had reached in July (Z = −1.01, n = 367, p = 0.31; Table 8).

Ghost shrimp

In 1996, a single gray whale foraged in Grice Bay. Seven days before this whale departed from the bay, significantly more ghost shrimp were collected outside (1170 shrimp) than inside (405 shrimp) feeding pits (paired t-test, t = −3.64, df = 9, p = 0.01), indicating a

65% removal rate by numbers. Ghost shrimp biomass was 30 g m^{-2} outside and 19 g m^{-2} inside feeding pits, indicating a 37% removal rate of biomass. This removal rate estimate, however, is not significant (paired *t*-test, $t = -0.98$, df = 9, p = 0.35). The mean dimension of feeding pits made by the whale was 2.9 ± 0.4 m long (mean ± SD), 2.0 ± 0.3 m wide, encompassing an area of 4.6 ± 1.0 m^2 (n = 36). An average of 54 g of shrimp were removed per pit. Ghost shrimp sizes inside (18 ± 18 mm) and outside (17 ± 17 mm) the feeding pits were not significantly different (Student's *t*-test, $t = 0.81$, df = 62, p = 0.42).

Grice Bay mud flats were only accessible to the whale during high tide. Generally, the tide level was high enough for the whale to forage approximately 12 h each day. It is unknown whether it foraged at night, but we assume that the whale could forage for 12 h each day. A whale requires between 400 (Nerini 1984) and 1200 kg (Zimushko & Lenskaya 1970) of prey each day. If 54 g of ghost shrimp biomass were removed from each feeding pit, then the whale would have had to create 7407 to 22222 pits in 12 h to attain the consumption 'estimates above', assuming that ghost shrimp are not an exceptionally high-yield prey. This means that the whale would have had to excavate a new feeding pit every 2 to 6 s.

The clam *Cryptomya californica* was so prevalent throughout Grice Bay that we thought this organism, in addition to ghost shrimp, might provide an important source of energy to the whale. If clam biomass was included in the whale's intake, then 302 g of clam biomass removed from each feeding pit would be added to the 54 g of ghost shrimp biomass, making a total ghost shrimp and clam biomass removal from each feeding pit of 356 g. In this scenario, the whale would have had to excavate between 1124 and 3371 pits in 12 h, meaning that a new feeding pit would have had to be created every 13 to 38 s to achieve the above consumption estimates.

To compare expected pit-making times, we made detailed observations of the whale on July 1, 21 d before its departure from the bay. The time required for the whale to excavate a feeding pit was 25 ± 11 s (n = 11). In general, 54% of the entire time period in which the whale was observed involved searching behavior, while 46% was spent feeding and breathing. This suggests that 34% of the whale's foraging time or 4.1 h per day was spent actively making feeding pits. Thus, the whale had time to excavate 598 feeding pits in 12 h, which equals one pit every 72 s.

Table 8. Comparison of amphipod lengths (means ± SD) in Cow Bay and Ahous Bay in 1997

Cow Bay		Ahous Bay	
Date	Length (mm)	Date	Length (mm)

Aug 20, 21	7.1 ± 2.1 (n = 177)	Sep 2	5.4 ± 1.9 (n = 138)
Jul 2	5.4 ± 1.7 (n = 339)	Sep 2	5.4 ± 1.9 (n = 138)

Benthic-pelagic prey-switching

Before August 22 in 1997, we observed gray whales foraging in planktonic prey habitats, primarily for mysids (Fig. 4a; Table 4). After August 22, the number of whales observed feeding in pelagic prey habitats decreased and the number of whales observed feeding in the benthic prey habitat in Cow Bay increased. More whales had not simply entered the study area to feed benthically; rather whales which had previously been feeding on planktonic prey switched to benthic prey (Table 4).

Reasons for gray whales switching from planktonic to benthic prey are either substantial increases in amphipod populations and biomass, or decreases in planktonic organism populations and biomass. Our data indicate there were no substantial changes in amphipod populations in Cow Bay as the summer progressed. Amphipod density ($F = 0.04$, df = 35, p = 0.96) and biomass ($F = 2.48$, df = 35, p = 0.10) were similar between July 2 and August 21 (Table 5). 'Small' amphipods did not increase in length as the summer progressed ($\chi^2 = 3.98$, n = 249, df = 2, p = 0.14). Only 'large' amphipods were significantly bigger (by 0.9 mm) in August ($\chi^2 = 66.54$, n = 408, df = 2, p = 0.00). Also, a higher proportion of 'large' amphipods was collected in August than in July (Table 5). Amphipod size, therefore, was the only variable that changed significantly as the summer progressed.

We believe decreased abundance of planktonic prey items played a bigger part than subtle changes in amphipod size to induce gray whales to feed on amphipods in 1997. No mysids were found in 12 plankton samples collected between August 19 and 31 at sites near Fitzpatrick Rocks where mysids had previously been sufficiently abundant to attract foraging whales. Whales had already abandoned this area when these samples were collected; however, several individuals were observed foraging in the mysid habitat about 10 km away at Rafael Point. The smallest number of whale observations (n = 18) was recorded in the mysid habitat between August 22 and September 7. In addition, crab larvae biomass was low (0.01 to 0.07 g m^{-3}) in samples taken on August 28. No whales were observed foraging in the porcelain crab larvae habitat after August 25 (Fig. 4b).

In contrast, during August and September in 1996, gray whales were observed foraging in planktonic rather than in amphipod prey habitats. Whales may have avoided amphipod habitats because mysids and, to a lesser extent, porcelain crab larvae were abundant during August and September. The maximum density of mysids (326 m^{-3}) collected during the 1996 field season was on September 1. Density of crab larvae collected on September 5 near 4 feeding whales was estimated to be 2776 ± 1761 m^{-3}.

DISCUSSION AND CONCLUSIONS

Mysids were the prey most extensively foraged by gray whales *Eschrichtius robustus* in central Clayoquot Sound between June and September. Although specific locations where mysids were collected changed, these invertebrates were always available at some sites along the shoreline of Flores Island. Since kelp forests fringe much of the gray whales' migration route south of the Bering Sea, mysids may be the most important prey in tertiary feeding grounds for these whales (Kim & Oliver 1989). Moreover, when their main feeding grounds were absent (Johnson & Nelson 1984) or inaccessible (Nelson et al. 1974, Hall 1980, Kim & Oliver 1989), the significance of mysids and invertebrates other than benthic amphipods to the gray whale diet was probably higher.

The occurrence of crab larvae has both life-history and spatio-temporal components (Knudsen 1964). Porcelain crab larvae may comprise more abundant or better-quality prey in nearshore waters at particular times, partially due to the hatching rhythms of *Pachycheles* spp. and *Petrolisthes* spp. Hatching increased for both genera of crabs between the end of July and mid-August. At first, the Zoea I larval stage was numerous in plankton samples. Then, 3 wk later, the larger Zoea II larval stage was more numerous. The 2 stages of *Pachycheles rudis* and *P. pubescens* last between 24–25 d (Knight 1966) and 34–40 d (Morris et al. 1980) respectively. Small-scale oceanographic events such as current and upwelling may also have served to concentrate these swarms in our study area at specific times.

Greater numbers of gray whales were consistently observed foraging at sites where planktonic prey was present in high densities and biomass. Whales were observed foraging for both mysids and porcelain crab larvae concurrently, indicating that they spread out between the 2 sources of food. This behavior is similar to Fretwell's (1972) ideal free-distribution concept, whereby competitors adjust their distribution in relation to habitat quality so that each individual enjoys the same rate of acquisition of resources (Krebs & Davies 1987).

The absence of gray whales from benthic prey habitats is usually explained by the availability of other prey such as mysids (Oliver et al. 1984, Kvitek & Oliver 1986, Guerrero 1989, Duffus 1996). In 1996, no benthic foraging was observed in late August/early September. At this time, planktonic prey were abundant and benthic biomass was generally low. In 1997, whales rapidly switched from planktonic to benthic prey in mid-August, at a time when planktonic prey were less abundant.

While prey density and biomass are linked quite distinctly to whale foraging, the predictability of prey may also be implicated. Distributions of planktonic organisms are less predictable in time and space than those of benthic organisms. It may be beneficial for whales to capitalize on planktonic species first, and forage on these ephemeral organisms when they are encountered. Whales may leave amphipod communities relatively undisturbed until planktonic prey are no longer abundant.

Like other predators, gray whales change their prey preference in response to their own estimate of the densities and profitability of each prey type (Sabelis 1990). Whales observed sporadically bottom feeding in the early summer months may have been exploring and sampling different prey habitats in order to assess the overall quality of food items available.

Size of benthic invertebrates may be an important variable controlling prey-switching behavior in gray whales. It may be beneficial for whales to forage for amphipods later in the summer because these organisms may improve as a food source as the summer progresses. Highsmith & Coyle (1990, 1992) found that the weight and caloric contents of Arctic amphipods increased during the summer, suggesting that energy-rich storage compounds such as lipids are accumulated in preparation for winter. We found that amphipods in Clayoquot Sound also increased in size as the summer progressed, but do not know whether their caloric content changed concurrently.

Since amphipod density and biomass were similar in Cow Bay and Ahous Bay in 1997, amphipod size may be the principal reason why gray whales initially did not bottom-feed in Ahous Bay. Amphipod size differed in 4 ways between Cow Bay and Ahous Bay: (1) there were more small amphipods in Ahous Bay; (2) their mean size was smaller than in samples collected near feeding whales and at other locations in Cow Bay; (3) there were fewer large amphipods in Ahous Bay than in Cow Bay where gray whales foraged; (4) large amphipods were smaller in Ahous Bay than in Cow Bay. Prey size and the mechanical limitation imposed by baleen 'mesh' size are important aspects of foraging decision-making by gray whales.

It is unclear which variables have more influence on prey-switching behavior in gray whales—characteristics of benthic prey populations such as biomass and individual size, or a decline in planktonic prey abundance. In 1997, whales had the opportunity to bottom-feed in Cow Bay throughout the summer, but generally foraged on planktonic instead of benthic prey. When whales switched to bottom-foraging behavior, amphipod density and biomass were not significantly different from those earlier in the summer; amphipod size was the only variable that had changed significantly during the season. These observations indicate that substantial changes in the benthic community were not a likely reason for gray whales switching between planktonic and benthic prey. Rather, the abundance of planktonic prey seemed to drive whales' prey choices.

Sabelis (1990) stated that prey quality is likely to be the ultimate cause of any behavioral change with respect to prey selection. However, differences in the quality of gray whale prey are difficult to measure because other variables are involved, including the energetic costs associated with capturing these prey organisms. Energetic costs are a function of diving depth and costs of specific foraging tactics. Gray whales are consistently characterized as benthic specialists, and in the high latitudes this may be so (Braham 1984). Animals spending the summer in Clayoquot Sound are predominantly pelagic foragers.

The solitary gray whale may have abandoned the ghost shrimp feeding ground in Grice Bay because 4 critical criteria which define foraging success were no longer fulfilled: (1) the length of time the whale had to search for food was too long; (2) it achieved only a low biomass removal rate; (3) ghost shrimp failed to supply the whale's minimum daily energy requirements; (4) the prey species preferred by the whale was no longer abundant.

Whale foraging in Grice Bay has aspects that require more study. This bay was not used by gray whales between 1984 and 1994; then, it was intensively used in 1995 by 5 whales, and sporadically in 1996 and 1997 by a single individual. Grice Bay is not easily reached; whales must traverse several narrow channels and intertidal mudflats to enter it. The small clam *Cryptomya californica* is abundant in the bay. Should this clam prove a useful energy source for whales, then this would make a significant contribution to the bay's attractiveness. Finally, the bay is shallow and whales do not have to dive for benthic prey, meaning lower energy expenditure; this may partly explain the discrepancy between the observed and the expected pit-making times.

The gray whales observed in central Clayoquot Sound were highly opportunistic foragers which preyed on concentrations of mysids, porcelain crab larvae, amphipods and ghost shrimp that were present in high density and biomass. Although mysid foraging predominated from June to September, porcelain crab larvae foraging was frequently observed during August. Benthic prey were also utilized by whales; amphipods fell prey to many whales, especially in 1997, whereas ghost shrimp were an important source of food for 1 whale only during the duration of this study.

Prey-switching behavior and prey-habitat selection in gray whales is probably influenced by 2 factors: a decline in the abundance of planktonic prey, and an increase in amphipod size which leads to a high proportion of the amphipod population being >6 mm in length. Data indicate that abundance of planktonic prey may be more important than benthic prey size in governing prey-switching behavior in gray whales.

While we can provide no insight into the decision-making mechanism of gray whales without more detailed experiments, our study indicates that less predictable (on the basis of availability) prey are preferred over more predictable prey. An ocean forager using very patchy resources (like most baleen whales) would be expected to be highly opportunistic and less selective; however, this small area within their range may provide an opportunity for whales to exhibit more complex foraging strategies. These strategies are an important aspect of the whales' presence in Clayoquot Sound and probably elsewhere in tertiary feeding grounds. With its return to pre-whaling levels, the eastern Pacific gray whale population has once again become a major resource for the recreational whale-watching industry and aboriginal hunters. Scientific management of these activities will require studies on the same scale as the present report to understand, and possibly predict, the spatio-temporal behavior of gray whales.

Acknowledgements. Research was conducted in the traditional territory of the Ahousaht First Nation. Thanks to Chief Earl George and the residents of Ahousaht. C. Malcolm, E. Hines, C. Tombach, S. Meier, H. Patterson, A. Bass, R. Palm, S. Frank, C. Joseph, D. Thomas, D. Frank and ORES volunteers assisted us in the field. J. Forde and W. Atleo provided us with logistical support. L. Hobson, Department of Biology, University of Victoria, provided access to his laboratory, and together with P. Dearden, and P. Lambert, Royal B.C. Museum and several anonymous reviewers, provided helpful comments on the work and this manuscript.

ABSTRACT

Hunting of whales has for over 1500 years been central to the identity, culture and subsistence of the Makah Indian Tribe. It was so important to the Tribe that when it ceded its aboriginal lands to the United States Government in the 1855 Treaty of Neah Bay, tribal leaders insisted that the right to harvest whales be protected for all time. Makah whale hunts continued until the mid-1920s, when commercial whaling operations had decimated the population. After the gray whale was delisted as an endangered species in 1994, the Makah Tribe announced that they intended to resume hunting whales. From the beginning, the Makahs' effort to exercise its right to whale has been met with much opposition. In addition to the resumption and revival of whaling, the Makah Tribe has, in conjunction with the National Oceanic Atmospheric Administration's (NOAA) National Marine Mammal Lab (NMML), studied gray whales in the Tribe's Usual and Accustomed fishing grounds (U&A) to increase understanding of whales feeding in the U&A during the summer and fall when most of the Eastern North Pacific stock is in the Bering, Beaufort or Chukchi Seas. During surveys in the U&A, gray whales were frequently observed at an average depth of 10 m in rocky habitats and were observed to shift distribution in mid fall from feedings sites in both the Pacific Ocean and Strait of Juan de Fuca to predominately the Strait. The number of gray whales observed per hour of survey effort is dynamic by year and season. From 1993 to 2009, 189 unique whales were seen in the Makah U&A. An average of 12.7 new whales were seen in the Makah U&A survey area during each year. Of these an average of 5.6 individuals returned and were observed in subsequent years. On average, whales seen in the Makah U&A survey are seen for a short duration in terms of years observed and time span of observations within a year. The duration of time a whale was observed within the Makah U&A was positively correlated with the probability that the whale would be seen in the next year.

INTRODUCTION

The Makah Tribe resides on the Makah Indian Reservation which is located on the northwestern tip of Washington State. Unlike other Tribes of the Pacific Northwest which were located near productive salmon rivers, villages of the Makah Tribe were located near marine waters abundant in marine mammals. The Makah Tribe utilized marine mammals as a source of food, economy, fuel, and building materials for at least 4,500 years (MCRC, 2006). Archeological findings show the Makah Tribe has harvested whales for at least 1,500 years before present; the primary species of harvest was gray and humpback whales (Renker, 2007). It is possible that the Tribe harvested whales for a longer period of time, but hunting tools made from wood and shell in earlier years have decayed too much to show definitive evidence of hunting. Marine mammals are central to the culture of the Makah Tribe and, as such, are highly revered species (Huelsbeck, 1988; Renker, 2007).

In 1855, the Makah Tribe signed the Treaty of Neah Bay with the United States Government. Treaties were a means for tribal governments to protect or reserve rights most important to them while ceding land and other rights to the United States. Sealing and whaling were so important to the Makah Tribe for their economy, sustenance, and culture that leaders made sure such rights were reserved. The Makah Tribe is the only tribe in the United States with explicitly protected rights to harvest marine mammals. Whale hunts were suspended in the 1920s due to the severe impacts of commercial whaling on gray and humpback whale stocks despite the great importance of whale hunting to Makah culture and subsistence (Renker, 2007).

The US Government removed the gray whale from the Endangered Species List in 1994 after concluding the population was robust and neither in danger of extinction or likely to again become endangered in the near future (Rugh *et al.* 1999). With the recovery of the gray whale population, the Makah Tribe decided to resume exercising its whaling rights. The US Government asked the Tribe to delay its hunts until an aboriginal subsistence quota could be obtained from the International Whaling Commission (IWC). At the 1997 annual meeting, the IWC approved a shared gray whale quota for the United States and Russia to meet the needs of the Chukotkan Natives of Russia and the Makah Tribe.

Domestic animal welfare groups claimed that despite centuries of hunting in the U&A, a Makah hunt could disproportionately impact gray whales that feed in the vicinity of the Reservation during the summer and fall when most of the Eastern North Pacific stock is in the Bering, Beaufort or Chukchi Seas. The gray whales utilizing feeding sites on the Pacific Coast have been referred to under many names, including summer resident and Pacific Coast Feeding Aggregation, but are now officially recognized by the IWC as the Pacific Coast Feeding Group (PCFG) (IWC, 2010). Whales considered part of the PCFG presently include animals that feed during the summer and fall months from northern California to southeastern Alaska. In the 1990s the US government initiated research to assess the potential impact of a tribal hunt on these whales. In 1993 and 1994 NOAA Fisheries' National Marine Mammal Laboratory (NMML) photographed gray whales incidental to harbor porpoise and Steller sea lion studies. In 1996, NMML started rigorously monitoring the gray whales around the Makah Reservation on an annual basis through photo-identification research; staff of Makah Fisheries Management often assisted this research. These efforts were aided by the involvement of Cascadia Research

Collective (CRC) which contracted to review photos collected by NMML and other collaborators to compare to their catalogue of gray whales photographed south of Alaska.

Using data collected by NMML, the Makah Tribe established time and area closures to minimize the potential that PCFG whales would be harvested. In 1999, the Tribe harvested its first gray whale in over seventy years. Domestic legal challenges from 1999 through 2004 put the hunt on hold until NOAA analyzed the impact of the hunt on the PCFG whales and granted a waiver under the Marine Mammal Protection Act. That administrative process is ongoing. In 2004 the Makah Tribe hired a marine mammal biologist to research gray whales in the U&A. Since 2004, the marine mammal biologist has conducted surveys both independently and cooperatively with NMML biologists. Research has been focused on whales from June through November, but research activities are conducted throughout the year. Presented in this paper is a summary of findings from research of gray whales in the Makah U&A from 1993 to 2009 with an emphasis on sightings between 1 June and 30 November.

METHODS

Study Area

The Makah U&A is located on the Northwest tip of Washington State, United States of America. The boundaries of the U&A were adjudicated in a US court based on historic fishing practices and not marine mammal hunting (*United States v. Washington).* Whaling crews were known to travel 50 to 100 miles (80 to 161 km) offshore and spend multiple days on the water (Morse, 1897). If the Makah U&A boundaries had been determined by marine mammal harvest then they would be much different than the U&A boundary in Figure 1. However, the Makah whale hunt is limited to its U&A based on historic fishing locations.

The Makah U&A is encompassed by two bodies of water: the Strait of Juan de Fuca and the Pacific Ocean. The rocky shorelines are interspersed with sandy beaches. Rocky habitats are dominated by kelp forests of bull kelp for waters 5-15 meters of depth. The confluence of currents from the California Current and the drainage of Puget Sound through the Strait of Juan de Fuca make the Makah U&A very biologically productive.

Survey Methodology

Gray whale surveys of the Makah U&A were generally conducted over two back-to-back survey days. One day of surveys travels to the east of Neah Bay along the shores of the Strait of Juan de Fuca to Sekiu Point, approximately 25 km from Neah Bay. The other survey day travels west along the shores of the Strait of Juan de Fuca to Cape Flattery and then south following the shoreline of the Pacific Ocean down to Sea Lion Rock (47°59.58'N, 124°43.45'W). The total distance covered in the southbound survey is approximately 60 km. Sea Lion Rock is located south of the southern border of the Makah U&A (48°02.25'N). Surveys for gray whales were generally conducted within one to two kilometers of shore since gray whales summering in the Makah U&A often congregate around 10 meters of depth. Portions of the survey in the Pacific Ocean, particularly south of Cape Alava, are conducted further from shore due to poorly charted submerged rocks. Surveys were conducted with a 21 ft (6.5 m) rigid hull inflatable and a 24 ft (7.3 m) aluminum cabin cruiser made by Almar.

Surveys were attempted on a bi-weekly basis in the summer and fall as weather and ocean conditions allows. Surveys were also conducted in the spring and winter with lower frequency; results of this survey period are not included in this report.

During surveys, observers periodically note location, weather, sea state, and other variables that may influence the probability of sighting a whale. When gray whales are sighted, their location, depth, and activities are recorded. Observers then attempt to take photographs of both lateral flanks as well as the flukes if the whale is diving deep. Photographs are taken using a Nikon Digital SLR camera with a 70-300 mm lens (35 mm film cameras were used during the early years of this project). The lens magnification allows photo-documentation of unique coloration patterns on the lateral sides and flukes of the whales (Darling, 1984). The frame numbers from photographs taken are recorded on the field data sheet with the aforementioned sighting information.

Photo-Identification Methodology

All photographs of gray whales and field data are provided to CRC. The CRC research team identifies photographed whales as described in Calambokidis *et al.* (2010) and then sends the results of the identifications back to Makah and NMML researchers.

Mapping

ArcGIS version 9.0 was used to map all sightings of gray whales in the Makah U&A from Makah or combined NMML-Makah surveys from 1 June to 30 November of 2004 through 2009. The time period 1 June to 30 November marks the end of the northbound migration and beginning of the southbound migration, respectively. Data were filtered to facilitate mapping of sightings during each month (all years included) and for each year (all months included). Graduated symbol sizes were used to document the number of gray whales seen during each sighting.

Data exploration

Key data elements explored included several parameters related to gray whale counts and sightings of uniquely identified gray whales. CRC provided identification numbers for all gray whales identified from photographs taken by NMML and the Makah Tribe between 1993 and 2009 in a database that also included the date and location for each observed whale. NMML provided data on research effort from 2000 to 2009; NMML research effort from between 1996 and 1999 was determined from summary tables in Gosho *et al.* (2001). Survey effort and sighting locations and counts were maintained in a database for all Makah Tribe and combined NMML-Makah Tribe surveys. These data were used to analyze: 1) whales per hour of effort from the total effort in a given month and year and the number of whales observed in the same time period; 2) monthly and yearly sighting histories of identified whales to assess fidelity to the survey area; and 3) "minimum residency time" for each identified individual by year using the length in days between the first and last day a whale was seen during surveys from 1996 to 2009. The residency time estimate may be a minimum because it was possible that a whale was present before the first day (or after the last day) it was sighted during a given year. This estimate may also overestimate residency time because whales could have left the survey area for some unknown length of time between the first and last sighting of the year.

RESULTS/DISCUSSION

Research teams of NMML and the Makah Tribe combined for 487 dedicated surveys of the Strait of Juan de Fuca and 270 surveys of the outer coast of northern Washington from 1996 to 2009 (Table 1). In addition, earlier opportunistic surveys and collections of gray whale photos were conducted in 1993 and 1994 by NMML. Not all surveys had equal effort and opportunity to observe whales. Many were not completed to the terminal point of the survey at Sekiu Point in the Strait of Juan de Fuca or Sea Lion Rock on the Pacific coast of Washington due to weather, fog, mechanical failures, or conflicting objectives. All surveys with entered data were included in our analyses and are presented in Table 1. In total, 189 unique gray whales were identified from the CRC photo-identification catalogue of PCFG whales from surveys conducted in the Makah U&A from 1993 to 2009 in the months of June through November.

Gray Whale Counts

We analyzed the number of whales observed per survey hour by NMML and the Makah Tribe from 2000-2009 to assess monthly and annual use of the Makah U&A survey area. Gray whale use of the Makah U&A survey area during June to November was variable by both month and year (Table 2). Gray whale use had strong yearly variation in whales observed per hour of effort (ANOVA, p = 0.00387); for example, there was a ten-fold difference in whales per unit effort for 2000 as compared to 2008 (Figure 2). Whale use of the survey area was greater from 2004-2009 than for 1996-2000. More years of data need to be collected, but it does appear that gray whale use of the survey area is cyclical (Figure 2). A clearer pattern of use of the survey area was apparent when we assessed whales per hour of survey effort by month. The number of whales observed per hour of effort is low in June and July, peaks in September and plateaus in late fall (Figure 3). Pair-wise comparisons found that September has significantly more whales per hour of observation than June or July (T-test, p=0.004 and p = 0.003 respectively), while pair-wise comparisons of other months were not significant. The observed increase in whales per hour of effort following July coincides with a shift in distribution of whales from predominately in the Pacific Ocean to predominately in the Strait of Juan de Fuca. The high observed average number of whales per survey hour in the month of November is driven by 2008 when a large number of whales utilized the Strait of Juan de Fuca (Table 2).

There are caveats to interpreting data on the number of whales per hour of survey effort. First, the range of surveys was not consistent by year. Gray whales congregate near the harbor of Neah Bay. If only one half hour of survey effort is conducted it may increase the estimated whales per hour as compared to a survey that travels to Sea Lion Rock and crosses many sandy beaches where gray whales are rarely observed. Survey effort is also influenced by weather which could bias the results. Weather patterns in the fall often bring rough seas on the ocean versus the calmer ocean conditions observed in the entrance of the Strait of Juan de Fuca. The Strait of Juan de Fuca is much easier to survey and this shift in research effort may partially explain the large jump in observed whales per hour in the fall compared to the summer. The last caveat is that survey effort from 1996-1999 was taken from summary tables in Gosho *et al.* (2001) and it is possible that effort was summed for both travel on surveys away and returning to Neah Bay rather than just on travel away from Neah Bay as was used for data from 2000-2009. If this is correct, then whales per hour of effort would be doubled for 1996-1999 and whales per hour for those years would be more similar to observations in later years (Figure 2).

Spatial distribution of gray whale sightings in the Makah U&A survey area was only assessed from data collected on Makah Tribe or combined NMML-Makah surveys (2004-2009). Spatial distribution patterns of observed gray whales are variable by season and year (Figure 4 and 5). Variability is likely due to seasonal and annual availability of forage (Feyrer, 2006). For instance, there is a marked shift in distribution from summer to fall months during which whales appear to shift from using coastal ocean areas to areas in the Strait of Juan de Fuca (Figure 4). Larger aggregations of whales were seen in 2006 and 2008 than in other survey years (Figure 5). Some of the observed variability is due to survey effort. For example, prior to 2007, Makah Tribe researchers rarely went east of Kydaka Point (48°17.45'N, 124°21.82'W) or south of Sand Point (48°07.38'N, 124°44.19'W) whereas after 2007 it was standard for Makah survey effort to extend east to Sekiu Point (48°16.58'N, 124°18.15'W) and south to Sea Lion Rock (47°59.58'N, 124°43.45'W).

Most gray whale sightings occurred in waters between 8 and 15 meters of depth in areas that are characterized by rocky substrate and kelp forests composed of *Macrocystis sp*. or *Nereocystis sp*. (Berry *et al.* 2005). This depth range coincides with the depth range of mysid shrimp (Nelson *et al.* 2009). Mysid shrimp have been reported to be the primary food source for whales near Vancouver Island (Dunham and Duffus, 2002; Olsen, 2006) and it is likely mysid shrimp are also the primary prey species in the Makah U&A. In 2009, gray whales were observed foraging in 30-35 meters of water at the southern extent of the survey area near Carroll Island and Sea Lion Rock; it is not known what these whales were foraging on as these depths are deeper than mysid shrimp are likely to be found.

Uniquely identified gray whales

Fifty-two percent of whales observed between 1 June and 30 November in the Makah U&A from 1993-2009 were only observed in one year (Figure 6, Table 3). In comparison, Calambokidis *et al.* (2010) found that 80% of whales observed between 1 June and 30 November have been seen in subsequent years within the larger and encompassing range of the PCFG. Comparing the 1993 to 2007 data from the Makah U&A survey area to the CRC catalogue of PCFG whales seen through 2008 yields a more similar result of 82% of whales seen were seen in multiple years within the PCFG.

Assessing site fidelity in the Makah U&A is challenging. On average, whales were only observed in 2.2 of the 14 dedicated survey years. When whales only seen in one year were excluded from the analysis the average number of years observed increased to 3.5 of the 14 years with dedicated survey effort. Gray whales seen in more than one year also have an average period of 2.2 years in which they are not seen between subsequent years sighted. Some whales are not seen in the Makah U&A survey area over long periods of time before being sighted again. For example, CRC 94 had a 14 year gap between subsequent resights and two other whales had a nine-year gap.

The majority of whales (78.9%) photographed in more than one year were seen in consecutive years within the Makah U&A survey area. The longest observed consecutive tenure of a whale in the Makah U&A was seven straight years (CRC 92, Table 3);

interestingly this whale also had a consecutive period of four years in which it was not observed. In total, this whale was observed nine years in the survey area.

The number of days between the first sighting of a whale in the Makah U&A and when it is last sighted during dedicated survey effort in a single year (hereafter called "minimum residency time") is likely a function of both survey effort and other factors (e.g., foraging success) which in turn influence whale site fidelity. Whales are rarely observed using the Makah U&A survey area throughout an entire feeding season; whales observed in the Makah U&A had an average minimum residency time of 23.5 days (range 1 to 151 days of a possible 183 total days) between 1 June and 30 November (Figure 7). Survey effort in the Makah U&A was very similar from 2000-2003 (Table 1) which suggests that the short observed average tenure of whales in 2002 (3.9 days) relative to other years was not driven by survey effort (Figure 7).

We examined whether a whale's minimum residency time within year Y influenced the probability it was seen in the year Y+1. We found that 39% of whales in the Makah U&A survey area between June and November in year Y were sighted in year Y+1 during the same time period. The percentage of whales seen in year Y+1 was positively correlated with whale residency time (Figure 8) in year Y. Sixty percent of whales with minimum residency time of 100 days were seen the next year. The fact that 40% of whales are not sighted in the Makah U&A in year Y+1 despite being observed over a 100-day span suggests that factors other than foraging success influences future year site selection. This may be due to gray whales over-utilizing their prey base and causing depletion of prey in year Y+1. With less available prey, the whales may not return to the same site or stay in the survey area long enough to be observed.

Calambokidis *et al.* (2010) paint a compelling picture of gray whales observed in the Makah U&A not demonstrating strong fidelity to the small survey area but rather to a larger regional area that extends from at least Oregon through Northern British Columbia. We found that gray whales sighted in the Makah U&A are seen for a short duration in terms of years observed and residency time. Whales sighted in the Makah U&A in five or more consecutive years (n=7) average 43.6 days of residency in the survey area (range 10.3 to 89.8 days of a possible 183 total days) during the period of consecutive sightings. This suggests that even whales that appear to have "strong fidelity" to the Makah U&A are also feeding in areas outside of the U&A.

We also examined whether the number of years a whale is sighted in the Makah U&A influences the number of months in which a whale is sighted. We found that 59.0% of whales sighted in just one year are seen multiple months within the Makah U&A survey area. Of whales sighted in multiple years, 48.5% are seen in just one month of each year they are observed (*e.g.,* always visiting in the month of June). Three whales were sighted in greater than six years in the Makah U&A survey area and were only observed in one month; interestingly all three were in different months. These results suggest individual gray whales may have spatial and temporal consistency in foraging among years and their use of the Makah U&A does not last for an entire feeding season but rather only for a short and defined time period. The number of whales sighted in only one month is greatest in June and lowest in August (Figure 9).

For the time period from 1996-2008, an average of 12.7 new whales were sighted in the Makah U&A survey area during each year; of these an average of 5.6 individuals (44%) were sighted in subsequent years. Calambokidis *et al.* (2010) found that in the area encompassing the Makah U&A and Southern Vancouver Island survey area an average of 22.7 new whales were seen each year; of these new whales, on average 10.1 whales (44%) were seen in subsequent years. The proportion of newly sighted whales that are seen in subsequent years is the same for both survey areas; the difference in total number of observed new whales and new returning individuals between the survey areas is likely driven by the larger sampling area of the Calambokidis *et al.* paper.

We performed a discovery curve analysis on the cumulative number of individual whales observed in the Makah U&A from 1993-2009 to estimate the population of whales utilizing the Makah survey area (Figure 10). We assumed that if the sightings of new whales were occurring from a finite population that we would see the number of new individuals per year decrease with each additional year of effort. Our assumption was incorrect as the cumulative number of individual whales observed increased linearly through time ($y=11.52x - 22968$; $R^2=0.9838$) which is not conducive for using a discovery curve to calculate abundance. Calambokidis *et al.* (2010) suggested that whales seen in just one year, but not in subsequent years, are not actually a part of the PCFG but are rather "stragglers" from the much larger group of whales which feed north of the PCFG survey area. A second discovery curve was attempted with whales observed in multiple years from 1993-2008. The best fit line to the data points was again linear ($y=5.7286x - 11417$; $R^2=0.9823$) which suggests either the population within the Makah survey area is not a closed population or we are on the beginning of the discovery curve for the Makah survey area.

General conclusions

Gray whale use of the Makah U&A survey area is variable within and between years. We currently do not know what drives this variability but it is reasonable to suggest it is linked to prey populations. Feyrer (2006) found that average mysid density is significantly correlated with the average number of whales in her survey area near Vancouver Island. It is possible that mysid density is also driving the observed variability in gray whale counts in the Makah U&A since most gray whale sightings occurred in optimal mysid habitat.

Site fidelity was assessed through examination of minimum residency time and annual capture histories. On average, individual whales utilizing the Makah U&A are observed for a small portion of the June-November feeding season. Most gray whales were only seen in one year; individuals sighted in multiple years averaged a 2.2 year period of time that they were not observed in the study area. A discovery curve analysis did not suggest that gray whales exclusively use the Makah U&A during the summer and fall feeding season. Together these results suggest that most gray whales sighted in the U&A survey area do not have strong fidelity to this area. This conclusion supports the conclusion of Calambokidis *et al.* (2010) that gray whales in the Makah U&A have fidelity to a region that extends from at least Oregon through Northern British Columbia.

ACKNOWLEDGEMENTS

Funding for research by the Makah Tribe was provided by the Bureau of Indian Affairs. Funding for NMML surveys and photo-identification matching was provided by NOAA Fisheries Northwest Region. We thank the many staff of both the Makah Tribe and NMML who have contributed in the collection of photo-identification photographs and collection of data during field surveys. We would like to give a special thank you to Nate Pamplin for establishing the Marine Mammal Program for the Makah Tribe and conducting surveys from 2004-2006. Photographs of whales during Makah Tribe and NMML surveys were identified by the staff, interns, and volunteers of Cascadia Research Collective. Reviews of this paper were provided by Jeff Laake, Joe Scordino, Brian Gruber, Steve Stone and Nate Pamplin. All surveys by NMML and the Makah Tribe were conducted under NOAA research permits 782-1438 and 782-1719.

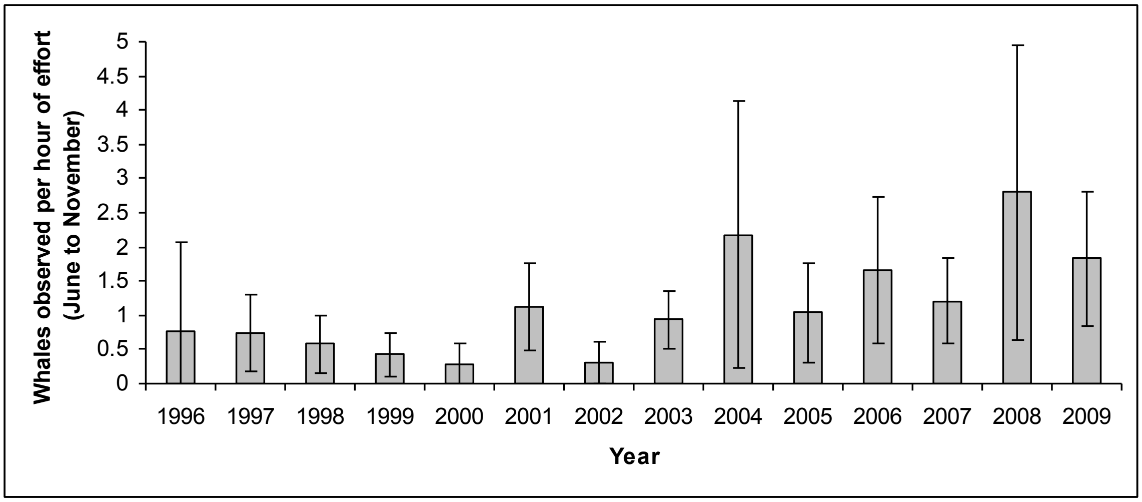

Figure 2: Whales observed per hour of survey effort within the Makah U&A survey area from 1 June to 30 November by year. Error bars are 95% confidence intervals.

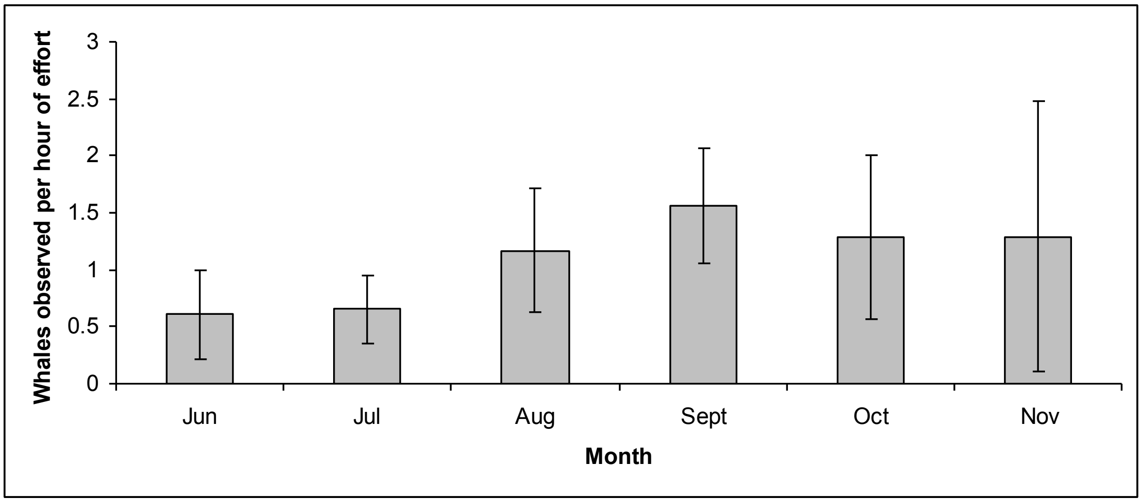

Figure 3: Whales observed per hour of survey effort within the Makah U&A between 1996 and 2009 by month. Error bars are 95% confidence intervals.

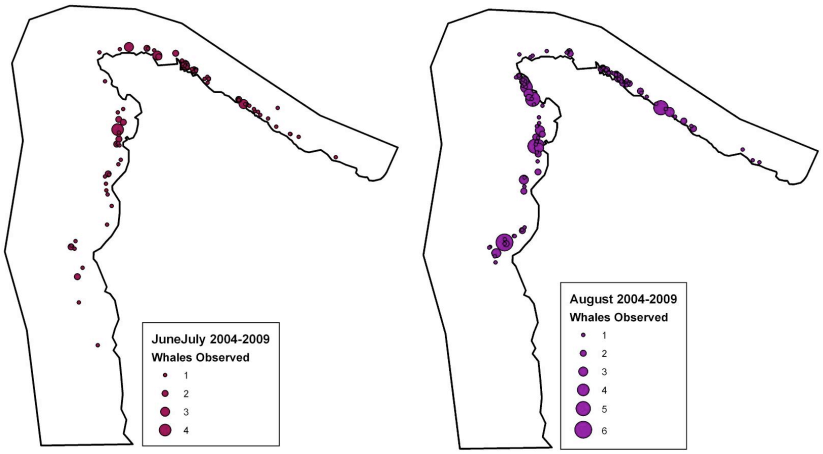
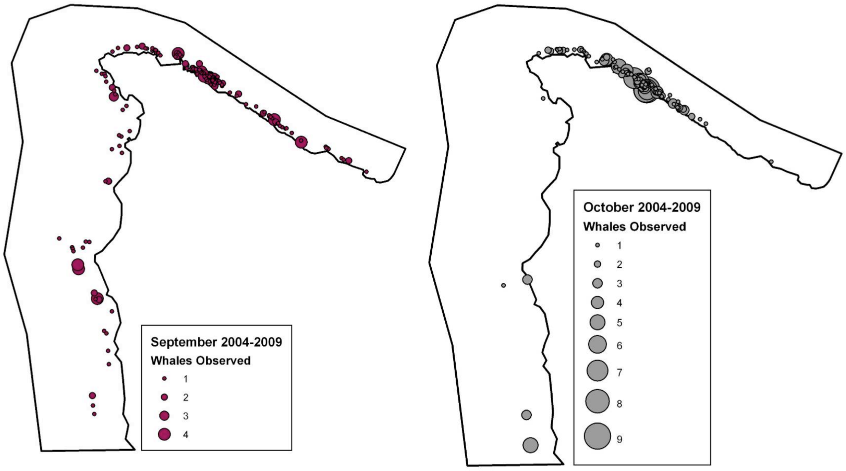
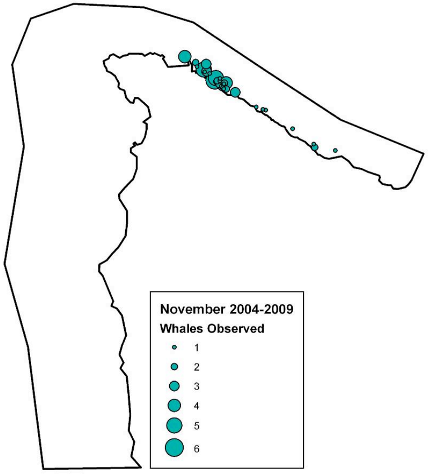


a. June and July 2005-2009 (n= 29) b. August 2004-2009 (n=26)

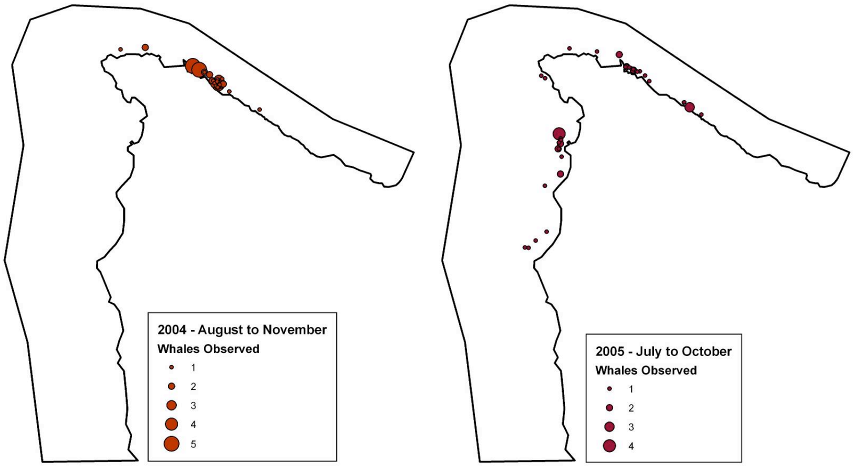


c. September 2004-2009 (n=28) d. October 2004-2009 (n=22)

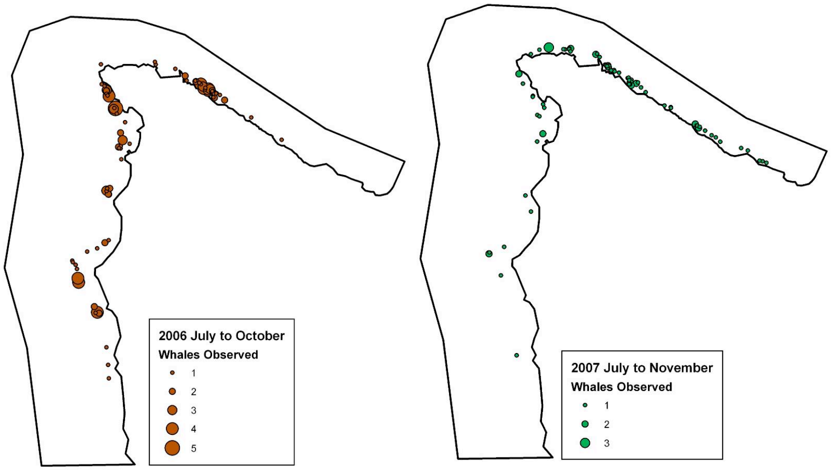


e. November 2004, 2007-2009 (n= 6)

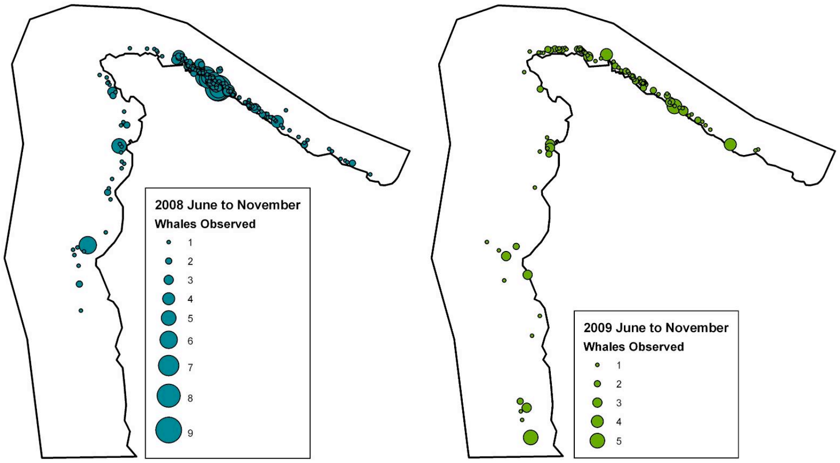
Figure 4: Whales observed per sighting during surveys by Makah and joint NMML-Makah surveys by month as indicated in each subtitle. Each subtitle includes the number of surveys included in the distribution analysis.



a. 2004 August to November (n=7)   b. 2005 July to October (n=15)



c. 2006 July to October (n=28)   d. 2007 July to November (n=27)



e. 2008 June to November (n=37)   f. 2009 June to November (n=34)

Figure 5: Whales observed per sighting during surveys by Makah and joint NMML-Makah surveys by year as indicated in each subtitle. Each subtitle includes the number of surveys included in the distribution analysis.

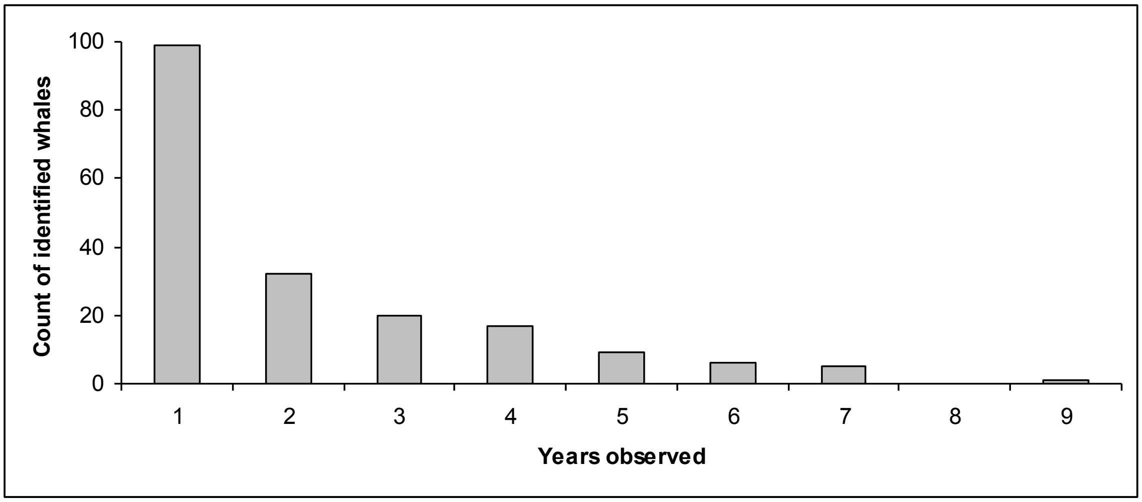


Figure 6: The number of whales identified from photographs taken during surveys in the Makah U&A research area during the months of June through November by the number of years the whale was observed over the 14 years of dedicated research surveys.

Table 3: Sighting history of gray whales identified from photographs on surveys of Makah U&A from June to November between 1993 and 2009. Sighting history includes: first and last year observed in the Makah U&A; years observed in Makah U&A; longest consecutive tenure in the Makah U&A; longest absence from being observed in the Makah U&A; and the year the whale was first observed at a survey site within the PCFG.

Summary of collaborative photographic identification of gray whales from California to Alaska for 2007

Final Report for Purchase Order AB133F-05-SE-5570. *April 2009*

Calambokidis, J., A. Klimek, and L. Schlender
Cascadia Research, 218½ W 4th Ave., Olympia, WA 98501

A collaborative effort involving multiple research groups to examine the occurrence and abundance of gray whales primarily in Summer and Fall from California to SE Alaska began in 1998 with the support of the National Marine Mammal Laboratory (NMML). Previous reports have summarized the results of this work through 2006 (Calambokidis et al. 2002, 2004, Calambokidis 2008). The purpose of this report is to summarize results of the matching of identification photographs for the 2007 field season and compare these results with those reported previously. This collaborative research effort has focused on the gray whales that feed through the summer and fall in the Pacific Northwest, a group that has been referred to as “seasonal residents” or the Pacific Coast Feeding Aggregation (PCFA). While the collaborative effort reported here began in 1998, there had been indications of the existence of such a group much earlier; photographic identification tracking of individuals began in the 1970s off Vancouver Island (Darling 1984).

Identification photographs of gray whales were taken by different research groups working from California to southeastern Alaska in 2007 (Table 1). Ten different groups contributed significant numbers of identification photographs of gray whales during the period. Some of these were done with support from NMML, but effort was also conducted outside or beyond the level of effort that was contracted.

Table 1. Summary of photo-IDs of gray whales by year and contributor through 2007.

Effort was distributed over a broad area and time period overall (Table 2). Some effort was undertaken early in the season in several areas, especially the Puget Sound and Grays Harbor areas of Washington (by Cascadia Research) and along the S and W sides of Vancouver Island (by Brian Gisborne, Volker Deecke, and Wendy Szaniszlo). These early-season efforts were important for looking at the identity of some of the animals that break off from the migration early in the season to feed in specific areas. These identifications were not included in the overall mark-recapture estimates or other elements of the analysis of PCFA animals that have generally only included animals seen after 1 June to avoid overlap with the migration.

Unique	2	36	9	9	31	53	41	64	14	7	8		157

A total of 519 identifications were made (157 unique individuals) in 2007. Of these identifications, 414 were made after 1 June 2007 representing 123 unique individuals. Of the 157 individuals identified, 42 (27%) were new to the Cascadia catalog and 115 (73%) were already known from past years. A higher proportion of these new whales were from the identifications made either before 1 June or in areas outside the core region (Oregon to British Columbia) where PCFA whales are known to occur. For the 34 whales identified only prior to 1 June, only 15 (44%) were known from past years (most of these from the N Puget Sound Region) and for the 123 whales seen at least once after 1 June, 100 (81%) had been identified previously.

Even though effort in most regions was similar to past years, there were shifts in the number of sightings by region reflecting changes in gray whale distribution in 2007. The numbers of identifications at all sites from N Washington north through British Columbia were dramatically lower than in other recent years. This was most dramatic off southern Vancouver Island where the daily effort by Brian Gisborne covering one of the areas of highest gray whale density has generally contributed close to 50% of the identifications from all contributors. Only 76 identifications of 44 individuals were made in this region in 2007 that contrasts with 2006 when

472 identifications (close to 50% of all the identifications that year) were made of 70 individuals. Both the number of individuals identified and the number of times each individual was seen were down despite similar effort showing that fewer animals used this area in 2007 and those that did spent less time there. Similarly, the number of identifications made in the Cape Caution area of northern British Columbia (mostly by CERF) also dropped from 23 individuals identified in 2006 to just 5 in 2007.

In contrast to the lower numbers of gray whales seen at study areas to the north, more whales were identified at some of the southern study areas in 2007 compared to previous years (where there was consistent effort). Both off of Grays Harbor in southern Washington and in Oregon, higher numbers of whales were identified than in most past years. One of the most dramatic changes was the 41 individuals identified in just a couple of days of effort offshore of Grays Harbor in 2007 and this is discussed in more detail in a later section. Of the 86 whales identified off Grays Harbor and Oregon in 2007, 46 or 53% of them had been identified in previous years off southern Vancouver Island.

Whales identified in 2007 matched to those seen in past years going back to at least 1998 when broader scale effort began. Between 29% and 58% of the whales identified each year since 1998 were also seen in 2007 (Table 3). This proportion as highest for 2005 and 2006 where 50% and 58% of the whales identified matched to 2007. The proportion was slightly lower for 1998 to 2004 (29% to 43%) but was fairly steady within that period.

Table 3. Number of gray whales identified from N California to SE Alaska (excluding Puget Sound area) after 1 June by year and the proportion that matched whales identified in 2007.

Year	**Unique IDs**	**Match to 2007**	**% match**
1998	135	46	34%
1999	157	46	29%
2000	139	52	37%
2001	175	56	32%
2002	206	75	36%
2003	161	70	43%
2004	182	71	39%
2005	139	69	50%
2006	131	76	58%
2007	123	123	100%

For the 10 years of fairly consistent effort at least for the core area of Oregon to northern British Columbia, a total of 428 whales have been identified after 1 June. Almost half of these (198 or 46%) were whales seen only one year and most of these (107) were seen only one time in that year. There was a clear relationship between the number of times per year a whale was seen and how many years it was seen (Figure 1). While only 19% of the identified whales were seen seven or more of the 10 years from 1998 to 2007, these whales accounted for 65% of the sightings of gray whales, both reflecting the high number of times they were seen each year and the large number of years they were seen.

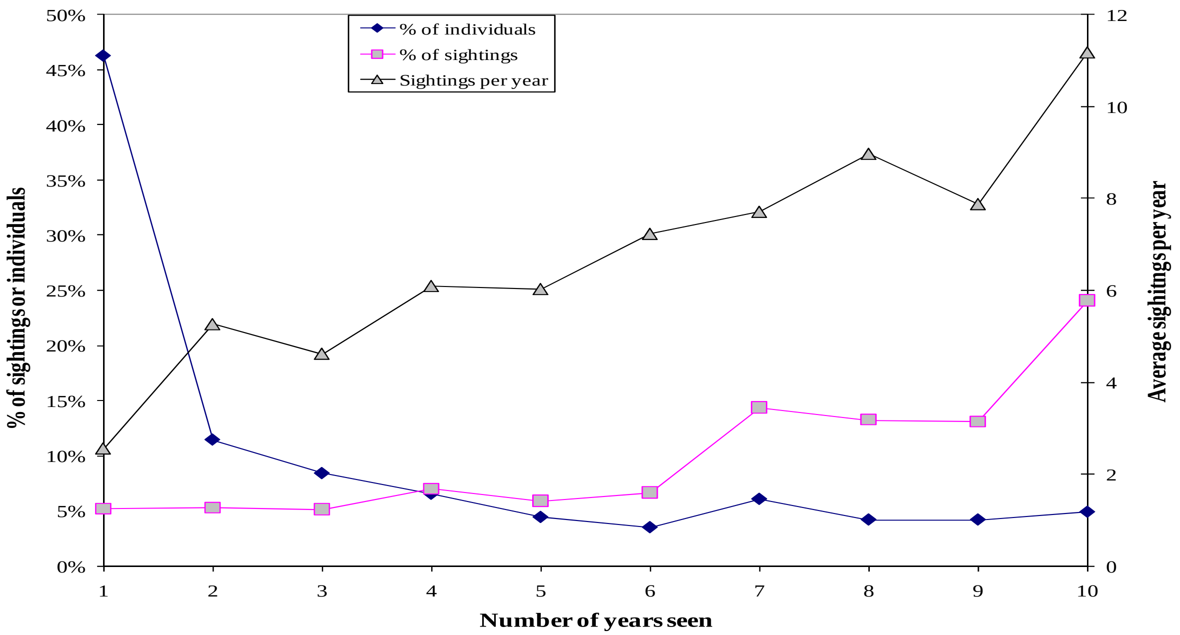

Figure 1. Relationship between number of years different whales were seen in the core region of Oregon to Northern British Columbia after 1 June for 1998 to 2007 and how many times per year they were seen and what percent of the individuals and sightings these whales represented.

A total of 171 gray whales have been identified in the regions that include the Makah Usual and Accustomed areas (N Washington and Strait of Juan de Fuca) after 1 June in any year (Table 4). The proportion of whales identified in other regions that match to this area decrease with distance from the Makah U&A (Table 4). The exception to this is that whales identified in Puget Sound generally did not match to this region. Other than Puget Sound, 40% or more of the whales identified from Oregon to northern Vancouver Island had been seen at least once in the Makah U&A. The proportion matching the Makah U&A dropped to intermediate rates (20 to 32%) for N California, N British Columbia, and SE Alaska, and to 1% or less for Kodiak and central and southern California.

Table 4. Number of gray whales identified after 1 June by region for all years and proportion matching the whales seen in the N Washington and Strait of Juan de Fuca (Makah U&A).

Total	675		

Sightings of gray whales in northern Puget Sound continued to reveal that this area is used as a springtime feeding area for a small regularly occurring group of gray whales (Table 5). Only six unique whales were identified from the 29 times good identification photographs were obtained in 2007 and all of these whales had been seen in past years. These whales were primarily identified from late March through May. All six of these whales had been identified in the region going back to at least 2000.

Table5. Sighting histories of gray whales identified in northern Puget Sound. Includes all individuals that have been sighted in this region since 2001. Numbers indicate times seen. Values for 2008 shown as X indicates animal has been sighted at least once in 2008.

Identification of whale killed in September 2007

As a part of the matching of the 2007 whales we specifically attempted to determine the identity of the gray whale killed in the Strait of Juan de Fuca on 8 September 2007 by a group of Makah whalers operating without the permission of the Makah Tribe or NMFS. We made initial attempts to identify this whale in the aftermath of this hunt but were unable to find a match of this whale because none of the photographs taken on 8 September showed the dorsal part of the side that we use for our photo-ID (a biologist only arrived on the scene only well after the whale had been mortally wounded preventing it from surfacing normally). These photographs did show markings on the front of the animal and we searched for some of these distinctive markings on the front of the whale while matching other collections from 2007. As a part of this effort we were able to find a match to photographs taken near Neah Bay by NMML in 2007 that helped link it to a good identification photograph. These results have also been reported in a statement from the Makah Tribe (http://www.makah.com/images/Whale_ID_PressRelease_5.6.09.pdf).

The whale that was killed was CRC-175 (Figures 2 and 3) which had a long sighting history with 143 sighting records in our database from a number of research groups between 1995 and 2007. The locations of the previous sightings extended from northern California to central Vancouver Island (Figure 4). The earliest sightings in our records were by Calambokidis on 22 and 23 July 1995 less than a mile south of Cape Flattery. The latest identification made prior to when it was killed on 8 September 2007 was on 30 August 2007, east of Neah Bay during a NMML survey. The whale had been seen frequently in the past in the Neah Bay area with sightings in at least 7 years in the Makah U&A. Most sightings were in June to October but there were four identifications made in mid and late May off southern Vancouver Island in 1993, 2000, and 2003. It had also been identified by many other groups including; Cascadia Research, NMML, UVIC (WL035 and WL060), Jim Darling, Wendy Szaniszlo, Makah Tribe, Volker Deecke (UK98-11), Brian Gisborne, and Carrie Newell (*Orion, Ruler,* and *Saucer*).

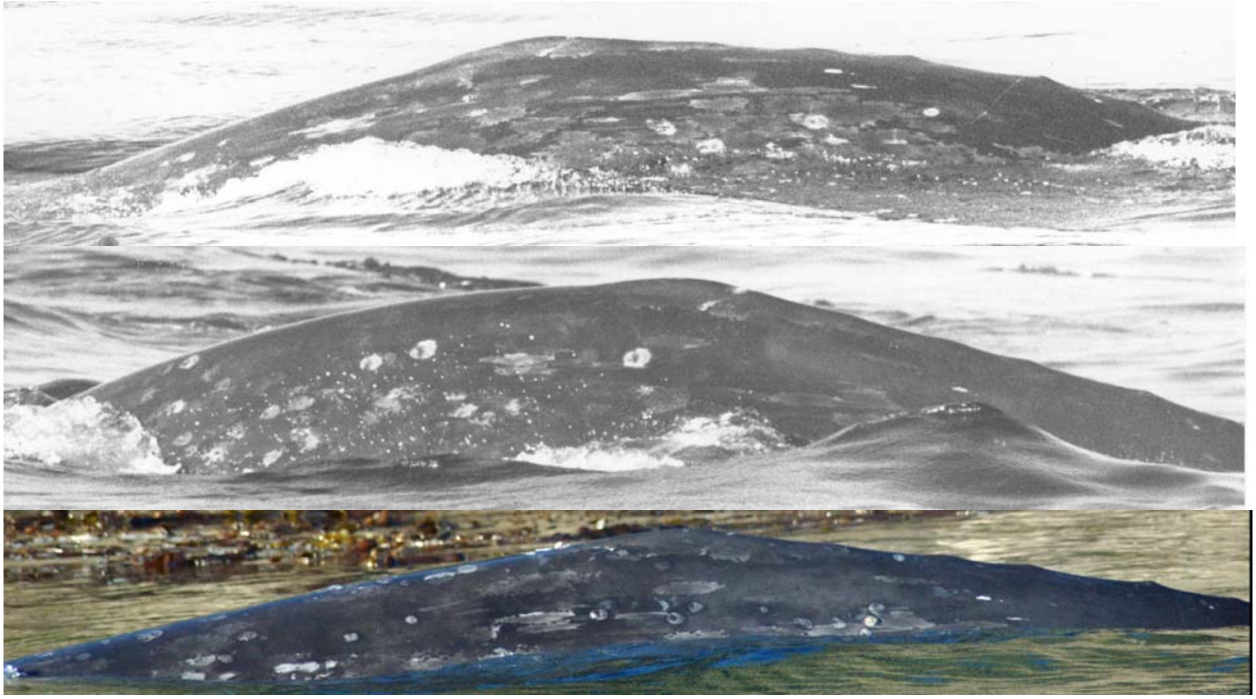

Figure 2. Left side views of CRC-175, the whale that was killed in Fall 2007 near Neah Bay. Top photo by Merrill Gosho, middle by Jim Darling, and bottom by Nate Pamplin. The variability in the lighting alters the distinctiveness of some of the marks.

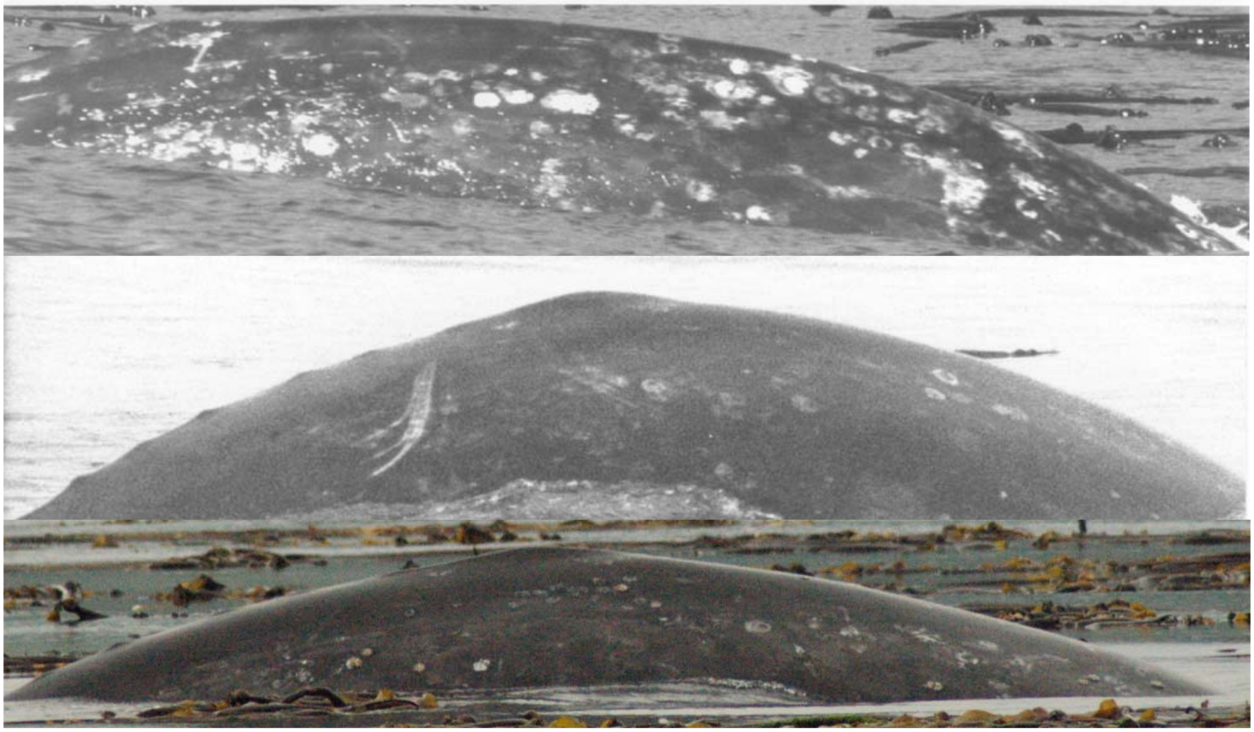

Figure 3. Photos of the right side of whale CRC-175. Top photo by Christina Tombach, middle by Merrill Gosho, and bottom by Nate Pamplin. These are a more difficult match than typical.

The timing and location that this whale was taken made it by definition part of the PCFA group. The sighting history also demonstrates that it was a well-known whale seen over many years. A whale that is killed and landed as planned by the Makah would provide a more reliable opportunity for obtaining identification photographs. Despite the challenges faced in 2007 with the difficulty of obtaining good identification photographs, the ability to identify this whale also demonstrates that this can be an effective way to identify future whales that may be hunted in the spring to determine if they are PCFA whales.

Figure 4. Locations CRC-175 was sighted off northern Washington and British Columbia prior to being killed in September 2007. Additional sightings off northern California and Oregon are not shown.

Surveys off Grays Harbor

As a part of a separate project examining both visual and acoustic detections of marine mammals off the central Washington coast in collaboration with Scripps Institution of Oceanography for the US Navy, we obtained sightings and photographic identifications of gray whales that are summarized below (see also Oleson et al. 2007, In prep). There were seasonal differences in the distribution and habitat utilization of gray whales corresponding to three time periods matching stages in their life history (Figure 5):

1) Sightings in December and January (corresponding to the southbound migration of gray whales from their primary feeding ground in Alaska to their breeding grounds in Mexico when whales were primarily in deep water far offshore (average of 29 km offshore and 126 m water depth).
2) Sightings for February to April (northbound migration past Washington as the main population heads back to Alaskan waters) tended to be close to shore mostly on a north-south distribution averaging about 10 km offshore.
3) Sightings in May to October (when primarily gray whales from the PCFA are present) were clustered in two areas, in and around the entrance to Grays Harbor and also 20-25 km offshore in depths of about 60 m.

Figure 5. Sighting location of gray whales by season (circles - winter, triangles - spring, and squares - summer and fall . Lines show survey tracks for approximately monthly surveys conducted from 2004 into 2008. Shaded area shows location of concentration of feeding gray whales seen from June to September 2007.

The offshore sightings of gray whales during the summer represented a surprising finding given the typical pattern of gray whales feeding in the Pacific Northwest, which tend to feed close to shore in shallow waters. These offshore sightings were all made between 8 June and 1 September of just 2007 and while they were grouped into just 6 sightings, they totaled 42 whales since each sighting represented a concentration of up to 14 whales in one area.

Identifications from the concentration of gray whales in 2007 found feeding almost 10 nmi offshore in the summer and fall. The identifications revealed that this unusual offshore feeding concentration consisted almost exclusively of animals known as “seasonal residents” in other parts of the Pacific Northwest. All but one of the 28 individuals had been identified in other feeding areas in the Pacific Northwest.

Mark-recapture abundance estimates

Data for 2007 was used to update estimates of abundance using Petersen mark-recapture estimates with adjacent years as samples (Table 6, Figure 6). As in past years, only identifications from after 1 June and excluding the Puget Sound area were used in the abundance estimates. Estimates of abundance based on 2006 and 2007 were 212 and 203 depending on the regional cut-offs used (Table 6). This estimate is just slightly higher than the estimates from 2005-2006 though still at the low end of the range of values obtained from these estimates based on adjacent-year samples (Figure 6). Rather than reflecting any real change in abundance these fluctuations are more likely the result of small shifts in distribution and effort affecting how these animals are sampled.

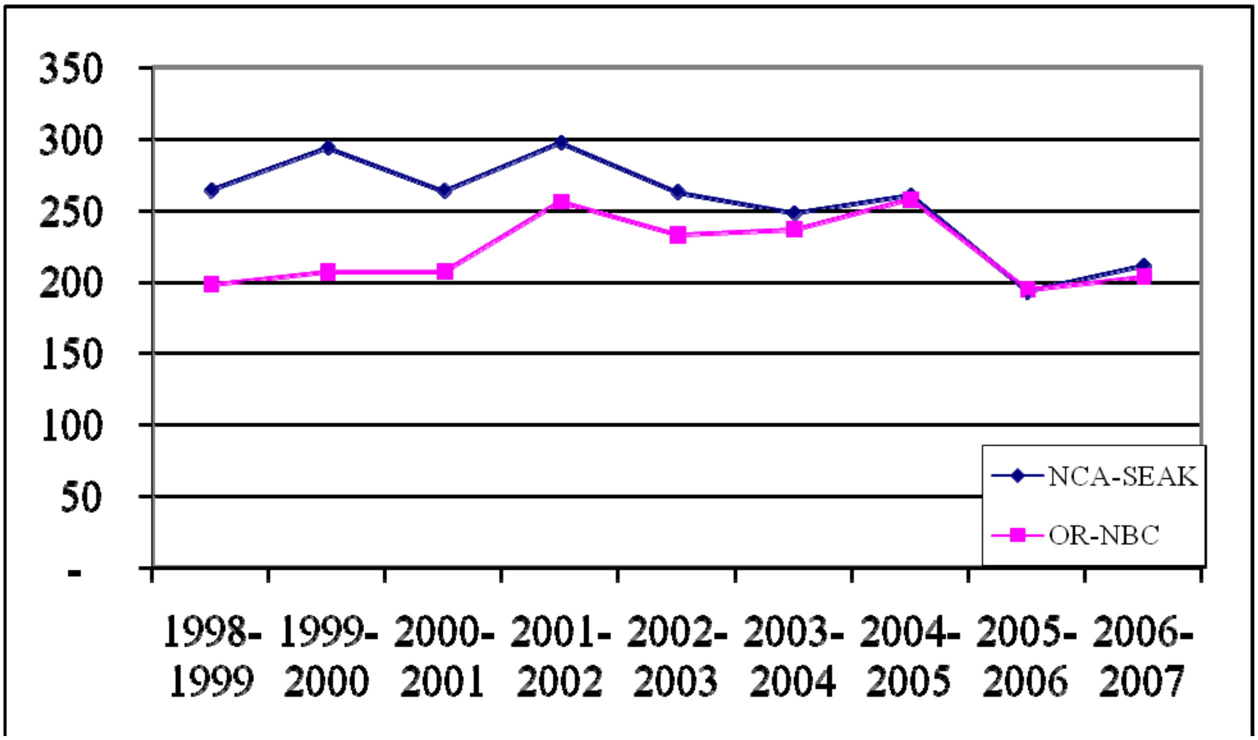

Figure 6. Plot of Petersen mark-recapture estimates of abundance based on photo-IDs of gray whales identified after 1 June and excluding (Puget Sound).

Table 6. Petersen mark-recapture estimates of abundance based on photo-IDs of gray whales identified after 1 June. Estimates below are shown for two different core areas (a larger Northern California to SE Alaska and a smaller core area of Oregon to British Columbia (both exclude peripheral areas including Puget Sound, Kodiak, and central or southern California).

Acknowledgements

This analysis would not have been possible without the collaborating organizations contributing identification photographs listed in Table 1. Support for the photographic identification reported here, the comparison of gray whale photographs and preparation of this report came primarily from the National Marine Mammal Laboratory (coordinated by Jeff Laake). Permission to conduct some portions of this research was provided by the U.S. National Marine Fisheries Service and the Makah Tribal Nation.

We thank the operators of the boats that allowed us to gather data from their boats in northern Puget Sound. A number of people assisted in the field effort and in the printing and matching of photographs at Cascadia Research. Erin Falcone compiled the data from the different contributors. Cascadia field effort on gray whales was conducted by a number of volunteers and staff at Cascadia.

TABLE OF CONTENTS

ACKNOWLEDGEMENTS

A number of people assisted in conducting fieldwork with Cascadia Research in 1998: Joe Evenson, Todd Chandler, Kristin Rasmussen, Lisa Schlender, Hanna Smith, Aaron Huston, Bonnie Martin, Heather Harding, Heather Medic, Nicole Stagner, Natasha Bodorff, and Megan Hess. Photographic matching was conducted by Lisa Schlender, Emily Walton, Joe Evenson and Hanna Smith. Lisa Schlender and Kristin Rasmussen assisted in data entry for surveys, identifications, and sighting reports. National Marine Mammal Laboratory biologists, Merrill Gosho and Pat Gearin provided identification photographs of gray whales taken as part of their surveys.

Research in 1998 was funded in part by the National Marine Mammal Laboratory, and we thank Merrill Gosho and Pat Gearin for orchestrating this support. We thank the skippers and staff of the whale watch boats in Westport, the *Victoria Express,* the *Deluxe,* and the *Lucky Piere*, which allowed us to collect data and obtain identification photographs from their boats. The Olympic Coast National Marine Sanctuary provided support for some humpback surveys, which yielded opportunities to survey for gray whales. Some support came from Cascadia's adoption program and we thank those participating in this program.

EXECTUTIVE SUMMARY

In 1998, Cascadia Research and the National Marine Mammal Laboratory conducted photographic identification surveys for gray whale found in the waters of Washington State and along the southern coastline of Vancouver Island. A larger regional effort was also conducted from California to Southeastern Alaska involving a number of other collaborators including researchers with Humpboldt State University, West Coast Whale Research Foundation, University of Victoria, University of British Columbia, Vancouver Aquarium, Department of Fisheries and Oceans, Coastal Ecosystem Research Foundation, and the operator of a coastal ferry service. This research updates previous research efforts, which have revealed that a large number of gray whales seen off Washington State and British Columbia exhibit localized site fidelity. The information provided by this research contributes to an ongoing study of abundance, movements, residence times, and return rate of gray whales that feed in the Washington State waters for extended periods. This report summarizes activities and preliminary results of gray whale research conducted in Washington State and southern Vancouver Island in 1998 by Cascadia and NMML. Results of the larger effort from California to Alaska will be summarized in a future report.

Between 2 March and 17 November 1998, Cascadia personnel conducted a total of 53 gray whale surveys in the waters of Washington State and off the southern coastline of Vancouver BC. The National Marine Mammal Laboratory (NMML) provided identification photographs from # surveys, conducted between 6 June and 18 November 1998. On 249 occasions, 74 different gray whales where successfully identified by Cascadia Research and NMML in 1998.

Fewer whales were present on the northern Washington and western Strait of Juan de Fuca than previous years and most of the identifications in this region were made late in the season (after 1 September). Of the 57 seen on the northern Washington coast and on the north and south side of the Strait of Juan de Fuca, 32 (56%) had been identified in past years, a lower proportion than previous years. Individual whales moved between S. Vancouver Island and the Strait of Juan de Fuca and Washington outer coast. At least six different whales were present (from 27 identifications) in northern Puget Sound; four of these were animals that have been seen regularly each spring in this area since the early 1990s. None of the four gray whales identified in southern Puget Sound had been seen previously, consistent with past findings that this area is not used by regular returning animals.

INTRODUCTION

In 1998, Cascadia Research and the National Marine Mammal Laboratory continued photographic identification surveys for gray whales, in Washington State and along the southern coast of Vancouver Island, BC. These surveys are part of an ongoing research effort to study the abundance, movements, residence times and return rates of gray whales that feed in Washington State waters in spring, summer, and fall (so-called "seasonal residents". Summer feeding aggregations of gray whales have been observed in a number areas along the coasts of California (Patten and Samaras 1977, Malonee 1991, Avery and Hawkinson 1992), Oregon (Sumich 1984), Washington (Flaherty 1983, Calambokidis *et al*. 1992, 1994, Wietkamp *et al*. 1992) and British Columbia (Darling 1984, Murison *et al.* 1984, Plews *et al.* 1985). Gray whales in these regions feed on a variety of prey including herring eggs/larvae, crab larvae, amphipods, mysids, and ghost shrimp, with locations of feeding often shifting from year and by season in response to shifting prey types (Darling *et al*. 1998, Nerini 1984).

Previous research has revealed that a significant number of the gray whales observed in Washington State exhibit localized site fidelity (Calambokidis *et al*. 1994, Calambokidis 1996, Calambokidis and Quan 1997, Calambokidis and Schlender 1998). The issue of "seasonal resident" whales has also gained significance due to the resumption of whaling for gray whales by the Makah. Currently abundance estimates, genetic make-up and recruitment mechanisms that may maintain this aggregation are unknown.

In addition to the field work reported here for 1998 a larger regional effort was also conducted from California to Southeastern Alaska involving a number of other collaborators including researchers with Humboldt State University, West Coast Whale Research Foundation, University of Victoria, University of British Columbia, Vancouver Aquarium, Department of Fisheries and Oceans, Coastal Ecosystem Research Foundation, and the operator of a coastal ferry service. Results of the larger effort from California to Alaska will be summarized in a future report.

This report summarizes activities and preliminary results of gray whale photo-ID research conducted by Cascadia Research and the National Marine Mammal Laboratory in Washington State and southern Vancouver Island in 1998.

METHODS

Between 2 March and 17 November 1998, Cascadia personnel conducted a total of 53 gray whale surveys in the waters of Washington State and off the southern coastline of Vancouver B.C. (Table 1) Surveys were conducted by: 1) placing observers on whale watch boats, the *Victoria Express*, the *Deluxe* and the *Lucky Piere* out of Westport, WA (between 21 March through 30 June 1998), 2) small boat surveys conducted in Puget Sound, the western and eastern portions of the Straight of Juan de Fuca, Washington outer coast and southern Vancouver Island, and 3) placing biologist aboard the National Marine Sanctuary vessel, the *Tatoosh*, in conjunction with humpback whale surveys being conducted in the Olympic Coast National Marine Sanctuary.

Biologist from the National Marine Mammal Laboratory (NMML) provided identification photographs from surveys they conducted between 6 June and 18 November 1998. The photographs from NMML represent surveys from the Washington outer coast, the western Straight of Juan de Fuca and southern Vancouver Island, BC.

Procedures during Cascadia vessel surveys were similar to those used previously (Calambokidis *et al.* 1994). Effort data was recorded every 30 min and when there was either a course change or a change in the environmental conditions. We recorded time position (latitude and longitude from GPS), and environmental conditions (sea state, visibility, precipitation, cloud cover, and swell height). When a gray whale was found, the time, position, number of animals, and behaviors were recorded. Whales were approached to 30-50 m and followed through several dive sequences until suitable identification photographs could be obtained. At the end of a sighting the time, location, and roll and frame numbers of photographs taken during each observation were also noted.

For photographic identification of gray whales, both left and right sides of the dorsal region around the dorsal hump were photographed. *Ilford* HP-5 negative film was shot using *Nikon* 35mm cameras with 300mm f4.5 lenses. We also photographed the ventral surface of the flukes for identification when possible. The latter method was not as reliable as the sides of the whale because they did not always raise their flukes out of the water. Markings used to distinguish whales included pigmentation of the skin, mottling, scarring, and barnacles, which varied among individuals. These markings have provided a reliable means of identifying gray whales over periods of close to 20 years.

We also utilized the relative spacing between the knuckles along the ridge of the back behind the dorsal hump. The size and spacing of these bumps varies among whales and does not change over the years we have tracked whales. Measurements were made using a scaled loop and compared to a database of values for all the whales in our catalog. A computer program (developed by Joe Evenson) provided a prioritized list of potential matches and then the match was verified or rejected based on the markings described above.

Comparison of whales to determine any matches were made in a series of steps. First, the negatives of gray whales were examined and the best shot of the right and left side of the whales (for each sighting) selected and printed (7 x 2.5 inch). To determine the number of whales seen during the season, the prints were then compared to one another to identify whales seen multiple days. Finally a comparison was made to our catalog of whales seen in past years. Whale photographs that were deemed of suitable quality but did not match our existing catalog (compared by two independent matchers) were assigned a new identification number and added to the catalog.

RESULTS AND DISCUSSION

On 249 occasions, 74 different gray whales where successfully identified by Cascadia Research and NMML in 1998 (Tables 2-3). Each whale was seen from 1 to 14 times with a mean of 3.4 (SD= 3.1). The most identifications and individuals seen was off southern Vancouver Island; there were 75 identifications of 32 animals (Table 3). The northern Washington coast and the western Strait of Juan de Fuca had the next highest number of individuals seen (21 and 14). There were a large number of identifications made in Grays Harbor (59) but these were of only seven individuals. The high number of resightings in this area is partly the result of the more intense effort from whale watching boats over a less than 2 month period in Grays Harbor.

Identifications off southern Vancouver Island were made between 1 July and 11 November, although the highest number were seen in July, when 23 different individuals were identified (Table 4). This compares to only 12 individuals identified in July on the Washington outer coast and on the Washington side of the Strait of Juan de Fuca, an area that was being more intensely surveyed. Large numbers of whales remained off southern Vancouver Island through September, although in lower numbers than July. Numbers of whales identified in Washington waters off the outer coast and in the western strait, dropped to 6 in August and then came back up to 10 individuals in both August and September (Table 4). There was an increased number of whales identified on the Washington side of the Strait of Juan de Fuca, including the eastern portion, in October and November with nine and seven individuals seen each month, respectively.

Identifications in northern Puget Sound were all made from March through May, coinciding with the period that we have seen animals in this region in past years (Table 4). Four of the six animals identified in this region were animals that have been seen regularly in this area going back to 1990 (Table 5). Our sightings of these animals in early March (two on the 12th and one on the 14th) are the earliest in the season we have positively identified these animals in any year, although sighting reports in this region typically begin in early March. We made no identifications after 20 May and sighting reports from this region also dropped off in May. As in past years none of these regular animals were seen in this or any other region later in the season.

Identification of gray whales in southern Puget Sound were made on six occasions and represented four individuals. One animals was identified several times in March and then not seen again and three other animals were identified from mid-October to mid-November. As in past years, none of these whales were individuals that had been identified in past year in any region (Table 5).

Individual gray whales were documented moving among three regions; the Strait of Juan de Fuca (both the eastern and western portion), the Washington outer coast, and the southern portion of Vancouver Island (Table 6). Most common were whales seen on both the Washington outer coast and southern Vancouver Island (eight whales). Three of these whales were documented making multiple trips between these regions.

The proportion of whales identified off northern Washington) that had been identified in previous years was lower in 1998 (63%) than had been seen in some previous years (Table 5). It appears that in addition to there being fewer whales present most of the season, more of the whales were animals that had not been common in this region in the past. The lower number of whales seen off the northern Washington coast and high numbers seen off southern Vancouver Island was likely related to prey; gray whales are know to shift areas they feed in response to shifts in prey types and densities (Darling *et al*. 1998). If prey was not as plentiful on the northern Washington coast this may have discouraged the animals that typically use this area from being there and make animals encountered in this area more likely to be whales moving between areas.

Updated analysis of abundance and population structure of seasonal gray whales in the Pacific Northwest, 1996-2012

John Calambokidis, Jeffrey Laake, and Alie Pérez

Abstract

The existence of a small number of Eastern North Pacific gray whales that spend the spring, summer and fall feeding in coastal waters of the Pacific Northwest has been known for some time and localized short-term studies have examined aspects of the natural history of these animals. We report the results of a 17-year (1996-2012) collaborative study examining the abundance and the population structure of these animals conducted over a number of regions from Northern California to British Columbia using photographic identification. Some 16611 identifications representing 1303 unique gray whales were obtained during 1996-2012 from Southern California to Kodiak, Alaska. Gray whales seen from 1 June - 30 Nov (after the northward and before southward migrations) were more likely to be seen repeatedly and in multiple regions and years;therefore only whales seen during those data were included in the abundance estimates. Gray whales using the Pacific Northwest in summer and fall include two groups: 1) whales that return frequently and account for the majority of the sightings and 2) transients seen in only one year, generally for shorter periods and in more limited areas. A time series of abundance estimates of the non-transient whales for 1996-2012 was constructed. The most recent estimate for 2012 was 209 whales (se=15.4). The estimated abundance increased in the late 1990s and early 2000s during the period when the eastern North Pacific gray whale population was experiencing a high mortality event and this created an apparent influx of whales into the area. The earlier estimates for 1996-1997 are biased low because the survey coverage area was much smaller but those data were included to improve estimates later in the time series. The abundance estimates since the early 2000s has been relatively stable. The proportion of calves documented was generally low in the early portion of the time series and may have been biased downward by under-reporting and weaning of calves prior to entry in the study area or prior to much of the collaborative seasonal effort. In recent years, early season effort has increased and so has the number of calf observations. Observations of calves returning to the Pacific Northwest in subsequent years documents one possible mechanism for recruitment.

1 Introduction

Beginning in 1996, a collaborative effort among a number of research groups was initiated to conduct a range-wide photographic identification study of gray whales in the Pacific

Northwest (Calambokidis et al. 2000, 2002b). An initial publication of findings from 1998 demonstrated there was considerable movement of individual whales among sub-areas from northern California to southeastern Alaska (which we broadly refer to as the Pacific Northwest) and also provided initial estimates of the abundance of whales within that geographical area (Calambokidis et al. 2002a). The ability to look at movements and employ more sophisticated capture-recapture models, however, was restricted by the lack of multiple years of data with broad geographic coverage. A subsequent report by Calambokidis et al. (2004) characterized the group of whales feeding in these survey areas during the summer-fall period as a "Pacific Coast Feeding Aggregation" (PCFA). They proposed that a smaller area within the PCFA survey areas – from Oregon to Southern Vancouver Island (OR-SVI) – was the most appropriate area for abundance estimation for managing a Makah gray whale hunt (Calambokidis et al. 2004). Subsequently the IWC has adopted the term PCFG for Pacific Coast Feeding group so we will use PCFG in place of PCFA.

This report updates information through 2012 from a collaborative effort to collect photographic identifications of gray whales from California to Alaska has continued since 1996 and these data now cover 17 years (1996-2012) and span fifteen survey regions along the coast from Southern California to Kodiak, Alaska (Figure 1). We provide estimates of abundance for the summer-fall seasons (1 June to 30 November) during 1996–2012 for survey regions between Northern California and Northern British Columbia (NCA-NBC), the region chosen by the IWC to represent the PCFG. For the National Marine Fisheries Service development of an Environmental Impact Statement, we also provide estimates for the smaller regions between Oregon and Southern Vancouver Island (OR-SVI) and Makah Usual and Accustomed area (MUA) which includes the outer coastal area of the Olympic Peninsula (NWA) and the Strait of Juan de Fuca (SJF), even though this area is quite small relative to the observed movements of whales within the PCFG.

2 Methods

Gray whales were photographed during small boat surveys conducted from California to Alaska by collaborating researchers (Table 1) between 1996 and 2012. Gray whale identifications were divided into the following regions (Figure 1): 1) SCA: Southern California, 2) CCA: Central California, 3) NCA: Northern California, 4) SOR: Southern Oregon, 5) OR: central Oregon, 6) GH+: Gray's Harbor and the surrounding coastal waters, 7) NWA: Northern Washington coast, 8) SJF: Strait of Juan de Fuca, 9) NPS: Northern Puget Sound, 10) PS: which includes southern Puget Sound, Hood Canal (HC), Boundary Bay (BB) and San Juan Islands (SJ), 11) SVI: Southern Vancouver Island, 12) WVI: West Vancouver Island, 13) NBC: Northern Vancouver Island and coastal areas of British Columbia, 14) SEAK: Southeast Alaska, and 15) KAK: Kodiak, Alaska. With some exceptions, research groups work primarily in one or two regions. Details of identifications obtained by the different research groups are are summarized in Tables 1-2.

2.1 Photographic Identification Procedures

Procedures during surveys by different research groups varied somewhat but were similar to one another in identification procedures. When a gray whale was sighted, the time, position, number of animals, and behaviors were recorded. Whales were generally approached to within 40-100 m and followed through several dive sequences until suitable identification photographs and associated field notes could be obtained.

For photographic identification of gray whales, both left and right sides of the dorsal region around the dorsal hump were photographed when possible. Most identification photographs were obtained with were obtained with 35mm cameras prior to 2004 and primarily with digital SLR after 2004 with both camera types paired most often with a large 300mm lens. Researchers also photographed the ventral surface of the flukes for further identification when possible. The latter method was not as reliable since gray whales did not always raise their flukes out of the water. Markings used to distinguish whales included pigmentation of the skin, mottling, and scarring, which varied among individuals. These markings have provided a reliable means of identifying gray whales (Darling 1984). We also identified gray whales using the relative spacing between the knuckles along the ridge of the back behind the dorsal hump. The size and spacing of these bumps varies among whales and has not changed throughout the years these whales have been tracked, except with injury. Figure 2 shows typical photographs and features used in making gray whale identifications.

Comparisons of whale photographs were made in a series of steps. All photographs of gray whales were examined and the best photograph of the right and left sides of each whale (for each sighting) were selected and printed (7 x 2.5 inch). To determine the number of whales seen during the year, the prints were then compared to one another to identify whales seen multiple days. Finally a comparison was made to the CRC catalog of whales seen in past years. Whale photographs that were deemed of suitable quality but did not match our existing catalog (compared by two independent persons) were considered “unique” identifications and assigned a new identification number and added to the catalog.

2.2 Data Analysis

The abundance of gray whales was estimated with open population models for three nested spatial scales consisting of contiguous survey regions (Figure 1; Table 3) 1) NCA-NBC: the coastal survey regions from Northern California (NCA) through Northern Vancouver Island/British Columbia (NBC) which matches the IWC definition of the PCFG, 2) OR-SVI: survey regions from southern Oregon through Southern Vancouver Island (SVI) identified in the Makah waiver request, and 3) MUA - survey regions NWA and SJF. Inland waters in WA (other than SJF) and in BC are excluded from the abundance estimates because these are used primarily by transient whales in the northward spring migration.

Gray whales photographed and identified anytime during the period between 1 June and 30 November (hereafter referred to as the “sampling period”) within the defined region were considered to be “captured” or “recaptured”. For each unique gray whale photographed, a capture history was constructed using 17 years of data from 1996-2012. For example, the capture history 00010010010000000 could represent a gray whale photographed in 1999, 2002 and 2005 in the PCFG. The same gray whale may have had a capture history 00010010000000000 for a smaller spatial scale such as OR-SVI or may not have been seen at all (00000000000000000) and would not be used at the smaller spatial scale.

Multiple "detections" of a single whale within the sampling period were not treated differently than a single detection. A "1" in the capture history meant that it was detected on at least one day during the sampling period. However, multiple detections in the same year were used to construct an observed minimum tenure (MT) for each whale. MT was defined as the number of days between the earliest and latest date the whale was photographed with a minimum of one day for any whale seen.

We fitted open population models to the 17 yearly time series of capture history data for each spatial scale to estimate abundance and survival. Open models allow gains due to births/immigration and losses due to deaths/emigration. Using the RMark interface (Laake and Rexstad 2008) to program MARK (White and Burnham 1999), we fitted a range of models to the data using the POPAN model structure. The POPAN model structure (Schwarz and Arnason 1996) provides a robust parametrization of the Jolly-Seber (JS) model structure in terms of a super population size (N), probability of entry parameters (immigration), capture probability (p), and survival/permanent emigration (φ).

It is essential to consider the population structure and its dynamics to build adequate models. In particular, we know from previous analysis of a subset of these data (Calambokidis et al. 2004) that some whales were seen in only one year between 1 June and 30 November and were never seen again. Transient behavior is a well-known problem in capture-recapture models and it is often addressed using a robust design which involves coordinated multiple capture occasions within each year and typically assumes closure within the sampling period (June-November). Region-wide coordinated surveys may be possible but would be difficult with variation in weather conditions. Also, the closure assumption within the year would be suspect due to variable timing of whales arrivals and departures into the PCFG, so it would require nested open models. We know from prior analysis that whales newly seen in year (y) were less likely to return (i.e., seen at some year >y) than previously seen whales but also newly seen whales that stayed longer during their first year (i.e., longer MT) in the PCFG were more likely to return. Likewise, previously seen whales were more likely to be seen in the following year (y+1), if they had a longer MT in year y. Calambokidis et al. (2004) postulated that these observations were consistent with whale behavior that was determined by foraging success.

Transient behavior in which an animal is seen only once can be modeled by including a different "first year" survival (Pradel et al. 1997) for the newly seen animals. Survival in the time interval after being first seen is dominated by permanent emigration rather than true mortality. Survival in subsequent time intervals represents true survival under the assumption that animals do not permanently emigrate except in their first year. Pradel et al. (1997) were working with release-recapture data (Cormack-Jolly-Seber) where modeling this transient effect on survival is straightforward. For a Jolly-Seber type analysis where the first capture event is also modeled, the inclusion of a transient effect is less easily accommodated.

We divided the whales into cohorts based on the year in which they were first seen ("newly seen"). In the model, their first year survival could differ from subsequent annual survival as in Pradel et al. (1997). "Newly seen" is not a particularly useful concept for the first year of the study (1996), because all whales were being seen for the first time. The survey effort and coverage in 1996 and 1997 were not nearly as expansive as 1998 and later. We considered models that had three different first year survivals (1996&97, 1998, and >1998) and we also considered a model that allowed for a different first year survival for each year (cohort) to allow for different transient proportion in each year. The first year survival was also allowed to vary as a function of MT with a model in which the relationship was constant across years and varied for (1996&97, 1998, and >1998). We also considered models that allowed a different first-year survival for whales identified as calves under the presumption that their true survival might be lower but that their probability of returning to the PCFG might be higher. Discussion at the 2012 intersessional AWMP meeting led to consideration of an additional covariate which split whales into 2 groups for estimation of post-first-year survival. Whales seen initially as calves and any whale newly seen in 1998 or was in the CRC catalog because it had been seen prior to 1998 were put in one group and the remaining whales newly seen in 1999 or later were put in another group. The expectation was that the first group would have higher post-first-year survival because many of the newly seen whales that entered after the stranding event in 1999/2000 might eventually emigrate. When this covariate was included it made such a large improvement that any model without it would have no support. Therefore, it was included in all 10 models for survival (Table 4).

In Calambokidis et al. (2010) we estimated a cohort-specific super-population size for each cohort using the median MT covariate value for unseen whales but during the April 2011 AWMP meeting it became apparent that this may lead to bias in estimating abundance. Therefore, we used the method outlined in the 2011 AWMP report which is similar to the method used by Calambokidis et al. (2004) in that we assume that all whales in the PCFG for the first year are seen so the super-population size for each cohort is the number seen and thus there are no unknown covariate values. We fixed capture probability (p) and probability of entry (pent) to 1 for each cohort in their entry year. We are not interested in the number of transient whales so we used an estimator of abundance for non-transient whales (2011 AWMP report) which is a modification of the Jolly-Seber estimator which for any year can be expressed as:

$$\hat{N} = n/\hat{p} = (u + m)/\hat{p}$$

where $n = u + m$, n is the number seen in a year being composed of new animals (u=unmarked) and previously seen animals (m=marked), and $\hat{p}$ is the capture probability estimate. For the PCFG we are assuming that any new whale is sighted ($p = 1$) and we are only interested in estimating the abundance of whales that will remain part of the PCFG which is the portion of the new whales that do not permanently emigrate from the PCFG. We can modify the estimator for year j as follows:

$$\hat{N}_j = u_j\hat{\phi}_j + m_j/\hat{p}_j$$

where ϕ_j is the first year survival rate of "new" whales. When ϕ and p contain whale specific covariates like minimum tenure (MT) the estimator becomes:

$$\hat{N}_j = \sum_{i=1}^{u_j} \hat{\phi}_{ij} + \sum_{i=1}^{m_j} 1/\hat{p}_{ij}.$$

To obtain an abundance estimate for 2012, we assumed that the parameter for first year survival intercept in that year was the same as in 2011. A variance-covariance matrix for the abundance estimates was constructed using the variance estimator in Borchers et al. (1998) for a Horvitz-Thompson type estimator with an adaptation for the first component of the abundance estimator for prediction of number of new whales that do not permanently emigrate. For the estimated capture probabilities (p) not fixed to 1, we fitted 3 models that varied by time (year) and/or varied by MT in the previous year (Table 4).

We used Test 2 and Test 3 results from the Cormack-Jolly-Seber structure (Lebreton et al. 1992) as a general goodness of fit for the global model and as a measure of possible over-dispersion creating the lack of fit. We fitted each combination of models for S (survival) and p (capture probability) and used AICc (Burnham and Anderson 2002) to select the most parsimonious model of the 30 fitted models. Model averaging was used for all models to compute estimates and unconditional standard errors and confidence intervals.

3 Results

The database contains 20187 records for whales photographed between 1996 to 2012 from California to Kodiak, Alaska; however 3576 are replicate identifications of whales on the same day. We define a sighting as one or more photographs of a whale on a day. The number of sightings varied annually from 131 and 1648 with a total of 16611 sightings of 1303 unique gray whales (Table 1). The average number of sightings/whale was 12.7 (range: 1- 280). Identifications were made throughout the year but with most effort from June to September. Number of sightings were most numerous in NCA, SVI, WVI, and NBC and (Table 2). The number of uniquely identified whales was greatest in NCA, NWA, SVI and WVI (Table 2).

3.1 Seasonal Sighting Patterns

Whales have been photographed in every month of the year (Table 5) but with very few during December-February when most of the whales are in or migrating to Mexico and survey effort is reduced. Previous analysis of these data have always used 1 June - 30 November as the sampling period to describe the whales in the PCFG because whales seen prior to 1 June and after 30 November are more likely to be whales that are migrating through the region. The southbound migration starts in December and the separation between May and June is clearly supported by the data. For example, of the 1303 unique whales sighted from California to Kodiak, Alaska, 494 whales were only seen between 1 Dec - 31 May and 88.5% of those were only sighted once (one day). Of the 809 whales sighted between 1 June -30 November at some time, 37.1% were only sighted once (one day). If sightings in Alaska are excluded, then only 30.7% of the 698 were seen only once (one day).

The break between May and June is apparent in various measures such as proportion of whales sighted more than once, sighted in more than one region, and sighted in more than one year (Figure 3). However, the break is more apparent if we separate out SJF, NPS and SVI from the other survey regions (Figure 4). The difference across months is not as strong for inland waters of Washington and British Columbia (NPS, SJF) because these are whales that have diverted from the migration and are either more likely to remain after 1 June or demonstrate high year-to-year fidelity during spring such as with NPS. Also, even though Southern Vancouver Island (SVI) is in the main migration corridor and not an inland water, the pattern across months is also weaker because the sampling has been focused on the spring herring spawn in Barkley Sound (effectively an inland waterway) and has purposefully undersampled passing migrant whales (Brian Gisborne, pers. comm.). The break between May and June is much more apparent for NWA and the other areas in the migration corridor which is consistent with the northbound migration of gray whales proceeding past Washington through May. Resighting rates of whales seen after 1 June remained high through November.

The proposed Makah gray whale hunt in the MUA area (NWA and SJF) may occur in NWA after 30 November and prior to 1 June. A hunt conducted in spring (March-May) potentially could take whales from the PCFG although those chances are less in NWA than in SJF. There have been 181 whale sightings (a unique whale-day) in NWA prior to 1 June of which 40.33% (73) were of whales that were seen in the PCFG after 1 June at sometime. If we restrict the comparison to whales seen in at least 2 years in the PCFG, then the percentage is only reduced to 36.46% (66). If we restrict the area, only 37.02% (67) were of whales that were seen in OR-SVI after 1 June at some time, and 33.15% (60) were of whales that were seen in MUA after 1 June at some time (Figure 5). In comparison, 54 whale sightings were in SJF prior to 1 June of which 70% (39) were of whales that were seen in the PCFG after 1 June at sometime, emphasizing the importance of restricting a hunt to coastal waters of the MUA (i.e., the NWA) to limit the take of whales from the PCFG.

Capture (sighting) histories of whales seen at least once in the PCFG from 1 June - 30 November are provided in Appendix Table 1 which show sightings of whales in 1 Mar -31 May only, 1 June - 30 Nov only and in both time periods within a year.

3.2 Regional Sighting Patterns

There is considerable variation in the annual regional distribution of numbers of whales photographed during the sampling period (Table 6) which is in part due to variation in effort. Although not a true measure of effort, the number of days whales were seen (Table 7) does reflect the amount of effort as well as abundance of whales. In particular, in comparison to other regions, the large number of sightings in SVI partly reflects large numbers of sampling days by Brian Gisborne who has routinely sampled SVI from summer through fall on almost a daily basis. On the other hand, the decline in sightings in SVI during 2007 was not due to reduced effort but to the distribution of whales with many of the whales having moved to waters off Oregon and Washington (Calambokidis et al. 2009b). Similarly, there were 40 survey days in SJF in 2010 but only 4 whales were seen on 4 different days (Table 6, Table 7) so this drop relative to other years was not due to lack of effort.

Whales were sighted across various survey regions and the interchange of whales (Table 8) between survey regions during 1 June - 30 November depends on proximity of the regions (Calambokidis et al. 2004). During 1 June-30 November for 1996 to 2012, 656 unique whales were seen in the PCFG range and 66.8% (438 of the 656 whales seen in the PCFG range) were seen within the smaller OR-SVI region and approximately 34.6% (227 of the 656 whales seen in the PCFG range) were seen within the smaller MUA area; however, there is variation in interchange between areas in the PCFG and the MUA. Of the whales sighted in regions from NCA to NBC, from 35.5% to 58.8% of the whales were seen at some point within MUA (Figure 6). If we exclude transients (whales seen in only one year), the interchange rates with MUA are much higher but the pattern is similar (Figure 7) with a range of 41.3% to 78.9%. Appendix Table 2 provides capture histories using data from 1 June - 30 Nov of whales seen in the MUA at least once. For each year, the table shows whether the whale was sighted in PCFG but not in the MUA during that year, only seen in MUA that year, and seen in both MUA and another PCFG area in that year.

Whales seen in the PCFG exhibited a wide range of movement across and within years. The 118 whales seen in 9 or more years provide a useful example. None of those whales was seen exclusively in a single region, and 68.6% were seen in at least 4 of the 9 survey regions from 1996 to 2012. However, whales did regularly visit the same regions across years with 91.5% were seen in at least one of the regions during six or more of the years they were seen and 67.8% were seen in a region two-thirds or more of the years they were seen. SVI was the region with the maximum number of years seen for 56 of the 118 whales, which in part reflects the larger amount of survey effort in SVI (Calambokidis et al. 2004a, Calambokidis et al. 2013). Thus, some whales regularly visit particular regions more often than others, but they are seen across the other regions as well.

Some of the whales not seen in the PCFG in a year were seen in Kodiak and Southeast Alaska (Table 9). Of the 25 whales identified in Southeast Alaska and the 122 whales identified in Kodiak, Alaska, 14 (56%) and 20 (16.4%), respectively have been seen farther south in the PCFG. For example, whale 130 was only seen in Southeast Alaska in 1999, but had been seen in every other year in the PCFG. Likewise, whale 232 was only seen in Kodiak in 2002, but was seen along Vancouver Island in 2000, 2001, and 2003 but then wasn't seen again until 2011 and may have been somewhere in Alaska waters. Whale 152 was photo-identified in Kodiak in 2002, 2005 and 2010, but was seen in the PCFG as early as 1995 in the Cape Caution, British Columbia, area, and in 1992 in the Clayoquot Sound, British Columbia, survey area but has not been seen in the PCFG after 1 June since 1999, when it was seen along the west coast of Vancouver Island for most of the summer/fall. Another example is Whale 68, which was seen in northern Washington during 1996 and 1997 and then was seen in Southeast Alaska in 1998 and 1999 but not subsequently. While these are only a few examples of whale movements, they illustrate the extensive inter-year movement of whales, which partially explains the gaps in the observations for some whales and the disappearance of others from the PCFG. Whales not seen in a particular year represent a combination of whales that may have spent little time in the PCFG (perhaps primarily staying in some of these neighboring feeding areas) and whales that may have used been missed in the PCFG (coverage of the PCFG is not complete and is concentrated in particular areas and along the coastal zone).

If we look at latitudes of sightings of individual whales across the 17 years using whales that have been sighted on at least 6 different days (Figure 8), we see that sightings of some whales are highly clustered; whereas, sightings of other whales are highly dispersed across several regions. We defined each whales primary range by the 75% inner quantile which is the middle of the range that includes 75% of the locations. The length of the 75% inner quantile in nautical miles exceeded 60 nautical miles (or 1 degree of latitude) for 47.6% of the whales (Figure 9) and it was more than 180 nautical miles for more than 26.5% of the whales. Thus, it makes little sense to compute an estimate of abundance for any region that spans less than a degree of latitude.

3.3 Annual Sighting Patterns

The average number of whales identified in any one year was 146, 95, and 33 for the PCFG, OR-SVI, and MUA, respectively (Table 10). However, those numbers do not represent the total numbers of whales that use each of these areas because not all whales using a region in a year are seen, not all whales return to the same region each year, and not all of the whales return to the PCFG region each year. The annual average number of newly seen whales (excluding 1996-1998 when the photo-id effort expanded to cover all survey regions) was 35.4, 23.8, and 12.1 for PCFG, OR-SVI, and MUA, respectively. The annual average number of newly seen whales that were "recruited" (seen in a subsequent year), excluding 1996-1998 and 2012, was 14.3, 11.8, and 6.1 for PCFG, OR-SVI, MUA respectively. Thus, there were a substantial number of new whales seen each year and 42.1, 50.5, and 53 percent of those were seen again in a subsequent year in the 3 regions respectively. The number of newly seen whales and the number newly seen and recruited (i.e., seen in at least one more year after the initial year it was seen) (Table 11) are displayed as discovery curves in Figures 10 and 11.

Of the whales that were seen during June-November 1996-2012 in the PCFG (NCA to NBC) about half were only seen in one year and the whales that were seen in more years were sighted more often each year and therefore represented a large proportion of the sightings (Figure 12). Of the 603 identified whales first seen before 2012 between 1 June and 30 November in the PCFG range (NCA-NBC), 49% were seen in only one year and only represent about 5% of the sightings (Figure 12). Many of the newly seen whales did not return in subsequent years. Some whales were seen in every year with 7.3% that were seen in every year after their initial identification, including 5 whales first seen in 1996 that were seen in all of 17 subsequent years. The remaining 44% were seen more than once but not in every year.

Likewise, examination of MT in the first sighting year demonstrates that whales who stay longer in their first year were more likely to be seen in a following year (Figure 13). Whales "first" seen in the first few years of the study (1996-1998) includes some whales that were truly new to the PCFG in those years but many were only "new" because it was the first year of the study or as the surveyed regions expanded over time. This is evident (Figure 13) in the much higher proportions for 1996-1998 than for the other years. These relationships will be important in the capture-recapture models for abundance estimation because whales that do not return after their first year (a large percentage in this analysis) would appeared to have not survived because they have permanently emigrated (with a small fraction that died).

3.4 Mothers and calves

In 2011 and 2012, early season effort both prior to 1 June and in the first half of June, identified 18 mothers with calves that had not been seen in any other year and therefore were not known PCFG whales. The vast majority (16, 89%), were seen on only a single day and the only other two were seen on 2 or 3 days. Four of these 18 (including the two seen more than one day) were seen in early June and would qualify as PCFG whales based on the 1 June definition but were likely just late migrating mothers from the overall gray whale population. In 2012 with more intensive effort early in the season and greater attention to mothers with calves, 11 known PCFG mothers with calves were identified, higher than any previous year. This represented 44% of the previously identified PCFG mothers that were seen that year, also representing the highest proportion documented and close to a reasonable reproductive rate for this species.

Through 2012, 45 different PCFG gray whales were seen as definite or probable mothers with 60 calves (Table 12). Despite the many years of study, only 11 whales were seen with calves in multiple years (2 to 4) with only three whales that were sighted with calves in three or more years. One individual (ID#81) was observed with a calf in 2001, 2003, and 2009 and another ID #232 was seen with a calf in 2001, 2003, and 2011. The whale (ID#67) with the most calves included one seen in 1995, 2002, 2004 and 2011. Overall, 3 of the 61 observed calves (Table 12) occurred prior to 1998, leaving 58, about 3.9 per year during our primary study period 1998-2012 . These represent a minimum estimate of the births occurring because: 1) collaborators did not always note the presence or absence of calves, 2) as described below, calves weaned from their mothers, making them unidentifiable as calves, as early as June and July. Both these factors would tend to result in underestimates of the presence of calves. With greater attention to mother and calves in 2012, the number of calves identified of PCFG moms was 12.

The number of mothers seen with calves varied dramatically by year from 0 to 12. In addition to the record numbers of calves seen in 2012 (partly due to a change in effort and focus) there was also a four-year period (2001-2004) which accounted for 27 of the 60 sightings of known mothers with calves indicating there is some real inter-year variation in numbers of calves. During this 4-year period an average of 6.75 calves were seen while an average of 2.7 calves per year was seen in the other 11 years between 1998-2012 . Among the known or suspected mothers seen in 1998 or before, of the years they were seen during 1998-2012, the average proportion they were seen with a calf was 14.8% although it was 21.1% and 27.3% during the peak years of 2001 and 2002, which would be closer to what would be expected if females were getting pregnant almost every other year. In the most recent years of data, the percentages for those females were also higher at 22.2% in 2010, 21.4% in 2011 and 42.9% in 2012. While these years with higher number of calves were likely higher birth years, it is also possible that longer weaning times those years may have contributed to a higher proportion of new calves still with their mothers being documented. Also, recently there has been an increased effort in identification of calves and more sighting effort in the spring.

In 31 cases, a calf was seen associated with its mother early in the season and then the mother or the calf was resighted later in the season separately, suggesting weaning or calf death had occurred. In at least 14 cases separation had occurred prior to a July sighting.

In two cases either the mother or calf was seen separated in June, however, in neither case was the calf resighted in the future year (although the mother was) suggesting these calves may not have survived. If you use the last time mom and calf were sighted together as the separation date, most of the separation dates were in July (32), but 11 were before July and 14 were in August through October. These findings are consistent with weaning most commonly occurring in July.

Of the 45 definite or probable mothers, 32 had been seen four or more years in the study area (13 had been seen only 1, 2, or 3 years). Even those animals with long sighting histories were seen with calves in only a small proportion of the years. However, often the initial sighting of these animals was in late August or later, past the period when weaning may have occurred (Table 12).

While a high proportion of calves were seen in 2012, we also looked at some of the whales first seen in 2012 (after 1 June) that had not been seen as calves associated with mothers to see if they were potentially weaned calves. There were 10 cases where animals first seen in 2012 were resighted five or more times (indicating they were regularly using the area). In four of these case there were comments made in the field that this animal appeared to be a calf or was small and in two additional cases (6 total), the animal appeared to be a younger animal based on photos showing it near another animal. Of first sighting of these 6 animals were in May (1), June (3), and July (2) so spanning the period where weaning occurs. We cannot tell if these might have been calves of PCFG or non-PCFG animals.

Sightings of mothers with calves or known PCFG mothers were in somewhat atypical locations and may suggest some differences in occurrence based on reproductive condition. Four of the mothers identified with calves in 2012 had been seen off Kodiak, AK in 2005 and three of these had not been sighted since they were sighted as mothers in 2012 and the fourth only seen one year in that gap. One mother (ID#281) was regularly sighted in the PCFG area every year from 1999 to 2007. In only one of those years was she with a calf (2002) and in 2008 she was seen on 19 April off Santa Barbara, S California apparently in the migration with a small calf but neither of them were seen that year in any of our effort farther north from Northern California to SE Alaska. Another case not included in our summary because the calf was never seen in the our study area and also there was uncertainty of who was the mother, was an apparent calf (ID 962) sighted off San Miguel Island on 27 July 2006 but which was accompanied by two adults (ID 359 and 718) both of whom were seen in most years from 2002 to 2008 in the Pacific Northwest (N California to SE Alaska), but not in 2006. Both the mothers and calves from these two sightings were not seen in the Pacific Northwest in their birth year (despite the mothers being seen most other years) and were only opportunistically sighted outside the region, suggesting there may be additional calves born to animals that use the Pacific Northwest that perhaps do not come into sampled areas (either within or outside the Pacific Northwest) in their birth year. This would negatively bias estimates of the number of calves born to these animals.

We examined the sighting histories of the identified calves to determine if they tended to be seen in future years. Animals that were not seen in future years could reflect either mortality in the first year of life or animals that did not continue to feed in the Pacific Northwest in future years. Of the 40 calves identified prior to 2011, 60% were resighted in a subsequent year. Using only the 29 calves seen through 2004 (to allow a longer follow up period to resight animals, 19 (65.5%) have been resighted in a later year. In comparison, for non-calves the proportion resighted for those newly seen up through 2004 was lower at 54.9% (230 of 419). Thus, calves appear to be more likely to return to the PCFG than non-calves. The remainder not seen in a following year could be the result of: 1) the calf dying, 2) the calf not returning to the area or not yet resighted during its return, 3) the calf not being recognized by photo-ID since calves can undergo changes in markings rapidly especially if not seen for several years. Given all these factors the resighting rate of calves does suggest a high proportion of surviving calves appear to become part of the feeding aggregation that uses the Pacific Northwest.

3.5 Migratory movements of PCFG whales

A combination of satellite tag and photo-ID data have provided insights into the migratory movements of PCFG whales. Three location-only LIMPET (see Andrews et al. 2008 and Schorr et al. 2009 for details) on gray whales near La Push, WA on 31 May 2012. These tags were deployed as part of a larger study jointly supported by the US Navy and NOAA (though a grant to WDFW)(see Schorr et al. 2013 for details). Tags transmitted for 3–7 days (Table 14, Figure 14) with maximum rate of movement between consecutive points set at 10 kilometers/hour (km/hr) for gray whales. These gray whales were of particular interest because the timing of deployments were still within the migration period but there was a concentration of whales in this area north of La Push that appeared to be feeding. While the duration of the transmissions was fairly short (possibly due to contact with the bottom during feeding), they did confirm these whales were not migrating and almost exclusively stayed in a very localized area consistent with feeding. One whale did shift slightly north to the area off Cape Alava, another known gray whale feeding area, before transmissions ended. All the tagged whales remained very close to shore throughout the transmission period, and in a median water depth of 29 meters (m) (Table 14) which is consistent with the generally shallow feeding depth for gray whales.

Two of the whales that were tagged were known by photo-ID: 1) CRC-813, a known PCFG whale with more than 57 confirmed sightings going back to 2004, and seen every year since in the Pacific Northwest primarily off the northern Washington coast, the Strait of Juan de Fuca and southern Vancouver Island; and 2) CRC-1176 a known individual seen previously in 2009 in spring off south and west Vancouver Island, in January 2011 off northern California and June 2012 off Northern Washington.

Two previous studies have collected data on satellite tagged PCFG whales (Ford et al. 2013, Mate et al. 2010) and both of these combined with photo-ID sighting histories have provided some interesting insights into movements of PCFG whales. Ford et al. (2013) reported on the results of 5 gray whales tagged with LIMPET tags (similar to what we used) in March 2009, 2010, and 2011 during the northward migration off SW Vancouver Island. Durations of these transmissions ranged from 8-16 days and unlike our case these animals consistently continued north migrating up the coast as far as SE Alaska before transmissions ended. Somewhat surprisingly, photo-ID revealed that three of these five were known PCFG whales (CRC 307, 178, and 135 for tags 1, 2, and 3 respectively):

- ID 307 (Tag 1) was only previously known from sightings in June and July 1998 off Vancouver Island. Transmissions from this tag lasted 13 days during which the whale traveled 1,354 km and ended up north of SE Alaska (58.14 N).

- ID 178 (Tag 2) was not identified later in 2010 (the year it was tagged) but had been seen close to 100 times in the PCFG area both in previous years going back to at least 1995 as well as in 2011, the year following when it was tagged. While this tag transmitted the longest of any of the five deployed (16 days), this whale covered the shortest distance (893 km) and ended up only just barely into SE Alaska by the end of transmissions
- ID 135 (tag 3) which was tracked moving north for 8 days after tagging documented as far north as Sitka. Photo-ID documented this animal feeding from June to mid-September later the same year (2010) off S Vancouver Island and this animal was also seen in that same area in 2011 and 2012.
- ID 1380 (tag 4) and ID 1381 (tag 5) have only been identified by photo-ID on the tagging date (20 and 22 March 2011).

Mate et al. (2010) reported on the deployment and movements of 18 PCFG gray whales tagged off N California and S Oregon from September to December 2009. All 18 of these were previously identified PCFG whales and most have resighted in subsequent years although there is one known to have died and three others that have not been seen for 2 or more years (Table 15). There were some interesting relationships between the satellite tag data and photo-ID results:

- Tag 5200827 (ID 659) which was documented to migrate from south to the breeding grounds but spent 9 days of San Miguel Island, S California on route south and stopped there briefly on return, had also been documented feeding off San Miguel Island on 27 July 2006, a year it was not seen at all in the normal PCFG regions suggesting it may have spent the entire summer south of our normal coverage area.
- Tag 5205938 (ID 32) was documented by Mate et al. (2010) to migrate north in spring 2010 to Icy Bay, Alaska after having been tagged off N California in December 2009 and migrating down to Baja. While this whale had been photo-identified almost 50 times in the years prior to having been tagged, most of these are from two years (1999 and 2002) and it was not seen in most other years. Almost all sightings of this animals were from north of Vancouver Island, the northern end of the area regularly sampled by photo-ID. These together suggest this is an animal that has maintained a somewhat regular use of feeding areas north of the normally sampled PCFG area.

In several additional recent cases PCFG whales have been documented during their migration north while on transit in S California. Cascadia receives identification photographs from whale watch operators in the southern California Bight during each spring during the northbound migration. Starting in 2013, identification photographs of gray whales were quickly reviewed by one of matchers familiar with PCFG whales and if the whale was recognized as a potential PCFG whale it was compared to our catalog. While this process is underway initial efforts yielded several surprising matches. On 16 Feb 2013, three PCFG whales were identified in a group of what appeared to be 4 gray whales that were seen off

Santa Barbara by naturalists aboard the whale watch boat Condor Express. There were three sightings of this same apparent group at 10:50, 14:15, and 15:20. In two of those sightings four animals were reported in the sightings and 4 animals were identified with three of them being known PCFG whales (ID 303, 561, and 878) with a 4th unknown whale (in one sighting only two whales were reported and they were 878 and the same unknown whale). These animals were consistently moving west at a consistent speed of about 3 knots. These were the only sightings that day during the two different whale watch trips. It is highly improbable in the overall migration for three PCFG whales to be migrating together in a group of four whales and suggests either some social association or close synchrony in timing of PCFG whales in the migration. Two other PCFG whales (254 and 227) were also identified during the migration north on 21 and 24 February but were not associated with each other. This effort to identify PCFG whales on the migration will continue and should better identify some of the timing and associations of these animals.

3.6 Open Population Capture-Recapture Models

If the yearly cohorts were pooled, Test2+Test3 statistics indicated a significant lack of fit for the PCFG and subsets (Table 16) primarily resulting from Test 3. This was expected due to the different "survival" rates of previously seen whales (true survival) and newly seen whales of which many never returned (i.e., permanently emigrated) (Table 17) . By separating the cohorts, survival for each cohort was time-varying and thus each cohort has a separate first year survival. The goodness of fit test (Test 2) demonstrated a lack of fit for NCA-NBC and OR-SVI (Table 16). For those regions, we estimated an over-dispersion values of $\widehat{c}$=2.25 and $\widehat{c}$=1.4 respectively to adjust AICc and estimated standard errors.

For MUA and NCA-NBC, the best fitted model (Table 18) was model 2 for p with capture probability varying across years and higher when MT was greater in the previous year. For OR-SVI, the simpler model 3 with no year variation in capture probabilty was the best model and in turn it selected a more complex survival model. For φ the best model was model 3 or 4 for MUA, model 6 for OR-SVI and model 4 for NCA-NBC. Both models 4 and 6 included a separate first year survival which depends on MT. There was not much support for the calf covariate for higher first-year "survival" probably because the sample size of calves was small relative to non-calves and because much of the effect would have been absorbed by MT. In models 3 and 4, there are 3 intercepts for first year survival (1996&97, 1998, >1998) and in model 6 the intercept differs for each year. These results were consistent with Calambokidis et al. (2004) who demonstrated strong support for the effect of MT on first year survival (Figure 15) and capture probability (Figure 17) in the following year. These results differ some from Calambokidis et al. (2010) who used an annual median-centered MT. Use of MT with median centering was necessary to construct open model abundance estimates in the manner described in Calambokidis et al. (2010). However, that was not necessary for JS1 and the use of MT without median-centering resulted in lower AICc values.

There was large year to year variation in capture probability. The values for NCA-NBC ranged from 0.42 to 0.98 depending on the year and value of MT (Figure 17). The lowest values were from 2007 which reflects the temporary emigration of whales from MUA and SVI to waters offshore of Oregon in that year. In contrast, for MUA capture probabilities were much lower ranging from 0.09 to 0.86 depending on the year and value of MT (Figure 18). The lower overall capture probability and weaker relationship between capture probability and MT reflect the transitory behavior of whales in such a small area. The lower estimates of of capture probability in 1999-2004 for MUA was due to decreased effort by NMML which spread their survey effort across MUA to WVI during 1999-2002, lost a vessel in 2002 and had no funding in 2004 (Figure 18).

First year survival estimates were dominated by permanent emigration. For NCA-NBC, the estimates varied from 0.32 to 0.82 for non-calf whales with MT=1 in their first year and from 0.75 to 0.93 for MT>80 in their first year (Figure 15). Calf survival is by definition a first year survival rate and potentially includes permanent emigration from the PCFG. Depending on the value of MT, calf survival estimates ranged from about 0.35 to 0.90 (Figure 16). The average calf survival estimate was 0.54 (se = 0.047). There was little support for a different first year calf survival (ϕ models 7-10 in Table 18) possibly because true calf survival with a potentially lower permanent emigration rate happened to be close to first-year survival of non-calves with a higher permanent emigration rate. Unfortunately there is no way to separate these with the existing data.

Survival subsequent to the first year was assumed to be constant but was less for non-calf whales that were newly seen in 1999 or later. Post-first-year suvival for calves and whales present in 1998 or earlier presumably represents true survival assuming there was little permanent emigration after the first year. Those estimates were 0.969 (se=0.0075) and 0.963 (se=0.0079) for OR-SVI and NCA-NBC respectively. The post-first-year survival estimates for whales that entered in 1999 or later and not identified as a calf were 0.906 (se=0.0159) and 0.905 (se=0.0177) for OR-SVI and NCA-NBC respectively.

3.7 Abundance and Recruitment

For NCA-NBC, OR-SVI and MUA annual estimates of abundance were constructed with model averaged values for JS1 (Table 19-20). Estimates for NCA-NBC in Figure 19 are only shown for 1998-2012 with the open models $p = 1$ for 1996 so it will certainly be an underestimate and the survey coverage in 1996 and 1997 was not as extensive as the later years.

The value of N_{min} for 2012 is 197 for NCA-NBC (Table 19). To gain a sense for how these values might be relevant to estimating a possible level of removal (e.g., due to harvest) we computed the MMPA's Potential Biological Removal (PBR) (typically reserved for stock-level assessments). Using the PBR formula, with an Rmax of 6.2% and a recovery factor of 0.5 (Caretta et al. 2013), the PBR for NCA-NBC (PCFG) would be 3.1.

New whales that are not identified as calves have appeared annually and many of these new (non-calf) whales have subsequently returned and been re-sighted (Table 17). In NCA-NBC from 1999-2011, an average of 31.1 (range: 8.0, 69.0) new whales not identified as a calf were seen each year. Of these new non-calf whales, on average 12.5 (range: 1.0, 28.0) whales returned and were seen in subsequent years. It is unknown what proportion of the non-calves used the PCFG as a calf but were not seen in that year. Currently recruitment appears to be offset by losses (either mortality or permanent emigration) as the abundance estimates have been fairly stable since 2002.

4 Discussion

The population structure of gray whales using the Pacific Northwest in summer and fall is complicated and involves two elements. One group of whales return frequently and account for the majority of the sightings in the Pacific Northwest during summer and fall. This group is certainly not homogeneous and even within this group, there is some degree of preference for certain subareas. Despite widespread movement and interchange among areas, some of these gray whales are more likely to be seen returning to the same areas they were seen before. The second group of whales are transients that are seen in only one year, tend to be seen for shorter periods that year, and in more limited areas.

The existence of these two groups in the study area and their dynamics complicate estimating abundance. While the JS1 estimator may not be optimal, it provides a practical way of handling transients in this open population. Excluding 1996-1997, the JS1 sequence of abundance estimates provides the most reliable assessment of trend for the non-transient abundance and the best estimate of current abundance in 2012.

Despite extensive interchange among subregions in our study area, whales do not move randomly among areas. Abundance estimates were lower when using more limited geographic ranges but these more limited areas do not reflect closed populations. While the use of geographically stratified models can be useful in cases where populations have geographic strata they use (see for example Hilborn 1990), this would be difficult in our case because of the frequent sightings of animals in multiple regions within the same season and these models typically only allow an animal to be sighted in one strata per period. This could be dealt with by assigning animals to only a single region per season but this would be forcing the data into a somewhat inaccurate construct.

Several studies have considered the question of gray whale population structure. There is widespread agreement that at least two populations of gray whales in the North Pacific exist, a western North Pacific population (also called the Korean population) and an eastern North Pacific (ENP) population (sometimes called the California population) (Swartz et al. 2006; Angliss and Outlaw 2008; Rugh et al. 1999). The population structure of the gray whales feeding in the Pacific Northwest has remained in question and only a few studies have examined this. Steeves et al. (2001) did not find mtDNA differences in a preliminary comparison of gray whales from the summer off Vancouver Island and those from the larger ENP population. Ramakrishnan et al. (2001) did not find evidence that the Pacific Northwest whales represented a maternal genetic isolate, although even very low levels of recruitment from the larger overall population would prevent genetic drift. More recently, Frasier et al. (2011) generated mtDNA sequences from a larger sample of gray whales from Vancouver Island than tested by Steeves et al. (2001). They found significant differences in the haplotype frequencies between that sample and mtDNA sequence data reported for ENP gray whales, most of which were animals that stranded along the migratory route. The Frasier et al. (2011) samples were from a relatively small area; however, Lang et al. (2011) evaluated biopsy samples from California to southern Vancouver Island in the PCFG and ENP samples from whales sampled north of the Aleutians and also found significant mtDNA halpotype frequency differences. These two studies provide the strongest evidence to date that the Pacific Northwest whales might be sufficiently isolated to allow maternally inherited mtDNA to differ from the overall ENP population.

Population structure in other large whales has been the subject of recent inquiry and has revealed diverse results for different species. Clapham et al. (2008) examined 11 subpopulations of whales subjected to whaling that were extirpated possibly due to the loss of the cultural memory of that habitat and concluded subpopulations often exist on a smaller spatial scale than had been recognized. Studies of other baleen whales, particularly humpback whales, have shown evidence of maternally directed site fidelity to specific feeding grounds based on photographic identification studies (Calambokidis et al. 1996, 2001, 2008). This high degree of fidelity to specific feeding areas is often discernible genetically. In the North Pacific strong mtDNA differences were found among feeding areas even when there was evidence of low level of interchange from photo-ID (Baker et al. 2008). Similar findings were documented for humpback whales in the North Atlantic which feed in different areas but interbreed primarily on a single breeding ground (Palsboll et al. 1995) like ENP gray whales. In the North Pacific the differences for humpback whales were often dramatic. For example, humpback whales that feed off California have almost no overlap in mtDNA haplotypes with humpback whales feeding in Southeast Alaska (Baker et al. 1990, 1998, 2008). One difference between humpback and gray whales is the coastal migration route of gray whales which means gray whales going to arctic waters to feed would migrate right through the feeding areas to the south. Other species of large whales have not shown as strong site fidelity to specific feeding grounds. Blue whales have undergone an apparent shift in their feeding distribution in the North Pacific apparently due to shifting oceanographic conditions (Calambokidis et al. 2009a). Fin whales in the North Pacific have long migrations and while there do not appear to be multiple distinct feeding areas as was the case for humpback whales, there were some distinct and isolated apparently non-migratory populations (Mizroch et al. 2009; Berube et al. 2004).

Even though the population structure of gray whales off the Pacific Northwest remains unresolved, there is a consistent group of animals that use this area and we provide several estimates of their abundance. Different abundance methods and geographic scopes yield varied results but all suggest the annual abundance of animals using the Pacific Northwest for feeding through the summer is at most a couple hundred animals depending on the estimating method and how broadly the region is defined geographically.

The rapid increase in the abundance estimates at the start of this study is in part due to the smaller area of coverage during 1996 and 1997. We included those years to improve the estimate in 1998-1999 and the estimate for 1998 did increase by 7% from previous analysis. The increase from 1998-2000 occurred during a period the overall eastern North Pacific gray whale population was experiencing a high mortality event that included unusually high numbers of gray whales showing up in areas they were not common. The high rate of increase in the late 1990s and early 2000s should be verified with additional data such as compiling photographic identifications for this area from multiple sources to attempt to verify if the abundance of animals prior to the start of our study was as low as suggested by these trends. Even though the rate of increase may be too high, we believe the abundance did increase and now appears to be relatively stable since 2002.

Acknowledgments

This analysis would not have been possible without the collaborating organizations and individuals contributing identification photographs (the primary contributors are listed in Methods and Tables 1 and 2). Support for the photographic identification reported here, the comparison of gray whale photographs and preparation of this report came primarily from the National Marine Mammal Laboratory. Permission to conduct some portions of this research in U.S. waters was provided by the U.S. National Marine Fisheries Service and the Makah Tribe. Portions of the research in British Columbia were conducted collaboratively with Fisheries and Oceans Canada (thanks to John Ford and Graeme Ellis). Volker Deecke assisted in analysis and matching of identifications from S. Vancouver Island. William Megill coordinated providing sightings and identifications from CERF, Dawn Goley and Jeff Jacobsen coordinated effort for HSU, Christina Tombach and Dave Duffus coordinated early efforts for UVIC, Carrie Newell provided identification photographs from Oregon, Merrill Gosho, Pat Gearin, Nate Pamplin and Jonathan Scordino provided photos form Washington. Brian Gisborne's diligence and hard work provided an immense amount of data and photographs from Vancouver Island. A number of people assisted in the field effort and in the printing and matching of photographs at Cascadia Research. Erin Falcone, Lisa Schlender, Jennifer Quan, and Amber Klimek helped compile the data from different contributors and conducted photographic matching. Randy Lumper conducted gray whale matching in the early years of this study. Jonathan Scordino, Steve Stone and Donna Darm provided many helpful comments, suggestions and edits.

Table 2: Regional distribution of numbers of sightings (one or more photographs of a whale per day) and resulting number of uniquely identified whales by reseach group for 1996-2012. Totals for whales are unique whales across all research groups. NPS is northern Puget Sound and PS includes southern Puget Sound, San Juan Islands, Hood Canal and Boundary Bay.

Table 3: Survey regions and region subsets used for abundance estimation. Numbers refer to locations on the map in Figure 1.

Survey Region	Region Description	NCA-NBC	OR-SVI	MUA
(1) SCA = Southern California				
(2) CCA = Central California				
(3) NCA = Northern California	Eureka to Oregon border; mostly from Patricks Pt. and Pt. St George	x		
(4) SOR = Southern Oregon		x	x	
(5) OR = Oregon Coast	Primarily central coast near Depoe Bay and Newport, OR	x	x	
(6) GH+ = Gray's Harbor	Waters inside Grays Harbor and coastal waters along the S Washington coast	x	x	
(7) NWA = Northern Washington	Northern outer coast waters with most effort from Cape Alava (Sea Lion Rock) to Cape Flattery	x	x	x
(8) SJF = Strait of Juan de Fuca	US waters east of Cape Flattery extending to Admiralty Inlet (entrance to Puget Sound) with most effort ending at Sekiu Point	x	x	x
(9) NPS = Northern Puget Sound	Inside waters and embayments from Edmonds to the Canadian border			
(10) PS = Puget Sound	Central and southern Puget Sound (S of Edmonds), including Hood Canal, Boundary Bay, and the San Juan Islands			
(11) SVI = Southern Vancouver Island	Canadian waters of the Strait of Juan de Fuca along Vancouver Island from Victoria to Barkley Sound, along West Coast Trail	x	x	
(12) WVI = West Vancouver Island		x		
(13) NBC = Northern British Columbia	British Columbia waters north of Vancouver Island, with principal effort around Cape Caution	x		
(14) SEAK = Southeast Alaska	Waters of southeastern Alaska with the only effort in the vicinity of Sitka			
(15) KAK = Kodiak, Alaska				

Table 4: Model specifications for survival (φ) and capture probability (p) parameters in POPAN models for gray whale photo-identification data. For survival models, β_0 is the baseline intercept for non-transient survival. Fy is 1 if it is year the whale was first seen and 0 otherwise. A subscript for Fy means that it applies only for that cohort except that Fy_{99}applies to cohorts 1999 and beyond and Fy_c represents each of the cohorts from 1996 to 2012. C is 1 if identified as a calf in its first year and 0 otherwise. R is 1 for calves or any whale seen in 1998 or was already in the catalog prior to 1998 and 0 otherwise. β_r is an adjustment to post-first-year survival. MT is minimum tenure value of a whale and β_M is the estimated slope parameter for φ or p. $\beta_{M,96-97}$ applies to 1996-97, $\beta_{M,98}$ to 1998 and $\beta_{M,99}$ applies to 1999-2011. $\beta_{Fy,96-97}$, $\beta_{Fy,98}$ and $\beta_{Fy,99}$ are the first-year survival intercept adjustments for 1996-97, 1998 and cohorts 1999-2011 respectively and $\beta_{Fy,c}$ represents 16 cohort-specific first year survival parameters for 1996-2011. β_{CF} is an adjustment for calf first year survival and β_{CM} is an adjustment for calves to the slope of MT for survival. For the capture probability models, β_t has 15 levels for t=1998,...2012 and β_0 represents the 1997 value. For 1996 p=1.

Model	Parameter Logit Formula	Number of parameters
φ		
1	$\beta_0 + \beta_{Fy} Fy + \beta_r R(1 - Fy)$	3
2	$\beta_0 + \beta_{Fy} Fy + \beta_M MT\,Fy + \beta_r R(1 - Fy)$	4
3	$\beta_0 + \beta_{Fy,96-97} Fy_{96-97} + \beta_{Fy,98} Fy_{98} + \beta_{Fy,99} Fy_{99} + \beta R(1 - Fy)$	5
4	$\beta_0 + \beta_{Fy,96-97} Fy_{96-97} + \beta_{Fy,98} Fy_{98} + \beta_{Fy,99} Fy_{99} + \beta_M MT\,Fy + \beta_r R(1 - Fy)$	6
5	$\beta_0 + (\beta_{Fy,96-97} + \beta_{M,96-97} MT) Fy_{96-97} + (\beta_{Fy,98} + \beta_{M,98} MT) Fy_{98} + (\beta_{Fy,99} + \beta_{M,99} MT) Fy_{99} + \beta_r R(1 - Fy)$	8
6	$\beta_0 + \beta_{Fy,c} Fy_c + \beta_M MT\,Fy + \beta_r R(1 - Fy)$	18
7	$\beta_0 + \beta_{Fy,c} Fy_c + \beta_M MT\,Fy + \beta_{CF} C\,F_y + \beta_r R(1 - Fy)$	19
8	$\beta_0 + \beta_{Fy,c} Fy_c + \beta_M MT\,Fy + \beta_{CF} C\,F_y + \beta_{CM} C\,MT + \beta_r R(1 - Fy)$	20
9	$\beta_0 + (\beta_{Fy,96-97} + \beta_{M,96-97} MT) Fy_{96-97} + (\beta_{Fy,98} + \beta_{M,98} MT) Fy_{98} + (\beta_{Fy,99} + \beta_{M,99} MT) Fy_{99} + \beta_{CF} C\,F_y + \beta_r R(1 - Fy)$	9
10	$\beta_0 + (\beta_{Fy,96-97} + \beta_{M,96-97} MT) Fy_{96-97} + (\beta_{Fy,98} + \beta_{M,98} MT) Fy_{98} + (\beta_{Fy,99} + \beta_{M,99} MT) Fy_{99} + \beta_{CF} C\,F_y + \beta_{CM} C\,MT + \beta_r R(1 - Fy)$	10
p		
1	$\beta_0 + \beta_t$	15

Table 11: Discovery of new unique whales over years 1996-2012 for PCFG,OR-SVI and MUA. Recruited only means that the whale was seen in at least one more year after the initial year it was seen. The number 'recruited' will be less than the abundance estimate because some whales die and others may permanently emigrate and do not return.

Region	1996	1997	1998	1999	2000	2001	2002	2003	2004	2005	2006	2007	2008	2009	2010	2011	2012

Table 12: History of mothers seen with calves during study. Each year a whale was seen, the first conrmed sighting date is shown for that year. Years where a calf was documented are shown with an asterisk. Total years seen includes 16 sightings of whales during 1984, 1988, 1990-1993 that are not shown but no calves were seen in those few cases. For one of the calves a mother was not identified.

ID	Calves	1994	1995	1996	1997	1998	1999	2000	2001	2002	2003	2004	2005	2006	2007	2008	2009	2010	2011	2012	Years seen

Table 13: Sighting histories of calves identified in the study area. First separate date represents sighting of either the calf or mother alone. An asterisk by the calf ID implies it is suspected to be a calf; others are all known to be calves.

Table 14: Deployment and movement summary for LIMPET satellite tags on three gray whales near La Push on 31 May 2012. Cumulative minimum horizontal displacement is likely an under representation of the true distance covered by an individual, as it is calculated as a straight line between Argos locations and does not account for any vertical displacement (diving).

ER Tag ID	Trans. durat (Days)	No. locations which passed filter	Cumulative min. horizontal displacmt (km)	Median distance to deployment (km) (max)	Median depth (m) (Range)	Median distance to shore (km) (Range)
001	2.9	31	57	2 (5)	28 (9-32)	1.1 (0.2-3)
002	4.4	62	162	3 (10)	29 (1-34)	1.3 (0-6.3)
003	6.8	93	203	3 (22)	3 (22)	1.7 (0.1-7.3)

Table 15: Identification histories of PCFG gray whales that were tagged by OSU in fall 2009. Numbers underneath years indicate the number of times the whale was sighted that year. Red highlight indicates two whales not sighted in a subsequent year post-tagging, another whale that has not been seen since Jan 2010 and a 4th whale known to have die (in 2011).

Table 17: Number of whales seen each year, number that were new that year in that region, and number that were new and were seen in a subsequent year for whales seen between June-November 1996-2012 in each region. The year a whale was seen as new can vary across regions and if it differs will be later in the smaller region.

Region		1996	1997	1998	1999	2000	2001	2002	2003	2004	2005	2006	2007	2008	2009	2010	2011	2012

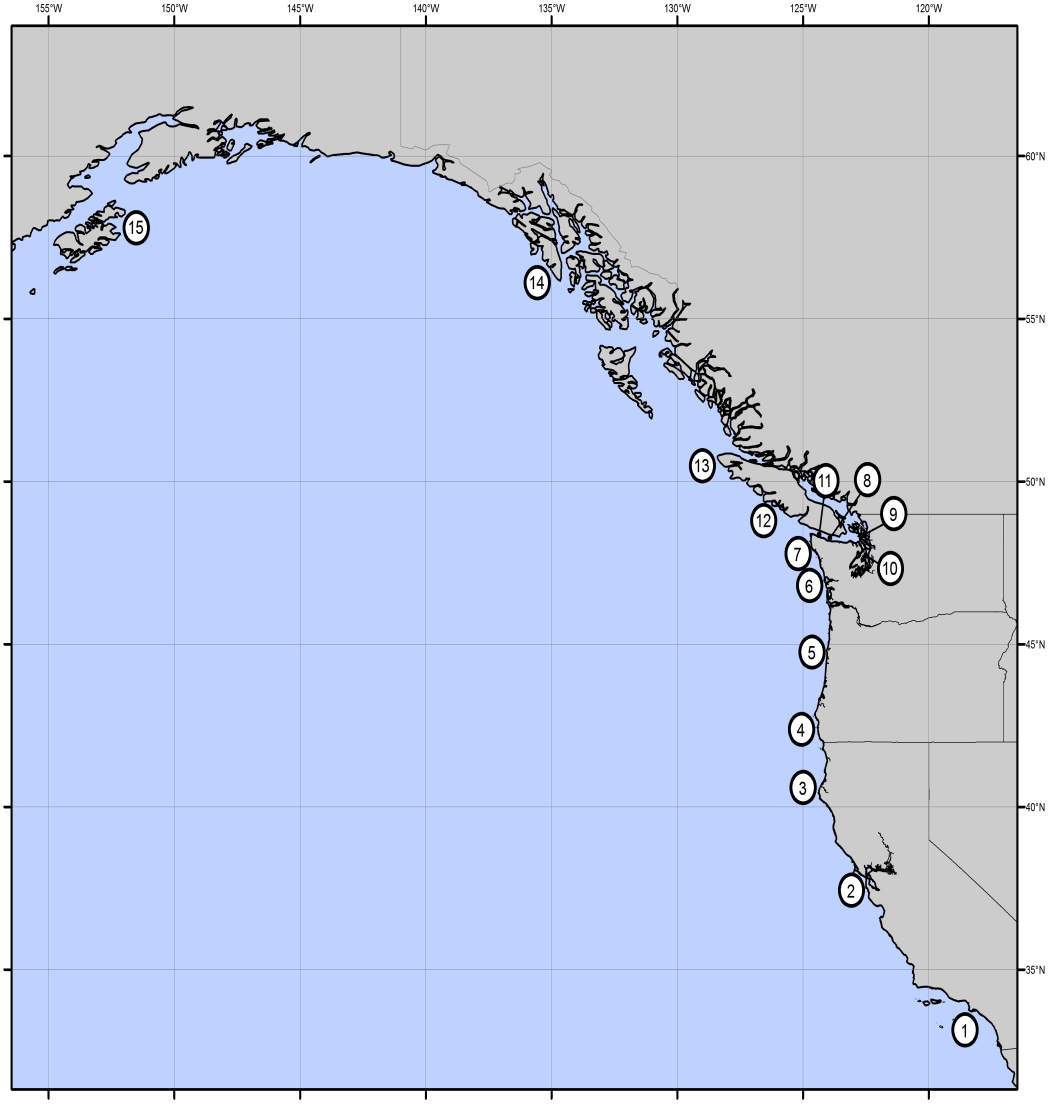

Figure 1: Locations for photo-identifications of gray whales. Numbers refer to values in Table 3.

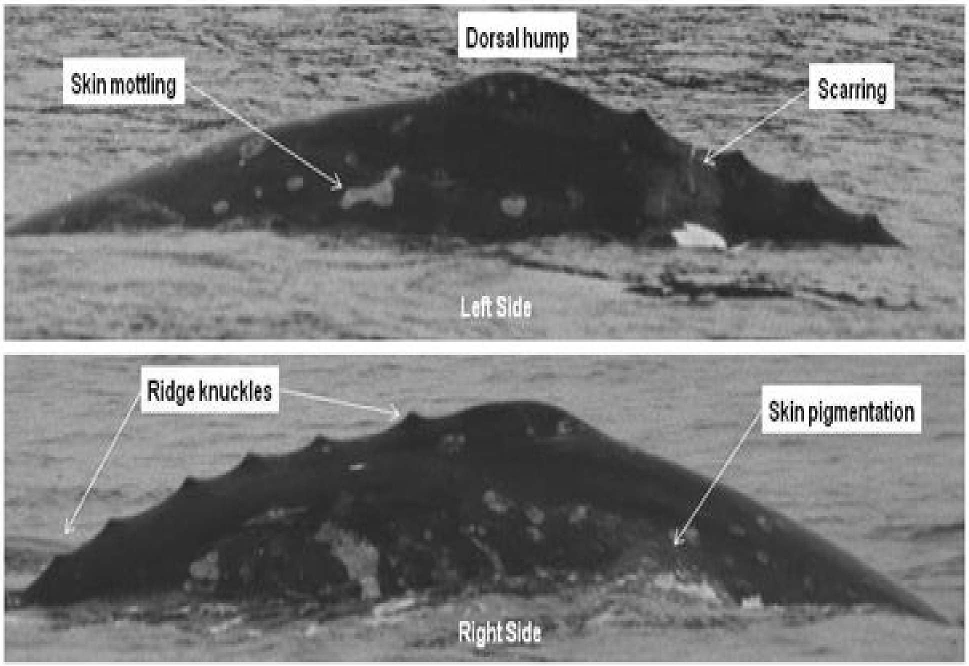

Figure 2: Characteristics used for gray whale photo-identification.

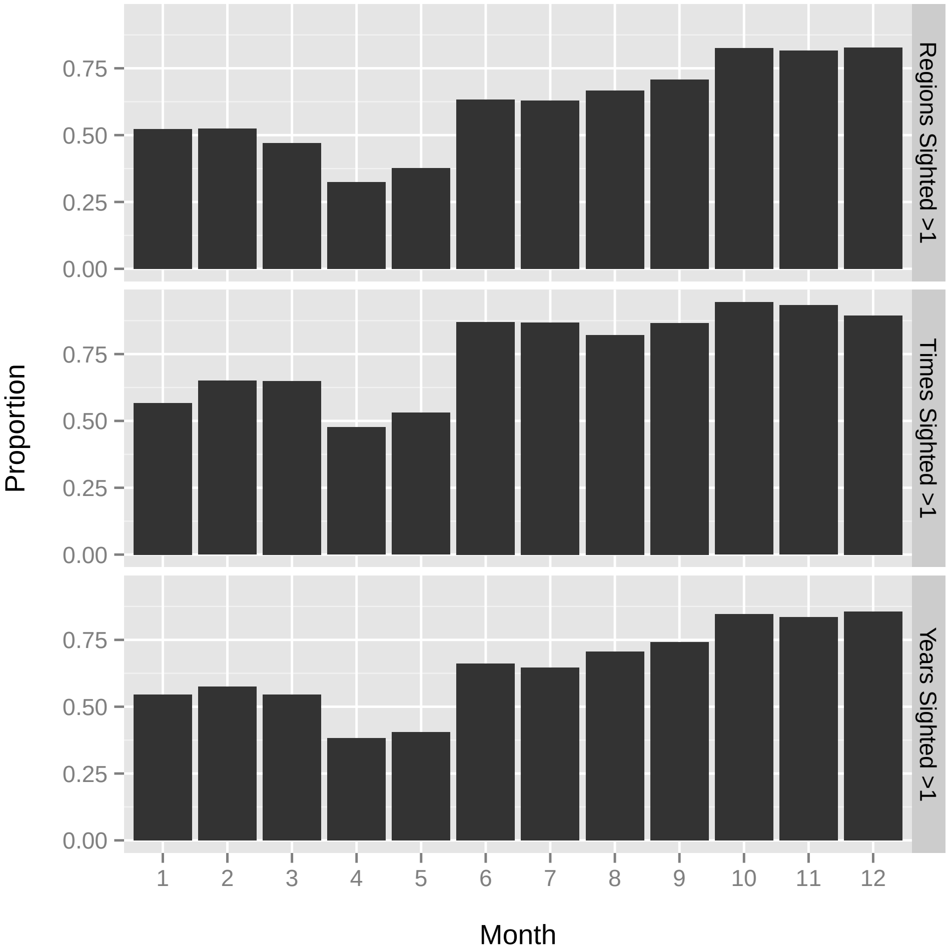

Figure 3: Monthly measures of proportion of whales that were seen in more than one region, seen on more than one day and seen in more than one year. The values include sightings from 1996-2012 in all regions from California to Alaska. Lower values imply whales were simply migrating through the area in a short time frame and were thus less likely to be seen at other times and in other regions. Values are not shown for months with fewer than 20 sightings. Whales seen more often are over-represented because they are used in each month they were seen. For example a whale seen in June, July and August will be in each summary. Thus, these values may be larger than values computed without splitting by month (e.g., overall proportion of whales seen in more than one year).

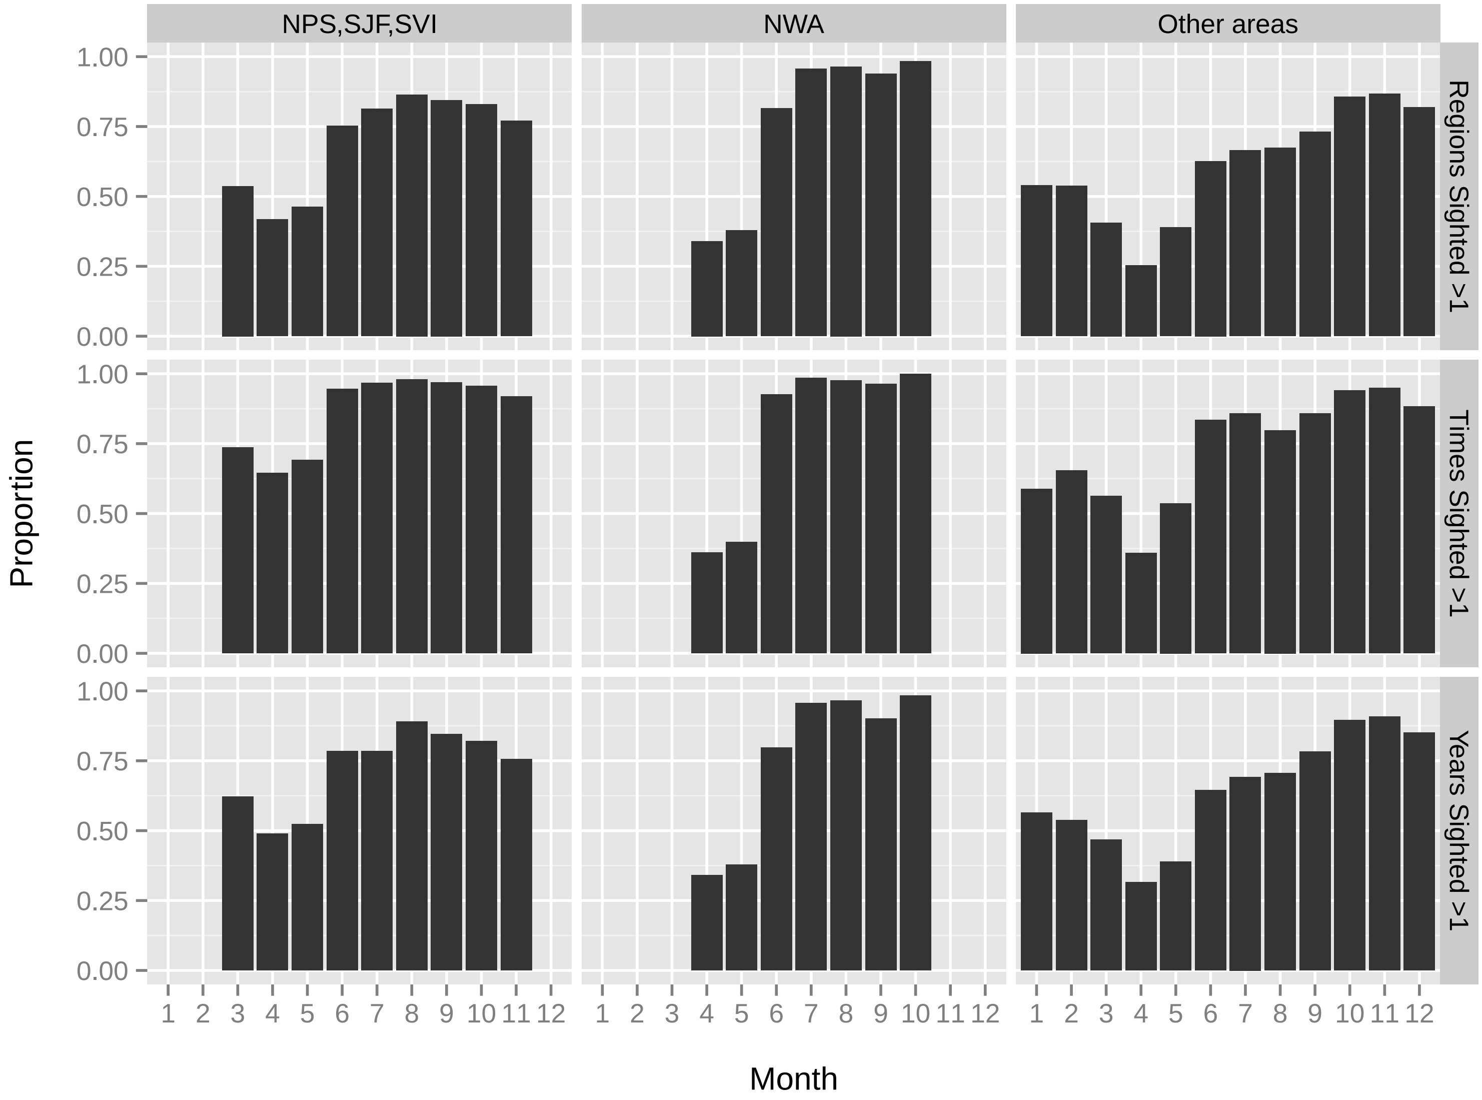

Figure 4: Region and monthly measures of proportion of whales that were seen in more than one region, seen on more than one day and seen in more than one year. The values include sightings from 1996-2012 in all regions from California to Alaska. Lower values imply whales were simply migrating through the area in a short time frame and were thus less likely to be seen at other times and in other regions. Values are not shown for months with fewer than 20 sightings. Whales seen more often are over-represented because they are used in each month they were seen. For example a whale seen in June, July and August will be in each summary. Thus, these values may be larger than values computed without splitting by month (e.g., overall proportion of whales seen in more than one year).

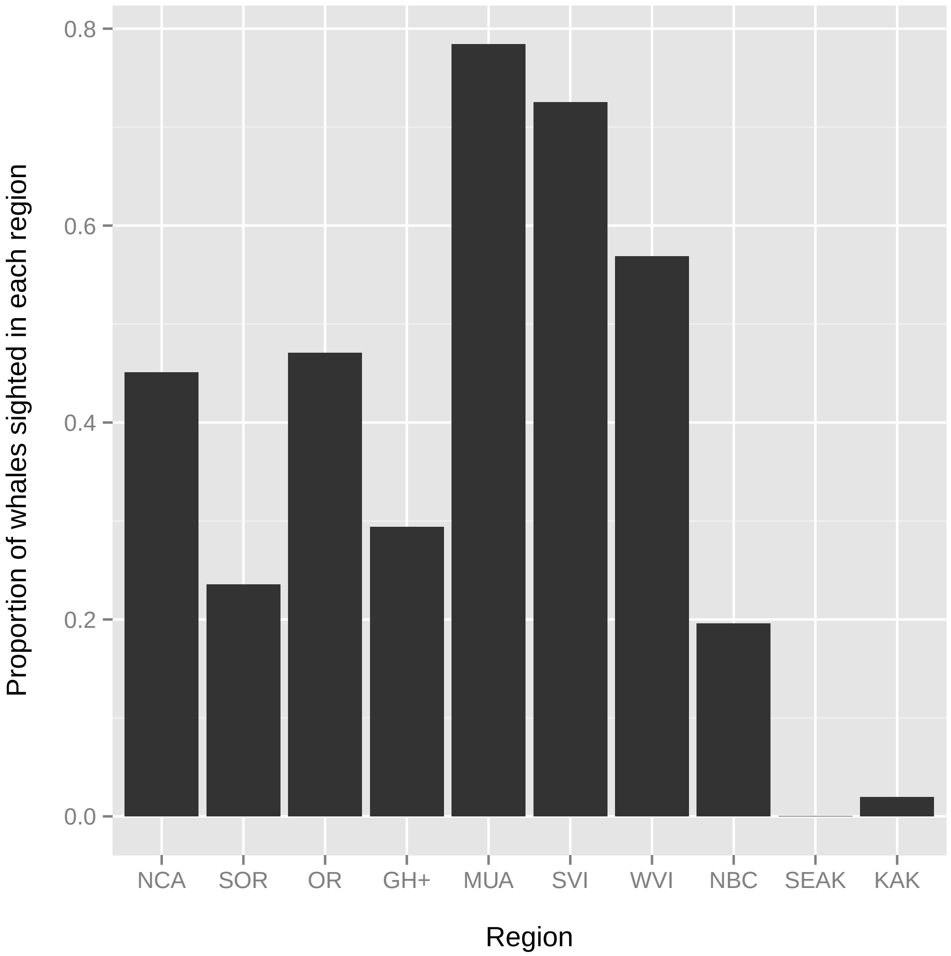

Figure 5: Proportion of the 51 unique whales seen in NWA during the spring and in the PCFG after 1 June that were seen in each PCFG sub-region after 1 June at least once from 1996-2012.

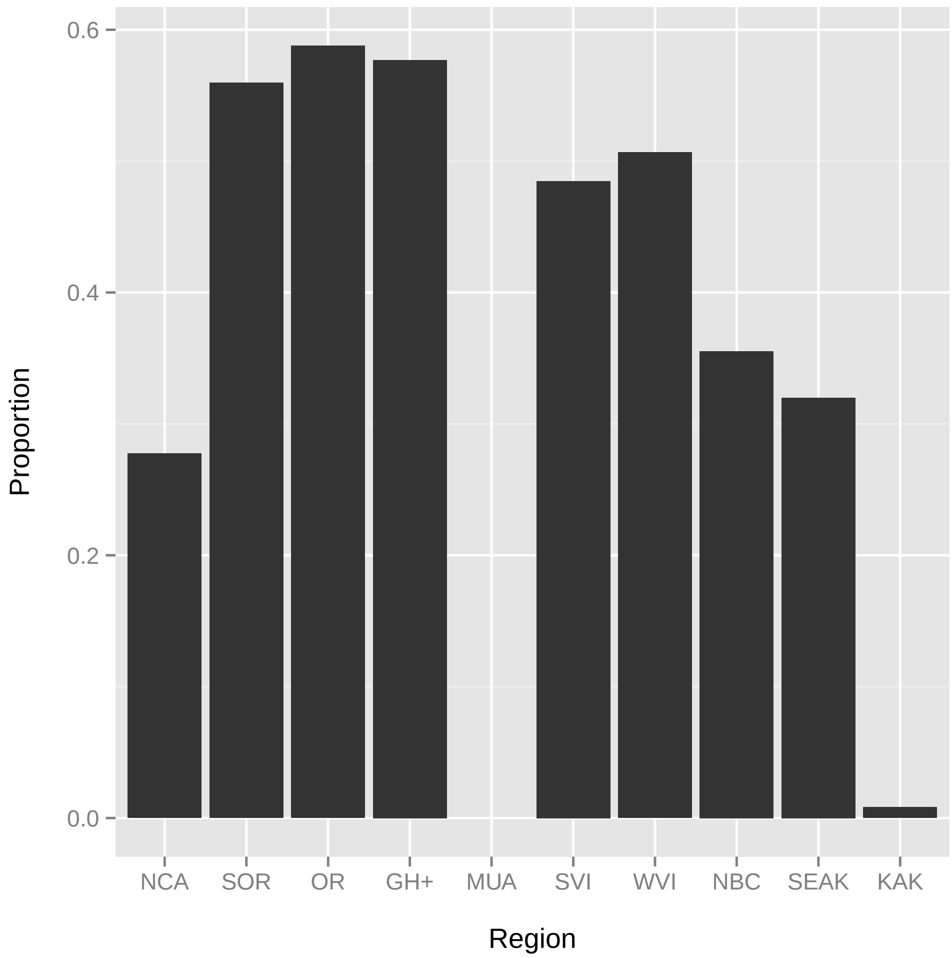

Figure 6: Proportion of whales in sub-regions from NCA to KAK that have been seen in the MUA using sightings after 1 June from 1996-2012.

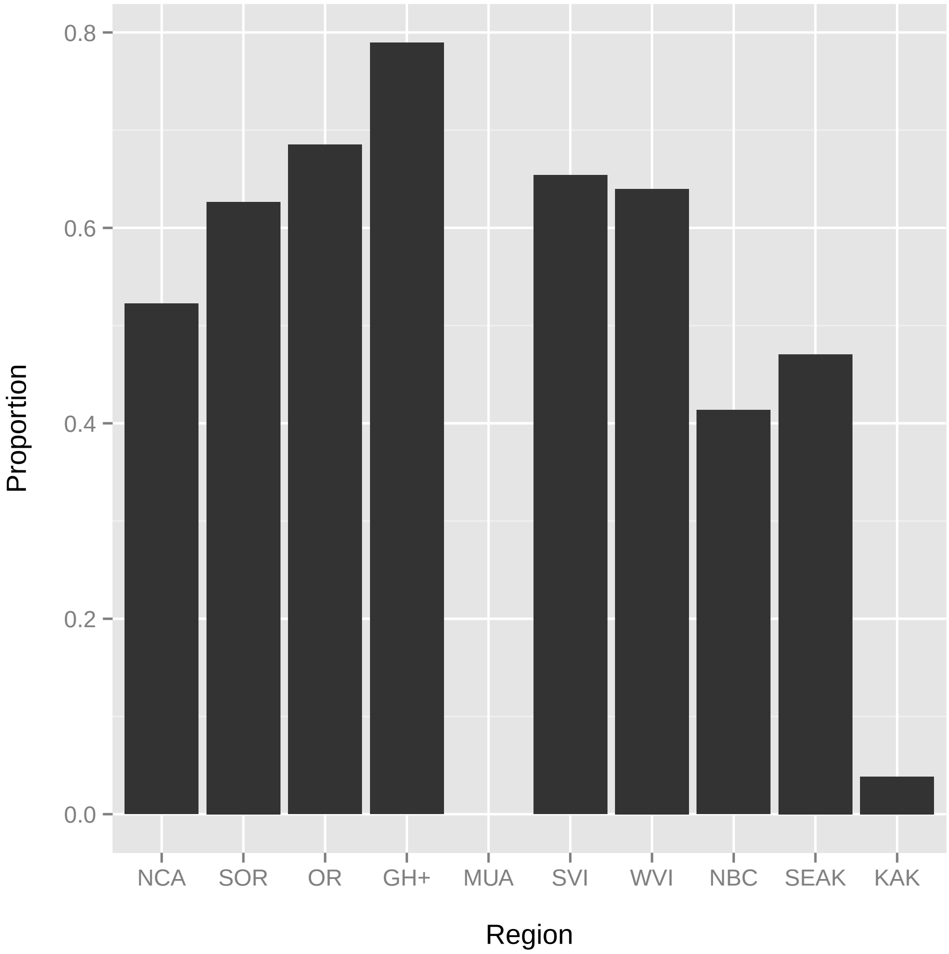

Figure 7: Proportion of whales seen in at least 2 years in sub-regions from NCA to KAK that have been seen in the MUA using sightings after 1 June from 1996-2012.

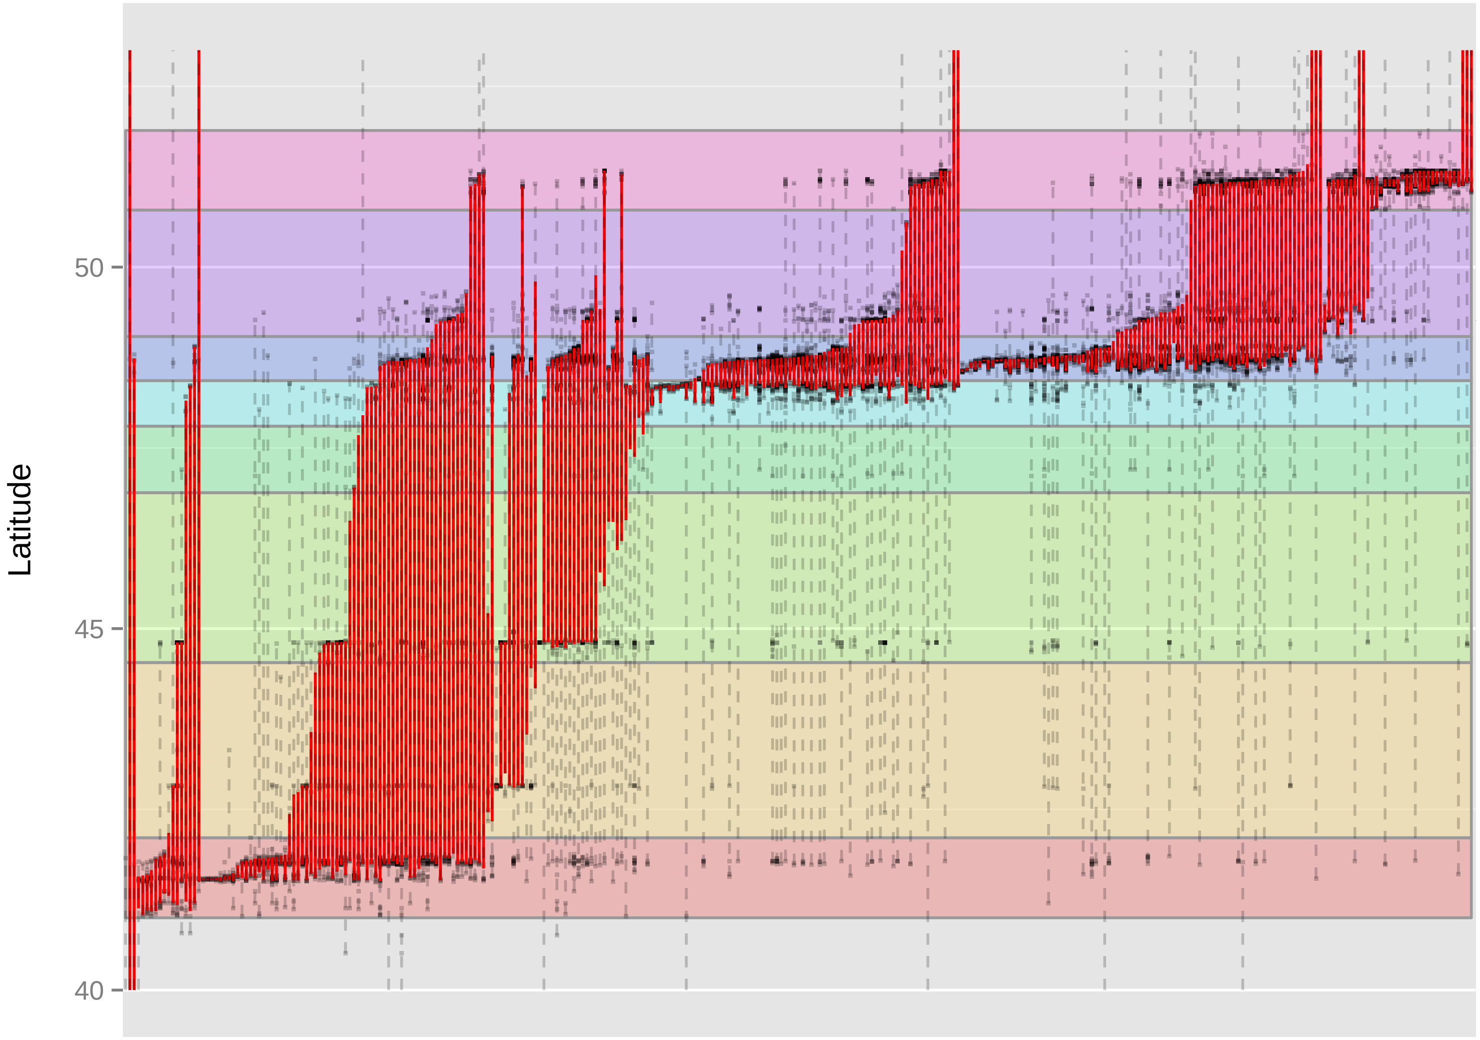

Figure 8: Distribution of latitudes of sightings (points) for whales with 6 or more sightings after 1 June from 1996-2012, the 75% inner quantile (solid thick line), and full range (light dashed line). Each position on the x axis represents an individual whale. Whales have been arranged on the plot by sorting first on the lower bound of the inner quantile (to a half-degree) and then the upper bound of the quantile. This has the effect of sorting from south to north and clusters whales with smaller quantile ranges followed by whales with larger ranges.

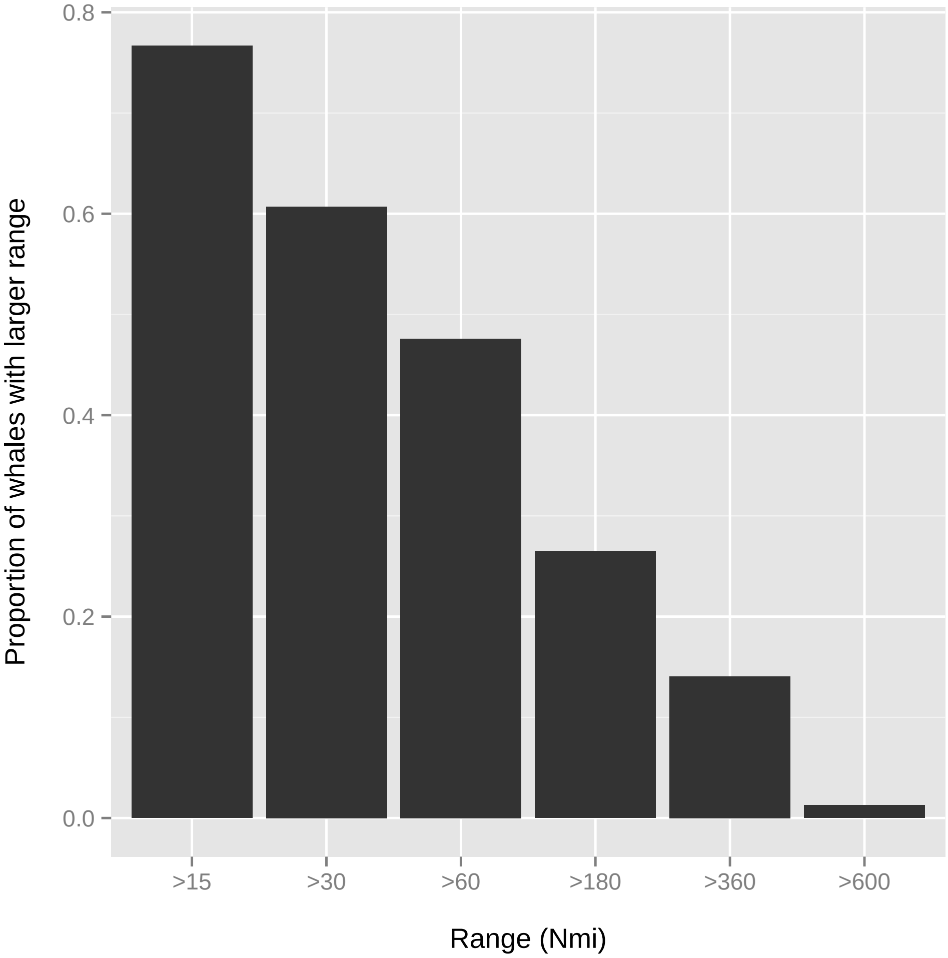

Figure 9: Distribution of ranges of 75% inner quantiles of latitudes expressed in nautical miles for whales sighted on 6 or more days during 1996-2012.

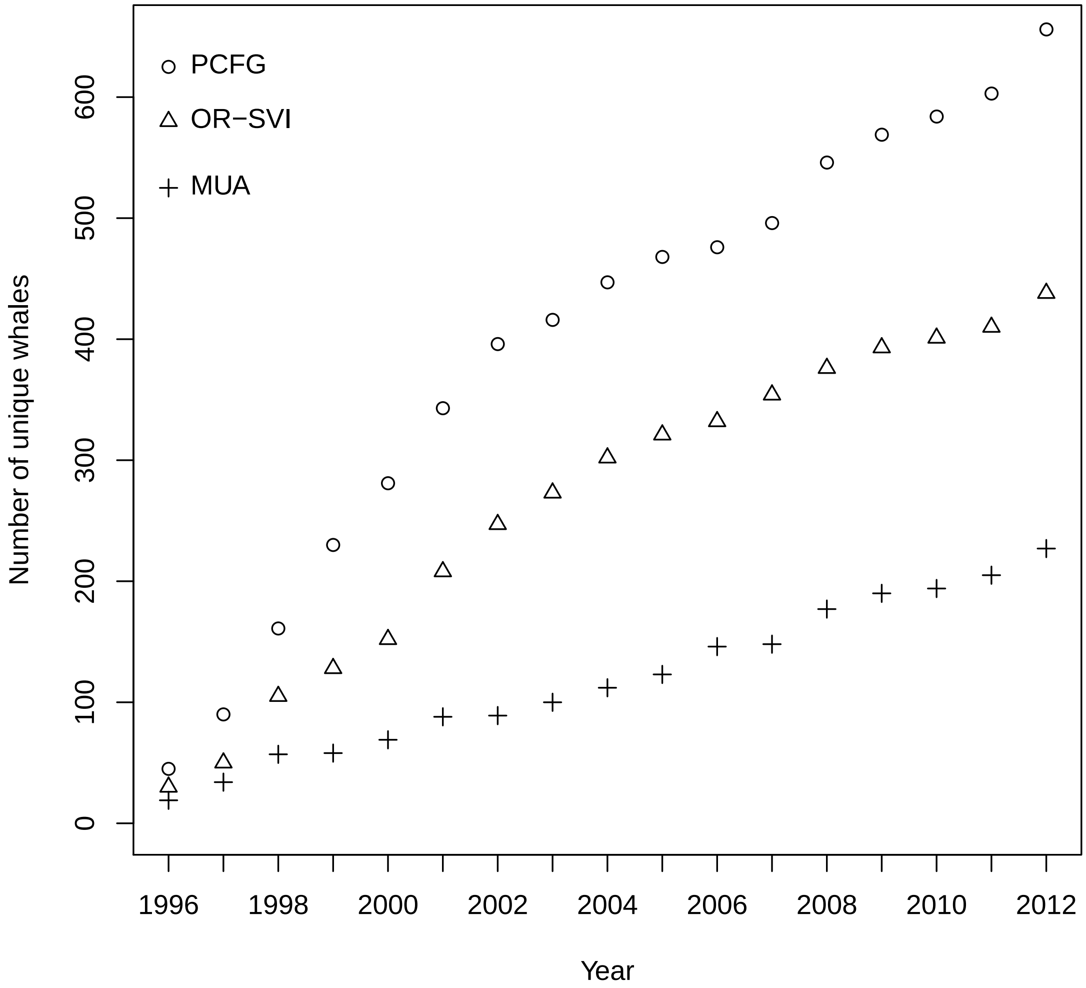

Figure 10: Discovery curves for unique whales seen in PCFG, OR-SVI and MUA for 1996-2012.

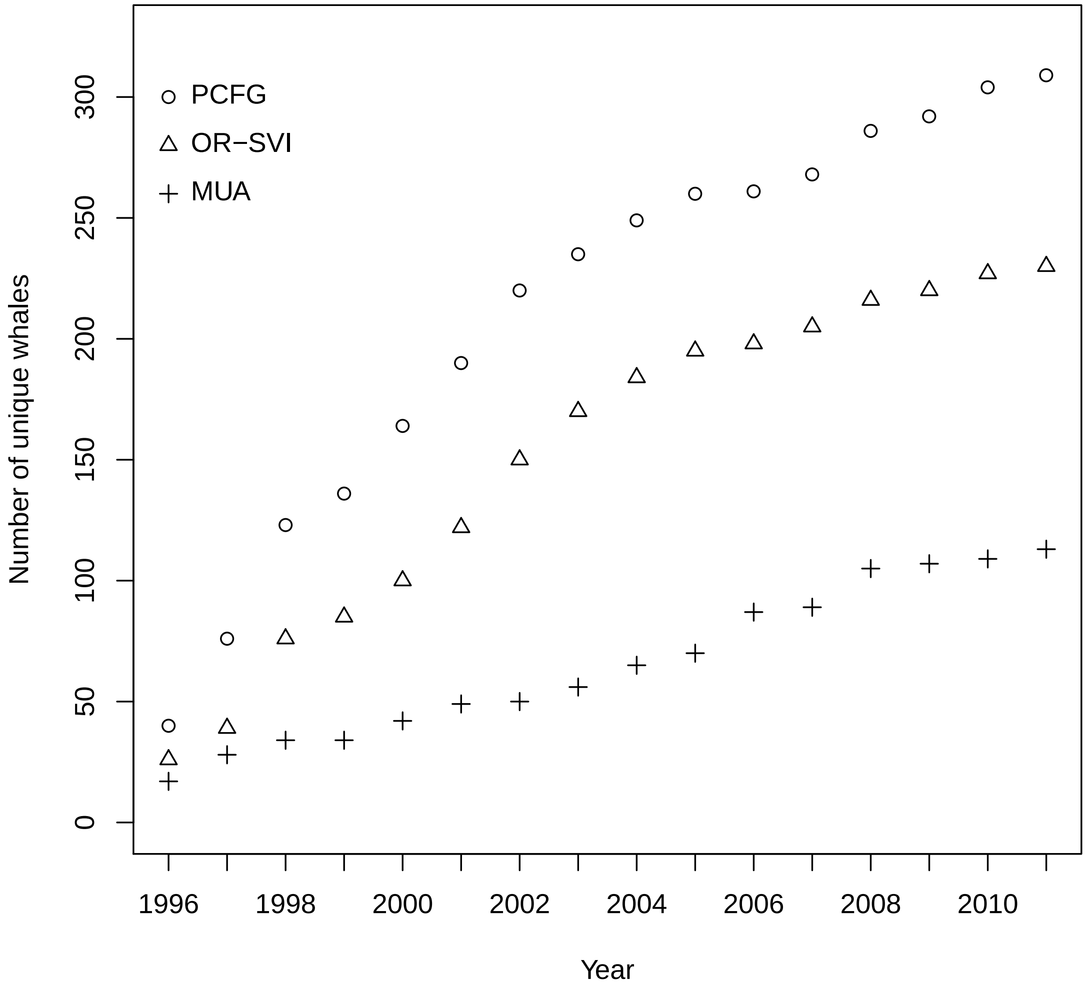

Figure 11: Discovery curves for unique recruited whales seen in PCFG, OR-SVI and MUA for 1996-2012.

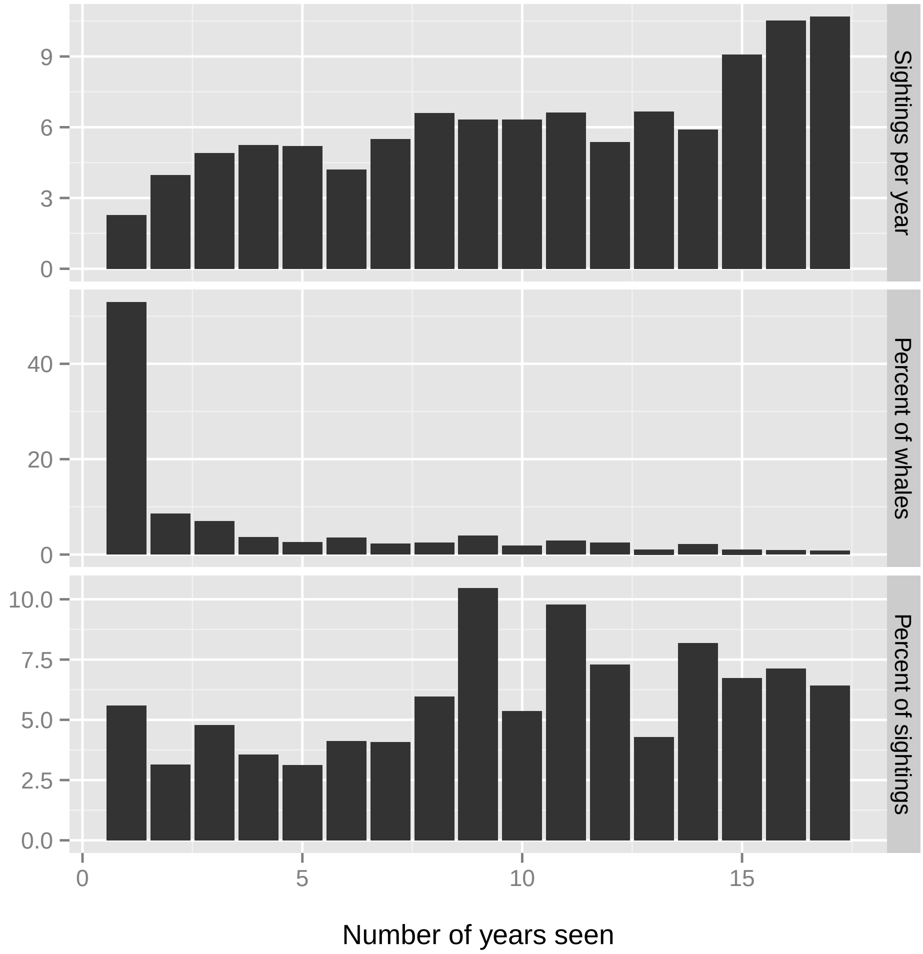

Figure 12: Average number of sightings per year and distribution of whales and numbers of sightings based on numbers of years a whale was seen in NCA-NBC between June-November during 1996-2012.

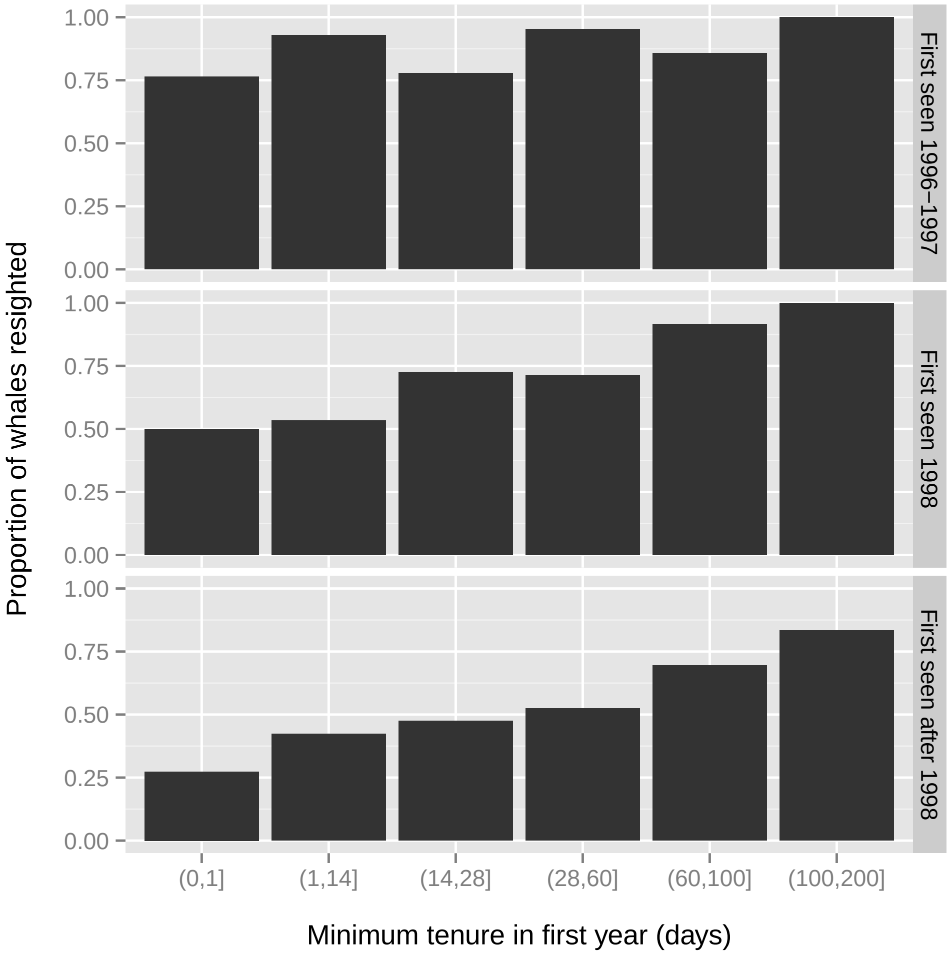

Figure 13: Influence of minimum tenure (MT) in the first year the whale was photographed on the probability it will be re-sighted in one or more following years for whales seen in NCA-NBC for June-November 1996-2012. The bar graphs are divided based on first year in 1996-1997, 1998 and after 1998. Re-sightings for 2012 are used but initial sightings for 2012 are excluded because there are no data beyond to evaluate re-sighting probability.

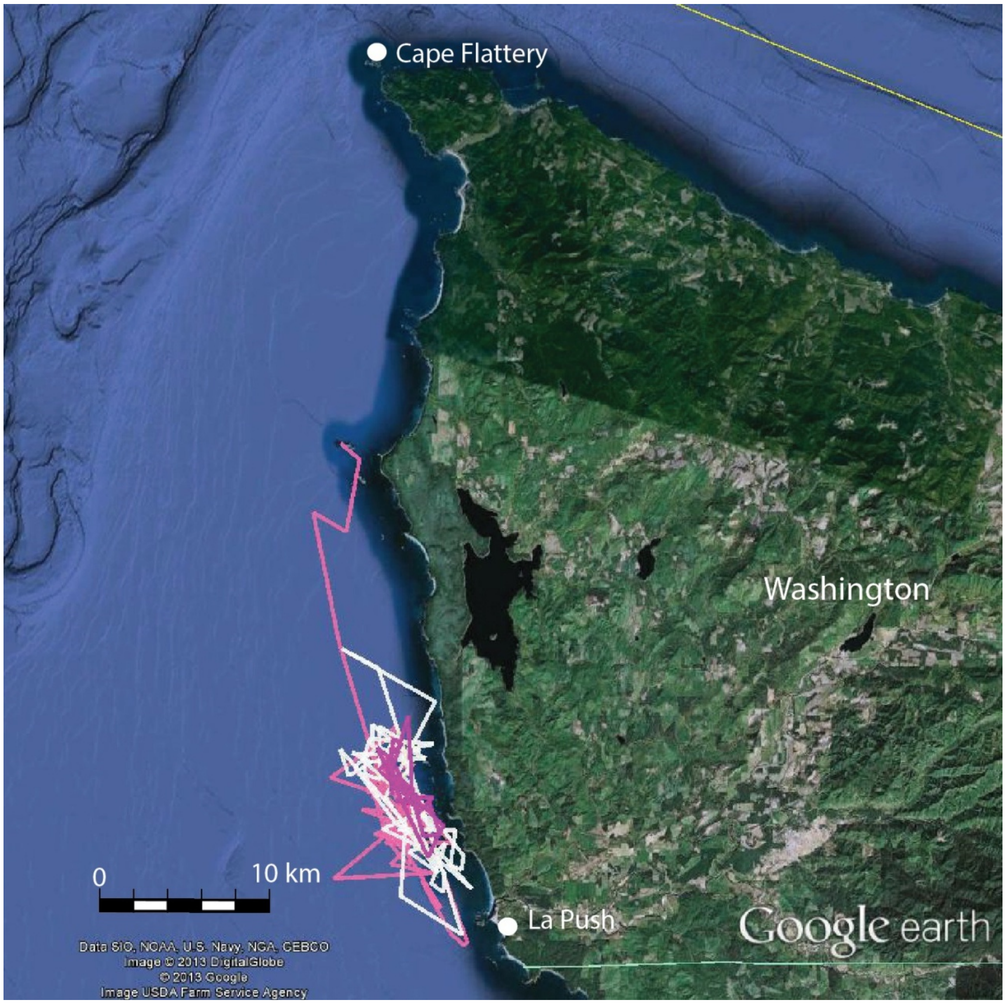

Figure 14: Map showing movements of three gray whales tagged 31 May 2012 near the northern tip of Washington.

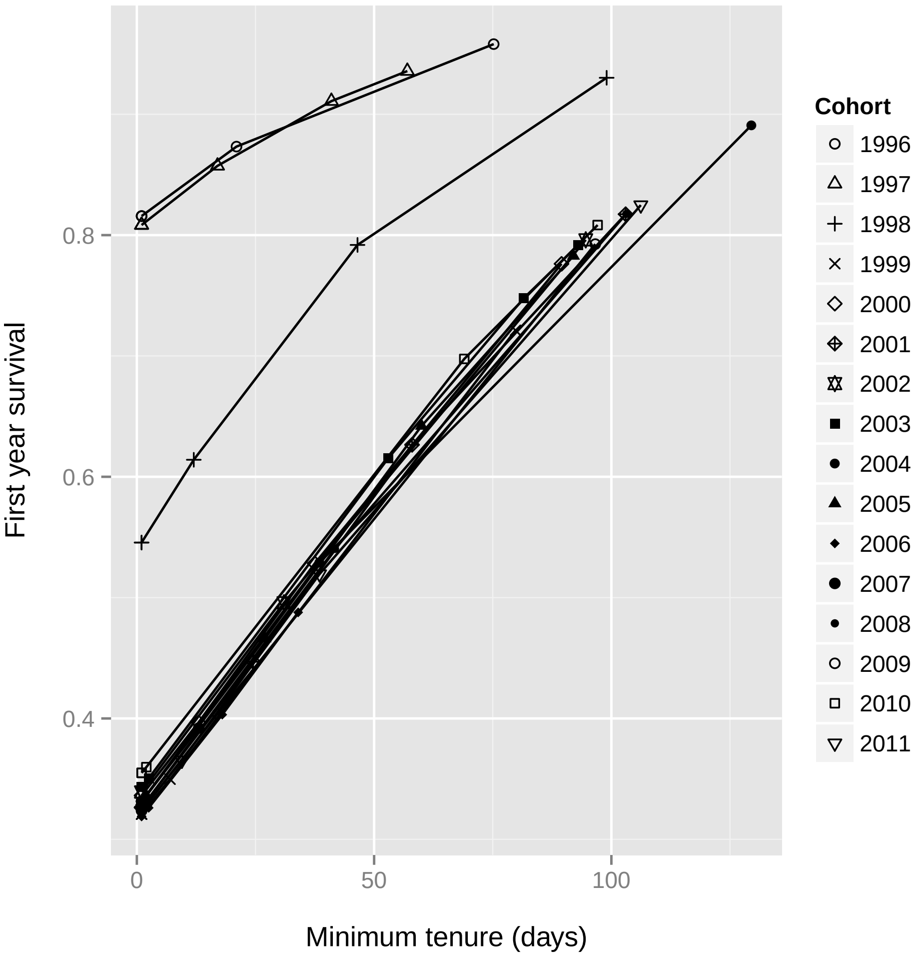

Figure 15: For NCA-NBC analysis of 1996-2012 data, model-averaged estimates of first year survival of non-calves for each cohort at 5%, 25%, 50%, 75%, and 95% quantiles of minimum tenure values for that cohort.

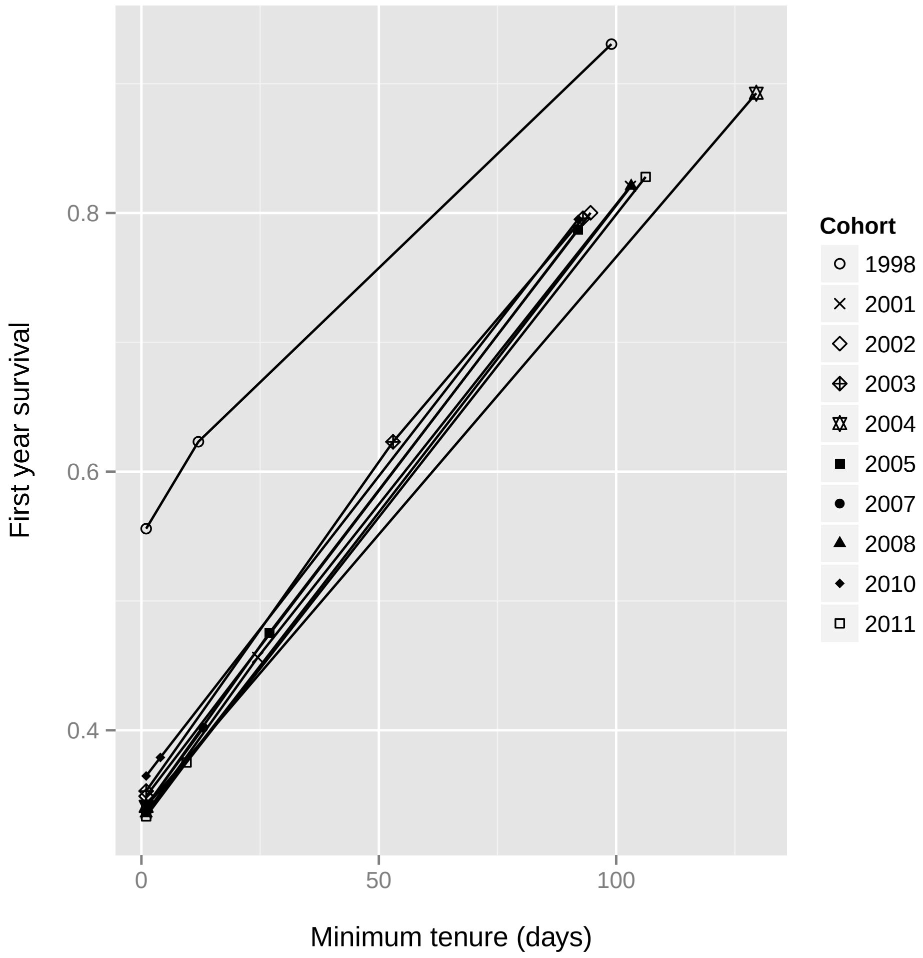

Figure 16: For NCA-NBC analysis of 1996-2012 data, model-averaged estimates of first year survival of calves for each cohort at 5%, 25%, 50%, 75%, and 95% quantiles of mini mum tenure values for that cohort.

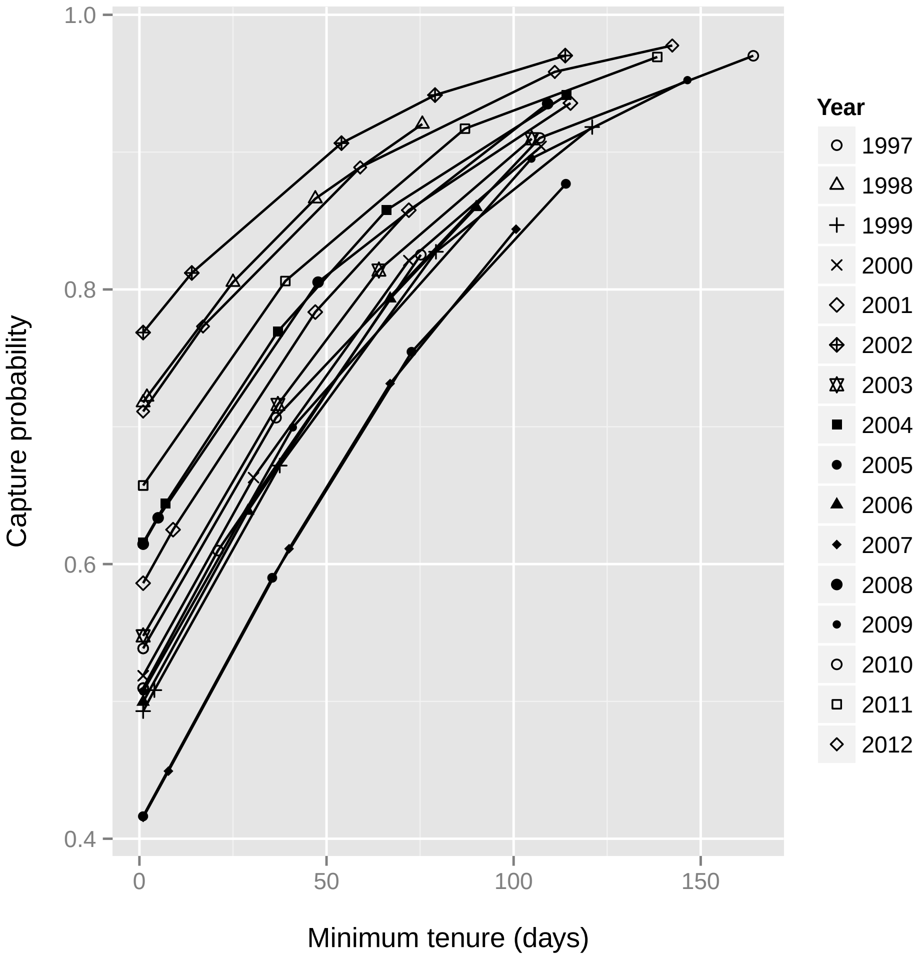

Figure 17: For NCA-NBC analysis of 1996-2012 data, model-averaged estimates of capture probability for each year at 5%, 25%, 50%, 75%, and 95% quantiles of minimum tenure values for whales in the previous year.

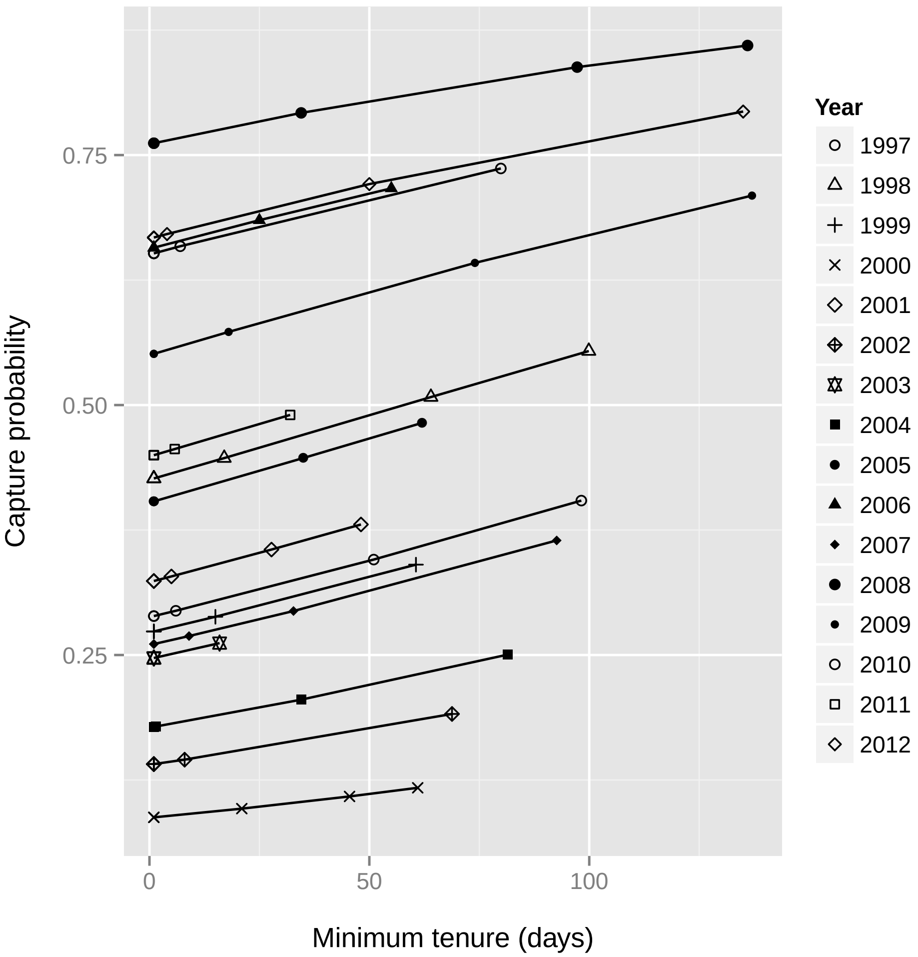

Figure 18: For MUA analysis of 1996-2012 data, model-averaged estimates of capture probability for each year at 5%, 25%, 50%, 75%, and 95% quantiles of minimum tenure values for whales in the previous year.

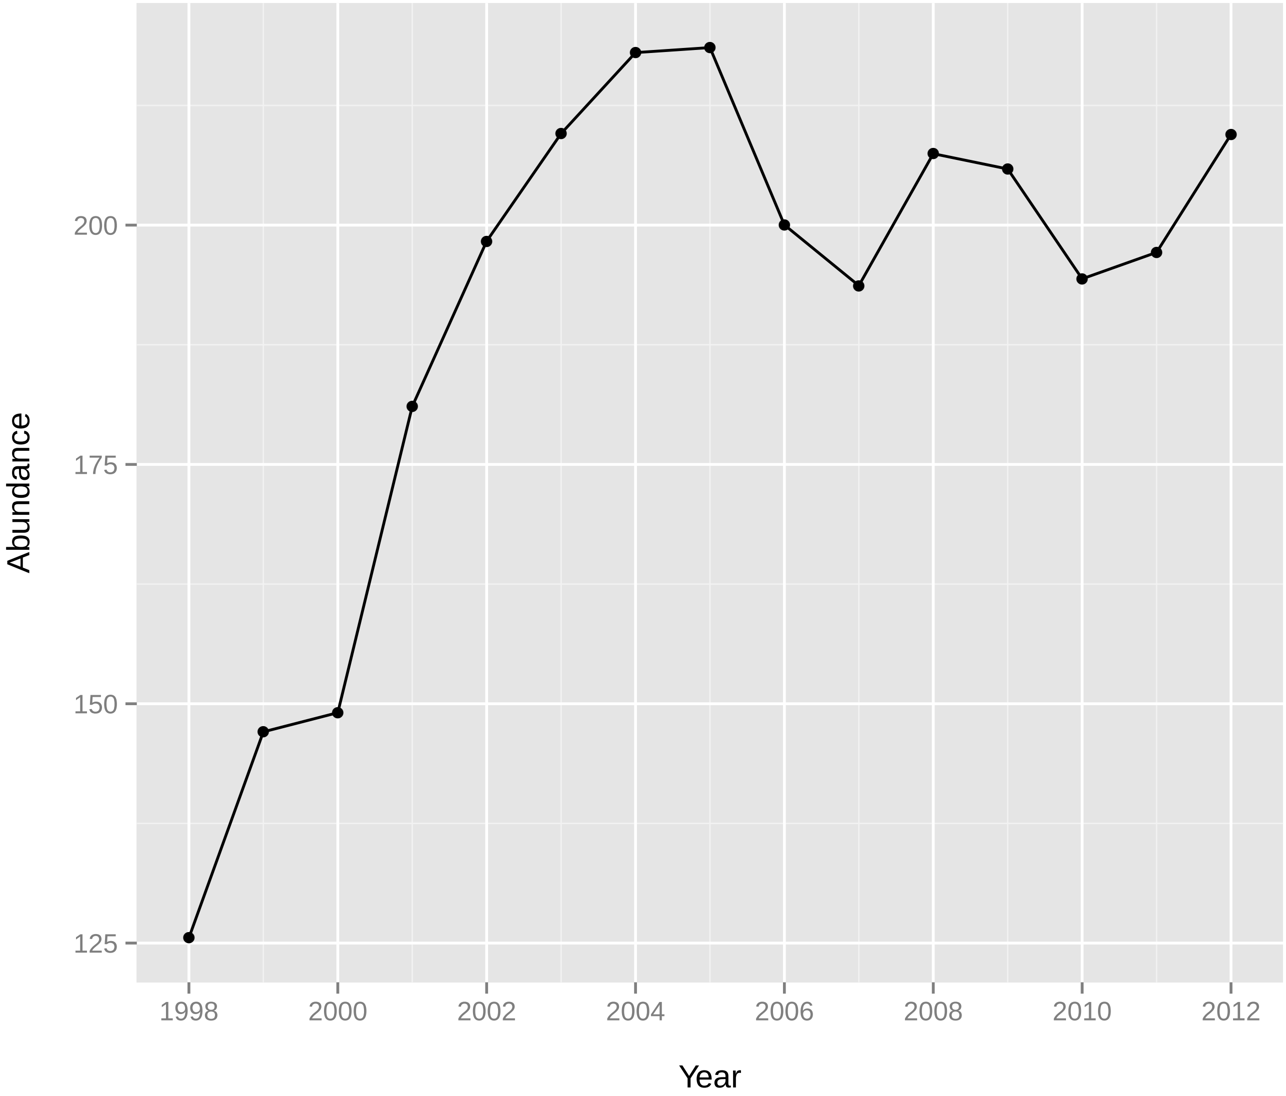

Figure 19: Annual abundance estimates for 1998-2012 in NCA-NBC using the open (Jolly-Seber; POPAN parametrization) population model approach JS1.

Appendix

Table 1 provides capture histories of whales seen in the PCFG at least once from 1 June - 30 November and displays by year, when they were seen only in spring (March-May), only from 1 June - 30 Nov and when they were seen in both time periods. Table 2 provides capture histories using data from 1 June - 30 Nov of whales seen in the MUA at least once. It shows when whales were seen only outside of the MUA but in the PCFG, only in the MUA and both inside the MUA and in the PCFG outside of the MUA

Table 1: Sighting histories of whales seen in the PCFG in at least one year. In year columns, a 1 means the whale was only sighted in the spring (March-May), 2 means it was only seen in June-Nov, and 3 means it was seen in both March-May and June-Nov. The region value is the nunber of years the whale was seen in that region.

TOWARD A FISHERIES ECOSYSTEM PLAN FOR THE NORTHERN CALIFORNIA CURRENT

JOHN C. FIELD, ROBERT C. FRANCIS, AND ARE STROM
School of Aquatic and Fisheries Sciences

> We have witnessed changes in the landscape around us with the advent of technology evolved from the axe and the plow. We should expect equally profound ecological changes from modern, large-scale uses of the hook and the net. (EPAP 1999)

ABSTRACT

Recently the congressionally established Ecosystem Principles Advisory Panel issued a report on how best to amend single-species management. A major recommendation was that fisheries management councils develop a fisheries ecosystem plan (FEP) for every ecosystem under their jurisdiction. This document would be an umbrella document containing detailed information on the structure and function of the ecosystem under consideration. The U.S. portion of the northern California Current ecosystem (NCCE) may be an appropriate test case to develop some of the key elements of a draft FEP. Fishing pressure in the NCCE has been intense for decades, and the possibility of consequent large-scale ecosystem changes is large. Although fisheries science in this region has considerably advanced our understanding of the intricate linkages between fisheries production and large-scale oceanographic and atmospheric climate forcing, fisheries management efforts throughout the region may be insufficient for assessing the ecological impacts associated with fishing. We use Ecopath models to assess the state of the NCCE in the 1960s during a cool regime with low exploitation rates and high rates of zooplankton production, and also in the 1990s during a warm regime characterized by low productivity, declining stocks, and intense exploitation. We compile population parameters and diet data for 34 species/species assemblages for both time periods to generate a food web of basic trophic interactions. These models are in agreement with the general consensus that this system has been functioning at lower levels of productivity since the 1977 regime shift. More work is needed to understand the status of many NCCE populations, but stock assessments and fisheries data suggest that the observed fluctuations in many harvested populations may be rapid, highly variable, and increasingly undesirable.

INTRODUCTION

To date, most fishery management efforts in the United States continue to focus on regulatory mandates contained in management plans based on species-specific stock assessments. The Magnuson Fishery Conservation and Management Act, which provides the legal authority for marine fisheries management, mandates that fisheries scientists and managers "prevent overfishing while achieving, on a continuing basis, the optimum yield from each fishery" (16 U.S.C. 1851). Although there is legal authority for taking into account how fishing activities affect fish habitat, this authority has generally not been used by managers, and the Magnuson Act contains no explicit direction on how managers should actively consider the indirect consequences of fishing on trophic dynamics or structure.[1]

Recognizing the promise of an "ecosystem-based" approach to improving fisheries management, the U.S. Congress recently requested that the National Marine Fisheries Service (NMFS) convene a panel of experts, the Ecosystem Principles Advisory Panel (EPAP), to examine how best to build upon single-species management approaches. The EPAP's primary recommendation was that fishery management councils develop a fisheries ecosystem plan (FEP) for every ecosystem under their jurisdiction (EPAP 1999). An FEP is envisioned as an umbrella document containing detailed information on the structure and function of the ecosystem under consideration (e.g., a conceptual model of the food web and other ecosystem components, total removals from fishing, and assessments of the human elements of the ecosystem that most significantly affect fisheries). The FEPs would be intended to increase managers' and stakeholders' awareness of how their decisions affect the ecosystem. As such, FEPs would be the next major step in translating today's directed management efforts into more holistic approaches.

Our efforts have focused on using the U.S. portion of the northern California Current ecosystem (NCCE), which includes the heavily fished shelf and slope ecosys-

---

[1] The extent to which the Magnuson Act explicitly mandates the consideration of ecosystem aspects could be arguable, as there is no mention of ecosystem considerations in the National Standards or in the FMP requirements. However, some authority is inferred in the definitions section of the act with regard to the word *optimum* with respect to yield from a fishery (Section 104-297 of 16 U.S.C. 1802), where it is suggested that optimum yield "means the amount of fish which will provide the greatest overall benefit to the Nation, particularly with respect to food production and recreational opportunities, and taking into account the protection of marine ecosystems."

tems between Cape Mendocino, California, and the northern tip of Vancouver Island, as a test case to develop what we believe to be some of the key elements of a draft FEP. Fisheries resources in the NCCE have been subjected to intensive fishing pressure for a protracted period. The abundance of coastal pelagic species such as sardine, anchovy, and herring has varied substantially over past decades, most likely in direct association with different modes of climate forcing. Precipitous declines in several stocks of Pacific rockfish (*Sebastes* spp.) and some roundfish have occurred over the last 20 years, and are evident in the corresponding declines of commercial landings (Ralston 1998). Similarly, many salmon fisheries of the NCCE, in particular ocean fisheries, have been in decline since the late 1970s. These declines are generally attributed to a combination of unfavorable ocean conditions (Hare et al. 1999), spawning and rearing habitat degradation and loss, and overfishing (NRC 1996). Juvenile salmon, a staple in the diet of many higher-trophic-level species, have been particularly affected by habitat loss and interdecadal variations in climate (Mantua et al. 1997; Hare et al. 1999); the recruitment of rockfish, the juveniles of which are also a staple in the diet of many larger predators in this system, has similarly been greatly reduced in recent decades (MacCall 2000).

The complex and fragmented design of interacting human and institutional elements hinders the transition to more holistic management efforts in this ecosystem. Under an ecosystem-based approach, management actions would be designed and monitored through an adaptive management approach (Ludwig et al. 1993), and management institutions should be designed so that resource ecology and institutional ecology overlap in a complementary manner. All of these issues of governance are particularly true in the NCCE, where numerous state, federal, and tribal institutions often seem to have different responsibilities with regard to the management of fishery resources. Of particular concern is the challenge of incorporating a longer time and broader spatial and biological view into this management arena. Thus the northern California Current may provide an opportunity to explore efforts for surmounting the impediments to sustainable and rational management of living marine resources.

WHY ECOSYSTEM-BASED MANAGEMENT?

In many fisheries it has become increasingly obvious that the ecological consequences of fishing are substantially greater and more complex than the biomass reductions of target species. These consequences may include but are not limited to mortality of nontarget species, alteration of benthic habitats and bottom topography, changes in age and size structure of fished (both target and nontarget) populations, changes in sex ratios of targeted populations, and changes in the genetic structure of fished populations (Botsford et al. 1997; NRC 1999).

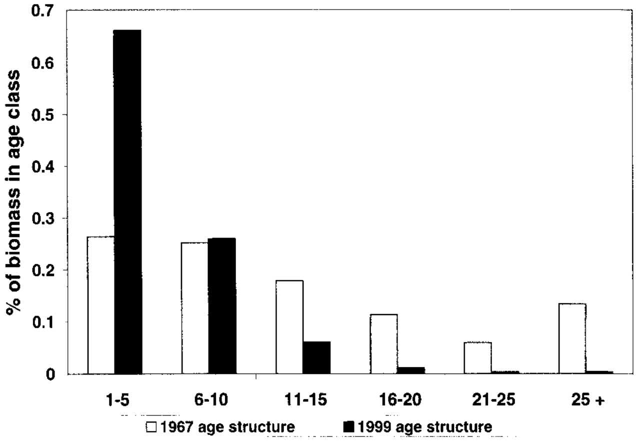

Figure 1. Changes in the age structure of the northern canary rockfish population (based on stock assessment data). Graph shows the percentage of population biomass in five-year groupings of age classes between 1967 and 1999, illustrating the shift in population biomass to younger, smaller individuals. During this same period the total population has been fished down to approximately 10% of its unfished population biomass.

As one simple example, figure 1, based on the stock assessment by Crone et al. (1999), shows how the age structure of the canary rockfish population has changed over the last three decades. This figure shows an extreme case of the truncation of the age distribution of this long-lived species. Recruitment of canary rockfish has been extremely low over the last two decades, and the large proportion of young individuals does not reflect increased recruitment, but rather removals of a substantial fraction of older individuals.

In addition to population impacts, structural changes to trophic webs have been described for numerous heavily fished ecosystems (Parsons 1993; Apollonio 1994; Fogarty and Murawski 1998; Pauly, Christensen et al. 1998). Furthermore, interannual and interdecadal climate shifts affect the productivity of marine populations, with dramatic effects on fisheries (Mantua et al. 1997; Anderson and Piatt 1999; Hare and Mantua 2000). The effects on marine ecosystems as a consequence of fishing activities, notably as direct effects of fishing gear on benthic habitats, are poorly understood in most systems, but have been shown to be substantial where evaluated (Auster et al. 1996; Engel and Kvitek 1998).

Figure 2 is a simplistic representation of how traditional approaches to fisheries management, which focus primarily on interactions between commercially important populations and fishing activities, could be broadened to include basic interactions between commercial and noncommercial species, the effects of fishing activities on habitat, and the large-scale impacts of climate forcing on ecosystem productivity and structure.

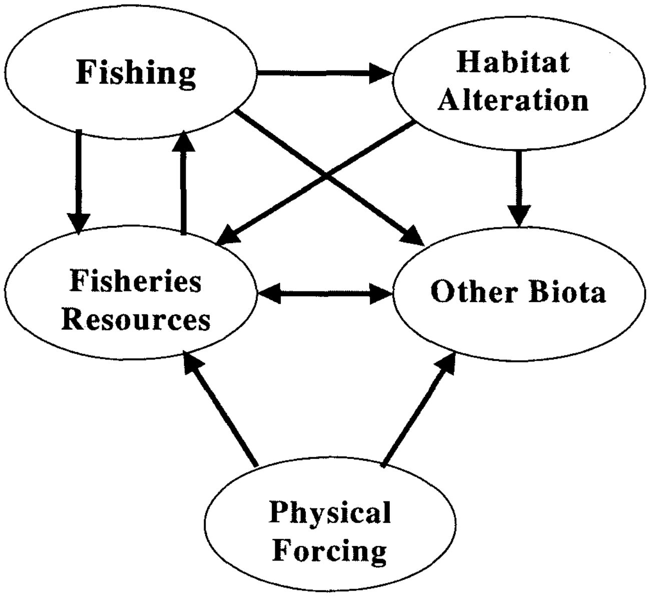

Figure 2. A conceptual outline for incorporating ecosystem considerations into fisheries management.

It is widely recognized that an ecosystem approach to fisheries management will have different meanings for different people. As with much environmental legislation, a mandated ecosystem-based approach will invite controversy about its implementation, regardless of the definitions put into the law. The discussion on what an ecosystem-based approach might mean to managers is broad and often tortuous, yet some mention of key views is worthwhile. For example, Grumbine (1994) suggests that managing for ecological integrity would mean that commodity extraction should be relegated to an ancillary goal. As the EPAP report (1999) points out, when fishing is examined from an ecosystem context the rationale for surplus production is unclear; before the advent of fisheries all production was recycled within ecosystems. Other stated consequences of fishing include inducing ecological changes among competitors, predators, and prey, and such changes could imply future levels of surplus production that approach zero for some populations well into the foreseeable future. This is in direct conflict with the assertion by some that the adoption of an ecosystem-based approach should lead to healthier and more dependable fisheries. For example, the NRC Council on Sustainable Fisheries Report (NRC 1999) suggests that the goals of an ecosystem-based approach are to "rebuild and sustain populations, species, biological communities and marine ecosystems at high levels of productivity and biological diversity, so as not to jeopardize a wide range of goods and services from marine ecosystems, while providing food, revenue and recreation for humans."

Like so many policy and management approaches, the purported objective in the NRC report is to maximize many variables at once, thereby implying that all of the objectives are mutually compatible. This approach, like that of traditional fisheries management, continues on the assumption that fisheries can safely remove surplus production without consequences to the ecosystem; as implied by the conclusion that although adaptation of such an approach will likely cause short-term economic losses and impacts to communities, the ultimate outcomes should not include decreased yield, since rebuilt populations should increase sustainable yield (NRC 1999).

These assumptions are difficult to justify given the current poor state of knowledge about the aforementioned ecological consequences of fishing on marine ecosystems, revelations that many long-lived species have considerably lower rates of production than previously thought and may take many decades to recover, and our inability to clearly define what might or might not constitute a "healthy" marine ecosystem. Moreover, there should be little reason to use higher potential yields as a selling point of ecosystem management, as the solution to a stock's inability to produce some level of sustainable yield would (and under the Sustainable Fisheries Act, legally should) ostensibly be reached through the adoption of quota reductions and stock rebuilding plans under a single-species approach. In the future, as policymakers and resource managers struggle to consider what ecosystem management is, perhaps it will be worthwhile to step back and consider what it is not.

One potential outcome of implementing an ecosystem-based approach could be reduced stability or predictability in future fishery yields. A reduction in predictability does not necessarily imply that most current yields are stable, but rather that the pursuit of stability for economic and allocation purposes may be in conflict with the notion of adaptive management of ecological resources. Holling and Meffe (1996) argue that the pursuit of stability is part of the explanation for why many resource management efforts have failed, because the objectives of many such efforts have been to reduce the natural bounds of variation in ecological systems in order to make them more predictable and more reliable for extractive needs. Holling and Meffe argue that the key to natural resource management, whether it be single-species or ecosystem management, is to retain critical types and ranges of natural variation in ecosystems, and to facilitate existing processes and variabilities rather than attempting to alter or control them.

Perhaps one example of such an approach can be observed in the recently approved fishery management plan for coastal pelagic species (PFMC 1998). The plan was based on the premise that the theoretical definition of maximum sustainable yield (MSY) as a constant level of catch should not be applied in fisheries for coastal pelagic species such as sardine, anchovy, and mackerel because of the high sensitivity of the productivity of these stocks to changes in environmental conditions. Instead, management is based on the application of a baseline "cutoff" population biomass, below which directed harvests are not allowed, and above which allowable landings are based on a fraction of the available biomass above the cutoff level. This approach allows for high harvest rates during favorable environmental conditions but forces fishing mortality to zero if the stock declines to a baseline biomass.

Apollonio (1994) suggests that in marine ecosystems, the ecological role of fishing is comparable to the role of apex predators. It follows that, analogous to the way biological feedback mechanisms underlie natural predator-prey relationships, appropriate feedback mechanisms between vessels and target species should exist to keep the system in balance. In order for fishing to be ecologically sustainable, Apollonio argues, the ecological impacts of fishing should be similar to the natural impacts of apex predators. This may imply that during unproductive years, decades, or even longer periods, the yield of many species, indeed of many ecosystems, may be unsustainable from the perspective of stock, species, or system productivity.

The Pacific Council's Coastal Pelagic Species FMP is one step toward the application of this principle, yet in practice these balancing mechanisms are scarce because of external subsidies, which have the effect of maintaining fisheries that might be otherwise unprofitable. Instead, fleet buildups continue far beyond what might be sustainable as stocks are fished down to (and often beyond) the estimated size that produces the maximum sustainable yield. The existence of strong incentives for vessels to switch rapidly from one fishery to another when catches decline, and the ability for effort to shift massively over short time periods would suggest that the feedbacks that might exist in a more typical predator/prey system are substantially diminished.

For the northern California Current, our initial work has focused on preliminary attempts to address three of the eight key minimum actions envisioned in the EPAP report as elements of demonstration fishery ecosystem plans. These include a characterization of biological dynamics of the ecosystem, development of a conceptual model of the food web, and the estimation of total removals and how those relate to standing biomass, production, and trophic structure. A summary of our early efforts to address these elements makes up the remainder of this paper.

The remaining five key elements of FEPs as envisioned by the EPAP panel are certainly no less crucial. They include descriptions of the habitat needs of different life-history stages for all plants and animals that represent the "significant food web" and how they are considered in conservation and management measures; an assessment of how uncertainty is characterized and what types of buffers are included in management actions; the development of indices of ecosystem health as targets for management; descriptions of long-term monitoring data and how they are used; and an assessment of the ecological, human, and institutional elements of the ecosystem that most significantly affect fisheries and are outside of Council/Department of Commerce authority (see Fluharty and Cyr, this volume, for greater detail). For all of these actions, the FEP process would provide an opportunity to refine, integrate, and further develop the substantial efforts that have already been made by government and academic workers.

THE NORTHERN CALIFORNIA CURRENT ECOSYSTEM

The continental margin of North America off the coasts of northern California, Oregon, Washington, and southern British Columbia is a productive coastal upwelling region that has long supported commercial harvest of a variety of marine resources. The entire California Current ecosystem (CCE) is an "open" system, meaning that it is a transition environment between subarctic and subtropical water masses and the freshwater systems that enter the ocean along its landward boundary (Hickey 1989).

This region is also an ecotone comprising a small number of endemic coastal species and a larger mixture of subarctic and subtropical species, many near the periphery of their distributional range (Bottom et al. 1993). The northern half of the CCE, the region of coastal ocean between Cape Mendocino, California, and the northern tip of Vancouver Island, B.C., is described as a zoogeographic transition between Californian and Aleutian biological provinces. We refer to this region as the northern California Current ecosystem, and presume that this system may be an appropriate ecological unit for regional management as the focus of this paper.

A growing body of research has shown that during the twentieth century, both El Niño-Southern Oscillation (ENSO) and Pacific Decadal Oscillation (PDO) processes had major impacts on the organization and dynamics of marine ecosystems of the NE Pacific Ocean and, as a result, on fisheries operating within those ecosystems (e.g., Wooster and Fluharty 1985; Francis et al. 1998; McGowan et al. 1998; Anderson and Piatt 1999). Because the effects of climate are so pervasive in the NCCE, as a first step to ecosystem reconstruction it is essential to understand past patterns of climate as they may have affected the NCCE. As an example of how past climate patterns have influenced the NCCE, we will briefly examine information about the presence of Pacific sardine in the region over the last two centuries.

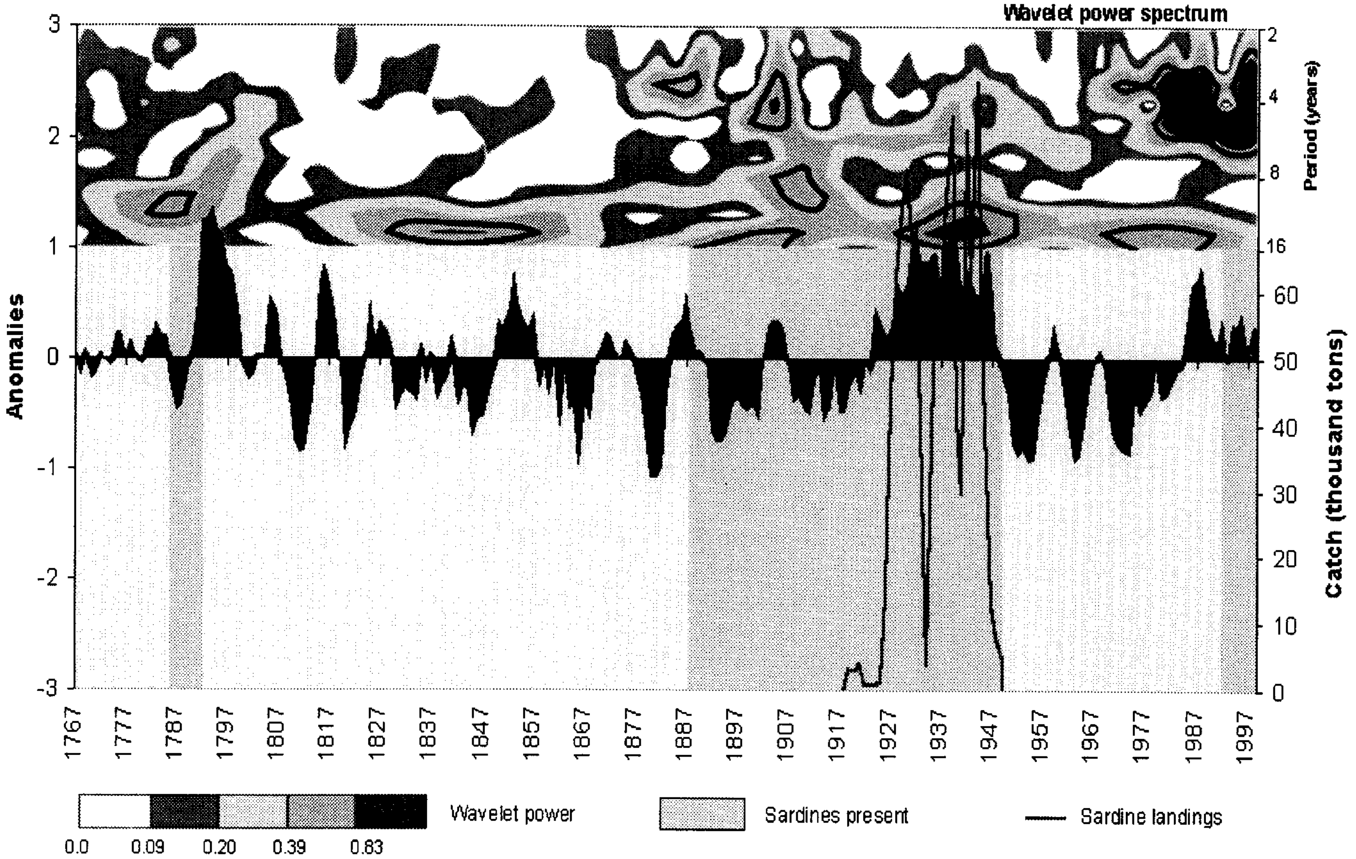

Figure 3. Pacific Northwest sardine occurrences charted against reconstructed winter PDO and ENSO wavelet power spectrum. (See footnote 1 for a summary of historical records of sardine presence/absence in the Pacific Northwest.)

Figure 3 is a composite that explores possible relationships between climatic influences and the presence and absence of sardines in the NCCE. Shaded areas indicate periods of sardine presence; solid lines indicate commercial landings in the Pacific Northwest. This information is plotted against a tree-ring reconstruction of the PDO time series (Dell'Arciprete et al. 1998) and a wavelet analysis of the ENSO cycle (top panel) as reconstructed by Mann et al. (1999). The wavelet analysis provides a graphic representation of the intensity, or magnitude, of climate variability at various frequencies (see Torrence and Compo 1998). Darker shades in the upper panel indicate more intense ENSO periods.

Figure 3 suggests that each range expansion of sardines documented since the latter part of the eighteenth century occurred during periods of increased North Pacific climatic activity.[2] The first period of increased activity occurred in the late 1700s, when sardines were

---

[2] It appears that three major northward expansions in the range of sardines have occurred since the late 1700s. During the first two, sardines were abundant enough to support substantial fisheries that persisted for a number of years as far north as Puget Sound and Vancouver Island. Between 1786 and 1792 a number of accounts, including those of trained naturalists, described the native fisheries for sardines along the Pacific Northwest coast; John Meares (1791) described how "In the Spring, the herrings as well as the sardines frequent the coast in vast shoals.... The sardine resembles that of Portugal, and is very delicious: they are taken here by the people in prodigious quantities." By the beginning of the 19th century, however, sardines were no longer being noted in the journals of explorers, naturalists, or traders, despite more extensive exploration in the Pacific Northwest region following the Lewis and Clark expedition.

Apparently sardines did not return to the Pacific Northwest until the late 1880s. Extensive scientific investigations of fisheries resources—including those conducted by the Wilkes expedition in 1841 (Wilkes 1984), the Pacific railroad surveys of 1853–57 (Suckley 1860), and the investigations of the U.S. Fish Commission in 1880–81 (Goode 1884)—failed to locate sardines in Pacific Northwest waters. The U.S. Fish Commission reported in 1884 that sardines ranged from Chile to Cape Mendocino, California. By 1888–89, however, this range had expanded to encompass Puget Sound. Sardines were found in Puget Sound waters during "the warmer part of the season, and are taken with herring and other species for market" (Collins 1892). Landings of fresh sardines in 1888 were reported to be 60,000 lbs. By 1895 sardines were occurring in "large numbers" in Puget Sound (Jordan 1895), and in 1902 were described as "abundant" (Kershaw 1902). The first official records of sardines captured in Canadian waters did not appear until January 1900, when two specimens were collected in the Strait of Georgia near Nanaimo (Clemens and Wilby 1961). Concurrent with the development of the California sardine fishery in the 1920s, a lucrative fishery for sardines began in British Columbia in 1917–18 and lasted until 1948–49, when stocks once again disappeared (Schweigert 1988).

Sardines were again observed in the waters north of Cape Mendocino in the 1980s (Emmett and Brodeur 2000) and returned to the Pacific Northwest and British Columbia in 1992 (Hargreaves et al. 1994), though not in sufficient quantities to warrant a resumption of large-scale commercial fisheries. The return may also have been short-lived. In 1998 and 1999 there was a series of massive die-offs of sardines along northern sections of Vancouver Island. These mass deaths coincided with the 1998–99 La Niña that caused sharp declines in coastal ocean temperatures (Drouin 1999).

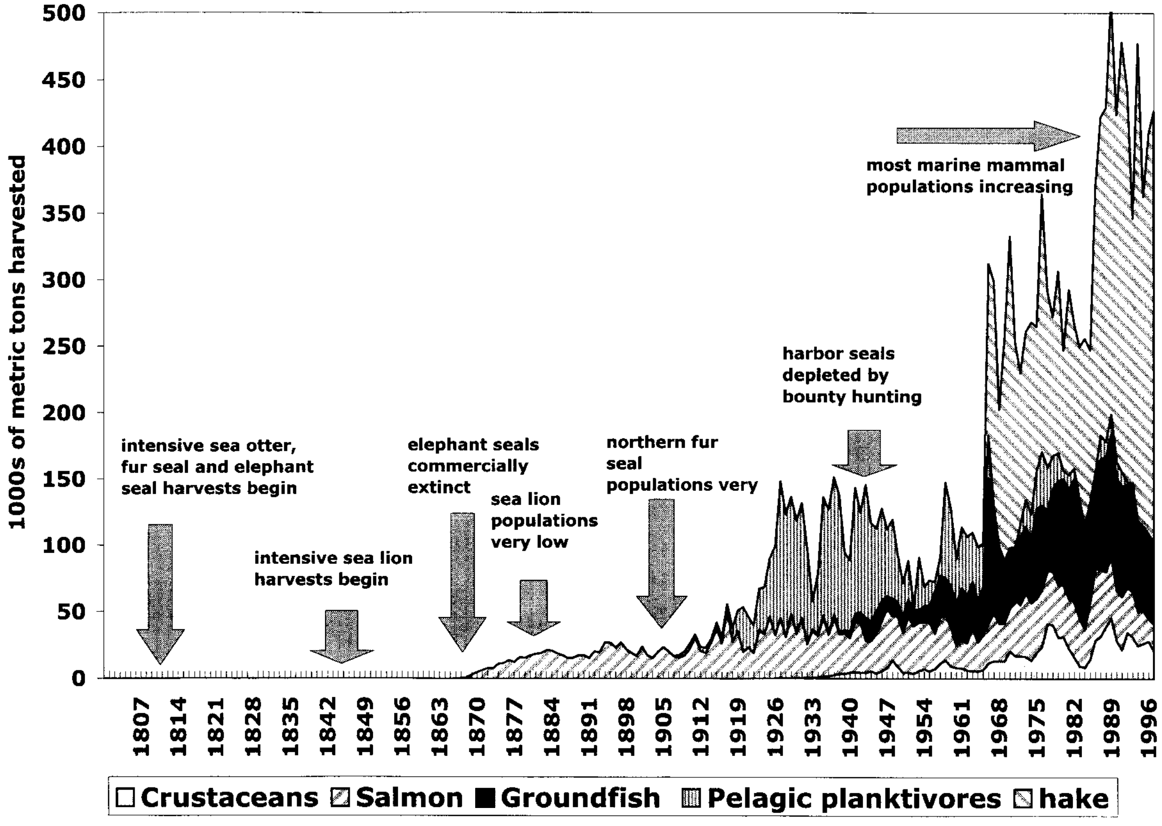

Figure 4. A summary of major removals by fisheries from the northern California Current ecosystem over the last two centuries.

apparently already in an expansion mode, the PDO was nearing a substantial peak, and ENSO activity may have been more intense and frequent than normal. It is unclear exactly when the sardines disappeared from Pacific Northwest waters during this period, but historical records suggest that they were no longer present by the early 1800s. Similarly, the expansion of the sardine population starting around 1880 coincided with increased power in both the ENSO signal and the magnitude of the PDO. Finally, the return of sardines to the British Columbia coast in the 1990s coincided with a general expansion of the coastal population, starting with the major climate shift of the late 1970s and the record El Niño activity of the 1980s and 1990s.

Sardines may epitomize the nature of change in key species in this system; their presence implies a different ecosystem state than during periods of their absence. This subsequently implies that key flows of energy and biomass in the system changed substantially prior to human intervention. Smith (1978) inferred changes of even greater magnitude in the abundance of Pacific hake in the California Current based on the scale record of Soutar and Isaacs (1974), which suggested that the abundance of hake (although these scales probably represent juvenile hake) at the turn of the twentieth century may have been as much as an order of magnitude greater than current levels. These observations illustrate that pronounced changes of boom and bust in the natural cycles of migratory coastal pelagic species such as sardines and hake imply massive changes in primary and secondary production within the NCCE. This in turn suggests that the ecosystem was structured very differently in previous centuries than it is now.

FISHERIES DEVELOPMENT IN THE NCCE

Fishing pressure in the NCCE has been intense for decades and has effected consequent large-scale changes in the relative abundance of many key populations. Knowledge of NCCE structure and dynamics comes primarily from stock assessments, fisheries and food habits data, and oceanographic records. These sources mostly cover recent decades, and indicate high levels of physical and biological variability on broad spatial and temporal scales.

Catch statistics provide perhaps the most complete record of population trends, and indicate that rapid and possibly undesirable changes are occurring in NCCE structure. Figure 4 presents a partial accounting of catch data and major biological removals over the last two centuries, illustrating both the magnitude of removals and the sequential nature of the development of the major fisheries in the region. This figure shows that although industrial-scale fishing pressure in the NCCE has been intense for only decades, various ecosystem components have been substantially exploited for at least two centuries.[3]

The first species to be the subject of major commercial exploitation were marine mammals. Fisheries for sea otters, fur seals, sea lions, and elephant seals grew to support enormous commercial harvests in the early and mid-1800s. Although few of these populations actively breed in the NCCE, all spend at least some of their time in Pacific Northwest coastal waters, and many are significant seasonal predators in the region. Estimates of actual take of most of these animals are difficult to derive: some estimates of otter and fur seal removals exist in fur trade records, but the number of elephant seals and sea lions taken for oil and meat can be only coarsely assessed.

Scammon (1874) suggested that hundreds of thousands of elephant seals must have been taken in the early part of the nineteenth century, and the species was commercially extinct by the 1870s. Specimen and museum collectors continued to take elephant seals even as the population was on the verge of extinction (Stewart et al. 1994).

Sea lions were originally taken for meat to supply the early hunters of sea otter along the California and Pacific Northwest coastline, and continued to be killed both as potential competitors for commercial fish as well as for their trimmings (the testes and penises of breeding bulls) following commercial depletion in the early twentieth century (Bonnot 1928).

Fishermen and bounty hunters along the U.S. and Canadian coastlines targeted harbor seals until the 1960s (Bonnot 1928; Newby[4]). Gray, humpback, sperm, and other whales were targeted for well over a century throughout the northeast Pacific. Such removals kept most pinniped and cetacean populations at low to moderate levels until the middle of the twentieth century, and only in the last several decades have populations of many marine mammals increased to substantial numbers.

Although many species of fish and shellfish throughout the NCCE have been harvested by native peoples for millennia, some at rates that may have approached later commercial levels (Yoshiyama et al. 1998), large-scale commercial harvests of fish in the region generally did not begin until many marine mammal populations had been substantially depleted. The salmon fisheries were among the first to develop: the first salmon cannery was opened in 1864 along the Sacramento River, but was soon moved to the much more productive Columbia River. By 1885, salmon catches in the Columbia alone topped 40 million pounds, and salmon fisheries had expanded to nearly every major watershed in the Pacific Northwest (Cobb 1930). Salmon fisheries continued to dominate the region, even as the soon-to-be legendary California sardine fishery was initiated in the early twentieth century.

Total coastwide sardine landings would reach over 700,000 metric tons (t) per year. Although the vast majority of sardine landings were made in the southern part of their range, up to 80,000 t a year were caught in the summer fisheries of the northern California Current between the 1920s and 1940s. When this fishery began to collapse in the 1940s, it did so from north to south, and it has long been suspected that changes in marine conditions played a role in this population decline (Ueber and MacCall 1992). In British Columbia, substantial herring fisheries had developed during the period of the sardine fishery, and grew rapidly following the sardines' departure from northern waters (Waddell and Ware 1995) while anchovy and mackerel populations underwent substantial (and perhaps sequential) fluctuations in the southern part of the sardines' former range (MacCall 1996). As the sardine population has increased over the last two decades, the fishery has also undergone a resurgence, with sardines once more being fished in commercial quantities between Baja California and British Columbia.

Pacific halibut was the first of the groundfish species to be targeted by commercial fisheries, although flatfish, lingcod, rockfish, and sablefish were all supporting substantial fisheries throughout the NCCE by 1900. Total landings of all groundfish grew gradually throughout the twentieth century, approaching 20,000 t per year in the early 1960s. During the mid-1960s the Soviet Union (and several other nations) began fishing for hake and rockfish in the coastal waters of Oregon, Washington, and British Columbia, and coastwide landings quickly reached several hundred thousand metric tons per year (primarily hake). As a result of the declarations of 200-mile fishing zones by both the United States and Canada in the late 1970s, these foreign fisheries were phased out as domestic fleets developed, and overall landings continued to grow as the fleets greatly exceeded the capacity needed to harvest the resource (PFMC 1993). Following the rapid development of domestic fisheries, it was found that many of these stocks were consider-

---

[3] Data are incomplete, and from a variety of sources; salmon landings since 1911 were compiled by Hare et al. (1999), prior to 1911 are inferred from canned salmon production described by Cobb (1930). Pelagic planktivores (sardine, anchovy, herring, smelt, and shad) data were taken primarily from PFMC 1998, except for herring data taken from Waddell and Ware 1995 and very early landings from Sette and Fiedler 1928. Early groundfish and crustacean fishery data were also taken from Sette and Fiedler 1928, with later data from U.S. Bureau of Fisheries Statistical Digests. Groundfish and hake data between 1954 and 1980 were taken from Lynde 1986 and more recently from the Pacific Fishery Management Council (PFMC 1999) and Waddell and Ware 1995. Currently missing are Canadian data for groundfish landings prior to 1920 and all Canadian crustacean fisheries; errors are possible from other data sources, and not all estimates include unreported landings or estimates of discards, and thus should be considered minimum estimates of total mortality.

[4] Newby, T. C. Changes in the Washington state harbor seal population, 1942–1972. Unpubl. Rep.

ably less productive than originally thought. Subsequently, allowable landings of many groundfish species have been greatly curtailed in recent years, and recovery plans for depleted stocks are likely to limit effort for less-depleted stocks in the near future.

Crustacean fisheries also developed early in the Pacific Northwest, particularly fisheries for Dungeness crab and pandalid shrimp. For at least a century, landings of these populations appear to have fluctuated widely over relatively short periods of time. Evidence indicates that these fluctuations represent actual population swings, and recent research suggests that Dungeness crab dynamics respond to both internal population feedback, and large-scale environmental forcing (Higgins et al. 1997). It follows that such extreme population variability may be a response to a combination of anthropogenic influences (e.g., fishing, habitat degradation) and fluctuating oceanographic conditions.

Additionally, Hannah and Jones (1991) document an apparent change in the age structure of pink shrimp (*Pandalus jordanii*), which they believe is at least partially attributable to fishing. The pink shrimp is a sequential hermaphrodite in which age-1 shrimp are typically male and turn female as they reach age 2 (few, if any, of this species live beyond age 3). Hannah and Jones's work documented a shift in the age structure of landed shrimp to a substantially greater percentage of age-1 shrimp and fewer age-2 and -3 shrimp. These changes were accompanied by an increased percentage of shrimp maturing directly into females at age 1.

To summarize, it is clear that major shifts in the biomass, productivity, and life-history characteristics of key trophic components have occurred in response to both human activities and environmental variability. Figures 3 and 4 are intended to scale the importance of considering the long-term effects of both climate and human disturbance, in order to develop a sense of history for what little we might know about the nature of past population changes in this ecosystem. These population shifts include volatile increases and decreases (crustacean populations); predictable large-scale spatial migrations (pelagics such as hake and sardine as well as many seabird and marine mammal populations); periodic species range expansions and contractions (sardine); changes in age structure of harvested populations (groundfish and shrimp); and recent steady biomass declines (many groundfish and salmonids).

These dynamic species assemblages and interactions define the trophic structure of the northern California Current, a structure that has changed substantially over time and space. Furthermore, the large-scale physical and biological properties of the NCCE (e.g., temperature and flow patterns, primary and secondary production) also vary greatly over time and space with atmospheric forcing. Meine (1999) suggests that the "development of an historic sensibility ought to be considered fundamental to conservation biology"; we would argue that such a sensibility should be an integral part of fisheries biology and management as well, and is relevant in the context of both climatic and anthropogenic forcing mechanisms.

Although much more could be known about the trophic structure of the NCCE, it is clear that many species assemblages (and their ensuing interactions) are complicated and highly dynamic (Brodeur and Pearcy 1992). Thus, it may be that static fisheries models are not adequate for governing dynamic trophic systems, yet tangible objectives for ecosystem-level management initiatives remain ill-defined. If ecosystem-based approaches to fishery management are to be mandated by law or otherwise implemented, a major question will be how, if at all, managers might be able to ultimately incorporate insights and results of climate, trophic, dynamic, or other ecosystem models into management or policy objectives.

ECOLOGICAL MODELING OF THE NCCE

One opportunity for evaluating both the nature and the scale of such trophic interactions is to use ecological modeling. As a starting point, our efforts have focused on quantitatively defining NCCE trophic structure, using available information to explore the productivity of key populations in this region and evaluate how historical removals relate to standing biomass, production, and trophic structure. So far, we have centered on the initiation of an Ecopath modeling project designed to amass critical data on abundance, food habits, and other trophic factors. Future objectives include using dynamic simulations to incorporate modes of environmental forcing into dynamic simulations.

The intent of the discussion here is to explore the potential applications of one type of ecological model as a tool for describing the interacting effects of climate and trophic assemblages and deriving insights which could ultimately be useful for managers. With regard to the utility and application of multispecies or ecosystem models in particular, Hollowed et al. (2000) provide a comprehensive review of the most commonly used methods and their potential utility for measuring fishing impacts on marine ecosystems.

Ecopath was originally designed by Polovina (1984) and evolved into a software application, including a dynamic version called Ecosim, by workers at the University of British Columbia (Christensen and Pauly 1992; Walters et al. 1997). Essentially, Ecopath is a steady-state model that emphasizes natural rates of growth and consumption of marine populations. Given adequate data from fish bioenergetics models or diet composition studies, it provides a framework for summarizing information over

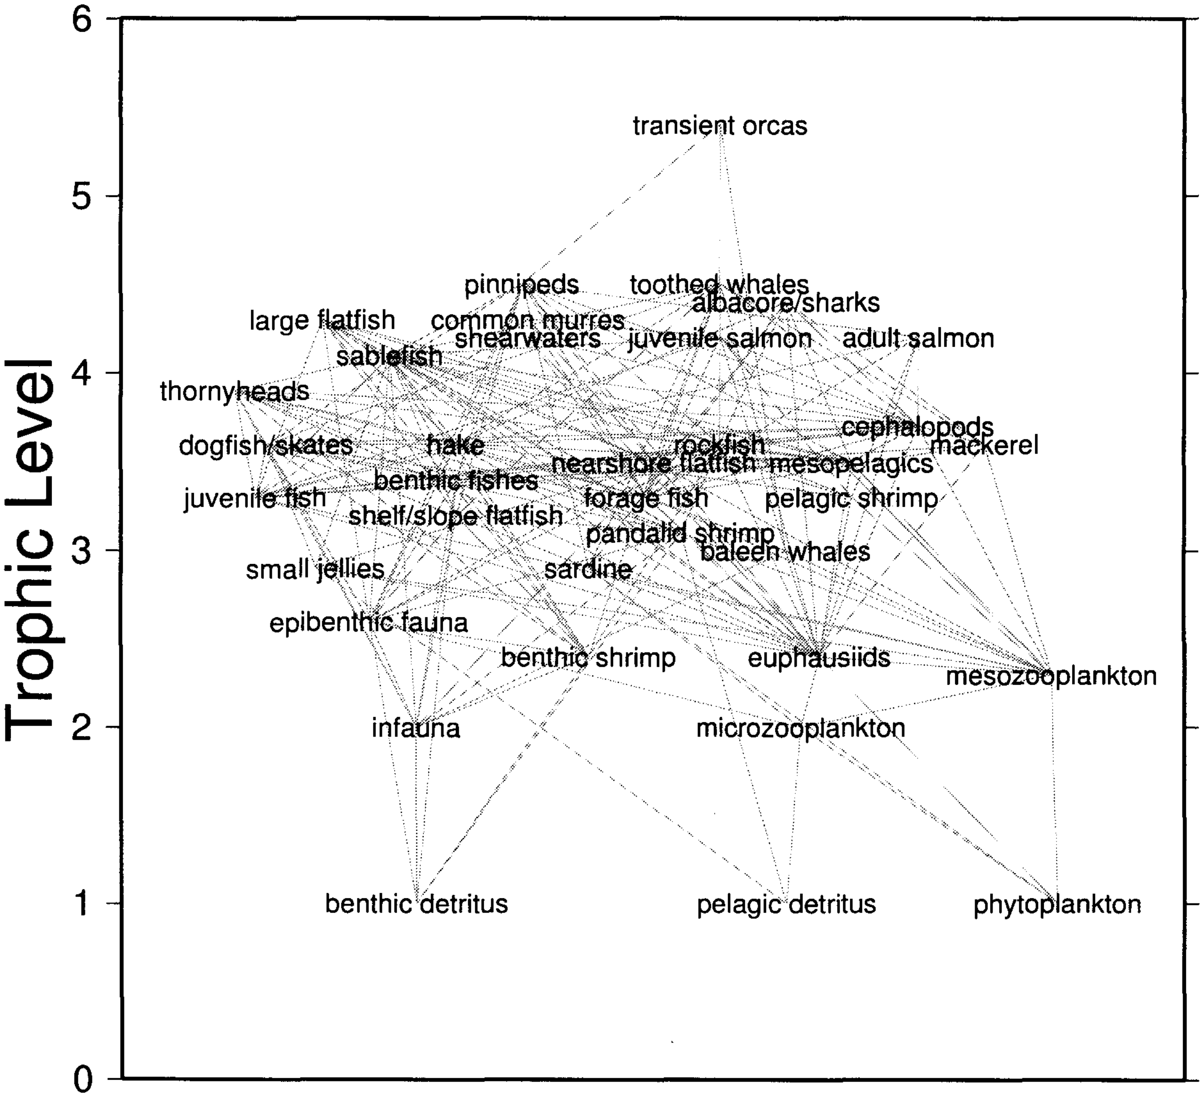

Figure 5. A model of the basic trophic components of the northern California Current food web. Despite massive aggregations of species and species assemblages, the picture illustrates the complexity of trophic interactions and the multitude of pathways for energy in this ecosystem.

trophic levels, emphasizing natural rates of growth and consumption of marine populations. This allows small-scale studies or models to be viewed in a common currency, in the context of the ecosystem as a whole. While the equilibrium assumptions of the Ecopath model do not allow for the determination of "true" biomasses or rates in a changing system, the modeler may use the software's bookkeeping to examine the basic trophic processes; for example, to learn whether a predator or fishery may be consuming more forage than is hypothesized to be available, and thus if its existence is putting pressure on other ecosystem components. The assumption is that over an appropriate period of time (say a decade or a regime) a mass-balance model can be generated to represent the basic trophic interactions between major ecosystem components.

Although the stochastic nature of most (if not all) populations and population parameters would suggest that a range of values would better explain seasonal and interannual changes, the static approach is useful from the standpoint of generating a "snapshot" of some mean state(s) of the ecosystem under different time periods or circumstances. The quick examination of many components of the system essentially extends the concept of maximum sustainable yield to multiple interacting species, suggesting a management framework for examining the consequences of altering species abundance and species assemblages.

It must be stated at the outset that these models rely heavily on "back-of-the-envelope" calculations—stable, oversimplified trophic webs—and thus cannot reliably model sudden ecosystem shifts to new states. Yet this generality and overstability may be their greatest recommendation. These models' potential may lie in developing metrics (e.g., the amount of primary production removed by fishing) relating measurable ecosystem quantities to levels of risk incurred by exploitation. At this time and despite great effort, measurable and meaningful metrics of ecosystem health, stability, and resilience have been elusive (Murawski 2000). Thus as a tool for developing management rules of thumb for avoiding ecological catastrophes, the comparison of simple, stable, pre- and postmanipulation equilibria or functional models with historic records of change in exploited ecosystems warrants further evaluation.

We have used preliminary Ecopath models to compare the state of the NCCE between the 1960s—a cool regime characterized by low exploitation rates and high rates of zooplankton production—and the 1990s—a warm regime characterized by low productivity, declining stocks, and intensively regulated fisheries following several decades of intensive exploitation. Population parameters and diet data for some 34 species or species assemblages were compiled or estimated for both time periods to generate a food web of basic trophic interactions (fig. 5).

The data used to estimate the parameters of this model come from a wide range of sources, including stock assessments, published literature, grey literature, and in many instances general review papers of basic population parameters. Model documentation and descriptions of data and data sources are available in Field and Francis.[5] The challenges in compiling adequate data to parameterize the model inevitably suggest suspect results; because of the paucity of information regarding the dominant planktonic and nektonic populations in this region, some gross estimation and generalization is unavoidable. Nevertheless, we believe such models are extremely useful both for visualizing the nature of the system being managed and beginning to understand how major changes in species abundance or productivity might reverberate up or down through the food web.

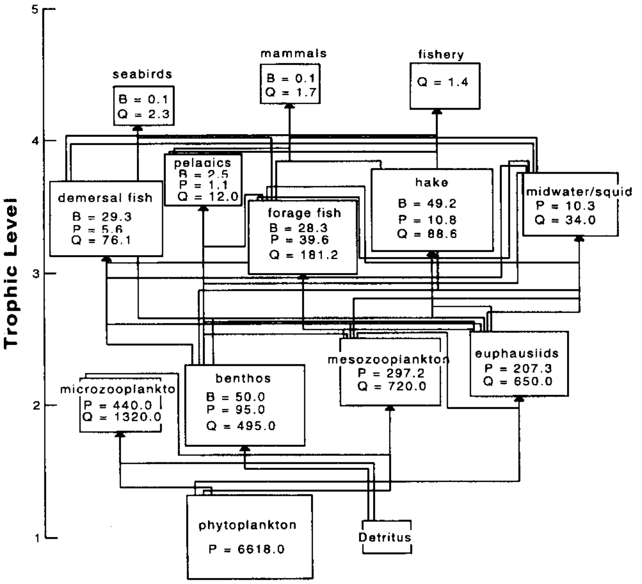

Figure 6. Simplified mass balance models of aggregated ecosystem components and major trophic flows in the northern California Current during the early 1960s. Units are wet weights of biomass (grams/square meter).

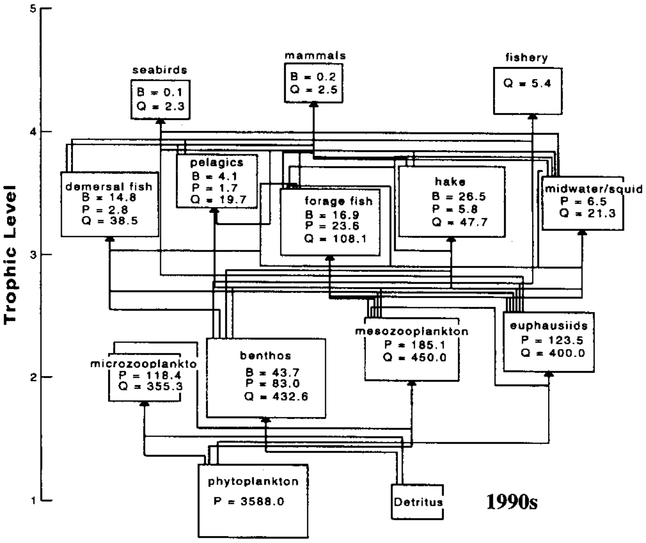

Figure 7. Simplified mass balance models of aggregated ecosystem components and major trophic flows in the northern California Current during the mid-1990s. Units are wet weights of biomass (grams/square meter).

Figures 6 and 7 show greatly simplified versions of trophic flow diagrams and energy pathways through the NCCE as modeled in the early 1960s and 1990s, and generated by aggregating the parameters for the 34 species and species assemblages shown in figure 5. The size of the boxes (if they were to be viewed in three dimensions) would be proportional to the log of estimates of average annual biomass (B) in the different assemblages. The average estimated production in the assemblages is given as P and consumption is given as Q. For lower trophic levels (in which annual production is the key parameter) these estimates are based on a top-down estimate of consumption requirements of upper-trophic-level predators, calibrated to the extent possible by existing assessments of planktonic and nektonic standing stocks and productivity for the two time periods in question. Although the parameters and estimates need further refinement, we believe that these figures represent a reasonable assessment of the key energy flows and trophic pathways through the system. At a minimum, these comparisons provide some measure of how the massive changes in the biomass of commercially important species have

---

[5] Field, J. C., and R. C. Francis. MS. in prep. Static and dynamic models of the northern California Current ecosystem. Fisheries Research Institute Reports.

reduced the consumption requirements upon the lower trophic levels necessary to sustain those populations.

One interesting consequence of this change is that there does not appear to be any evidence for major shifts or increases in the abundance of other species or species assemblages to take advantage of what might be perceived as an increase in the availability of forage resulting from declines in the relative abundance of commercially important predators, as has been suggested in other systems such as the Georges Bank (Fogarty and Murawski 1998). Although data on the relative abundance of target and nontarget species are sparse, preliminary work to develop diversity indices of upper-trophic-level predators based on fisheries survey data for the early 1970s and the mid-1990s also suggests no major shift in the relative composition of groundfish assemblages in the INPFC Columbia area (S. Gaichas, pers. comm.), although Emmett and Brodeur (2000) have found substantial shifts in the relative abundance of pelagic predators.

The above situation may be in contrast with other heavily fished ecosystems, in which major shifts in species or community composition have followed major disturbances. Until recently, levels of secondary production throughout the 1990s have seemed far below long-term averages; the abundance of many key forage species has been greatly reduced (Emmett and Brodeur 2000); recruitment of rockfish and survival of salmon smolts have reached all-time lows (Hare et al. 1999); and the average weight-at-age for some species, such as hake and yellowtail rockfish, have been below the long-term means (Dorn et al. 1999; Tagart et al. 2000). Massive changes in the species composition and biomass of euphausiids, copepods, and other planktonic organisms have also been documented (McGowan et al. 1998; Mackas et al., in press). All of these factors suggest that this system has probably been functioning at lower levels of productivity over recent years, as associated with the aforementioned changes in climate forcing and physical conditions following the 1977 (and perhaps 1989) regime shift (Hare and Mantua 2000). As alluded to earlier, the evidence for a large-scale climate shift that has affected the distribution and abundance of key populations in the NCCE is widespread, and improving our knowledge of the mechanism and consequences of these shifts is the focus of major investigations by CalCOFI, GLOBEC, the JISAO Climate Impacts Group, and many other research entities.

The nature in which such a shift in productivity may be interacting with the concurrent and ongoing removal of a substantial fraction of the higher-trophic-level biomass in this ecosystem remains unclear. Our hope is that further insight into the nature and consequences of climate shifts, and into the interaction between such changes and ongoing effects associated with fisheries removals might be uncovered through both static and dynamic modeling of this and other ecosystems. Over recent years dynamic models have been used to consider the impacts of fishing on marine ecosystem dynamics (Kitchell et al. 1999; Trites et al. 1999; Olson et al.[6]), and we expect that such modeling efforts might have much to offer in terms of insights toward considering large-scale ecological interactions in fisheries management.

As suggested earlier, another application of such models could be in deriving metrics or indices, which might be useful in assessing ecological health or stability, or comparing the nature and magnitude of human-induced disturbance between ecosystems. Jarre-Teichmann and Pauly (1998) used an index of the flow from primary production to higher trophic levels imbedded in the Ecopath software to assess the relative effect of fishing removals as a percentage of the production necessary to support fisheries on coastal pelagic species in several coastal upwelling systems. Their findings suggested that major fisheries for coastal pelagics removed between 1% and 15% of the primary production in these systems during distinct time periods. Perhaps more significantly, the magnitude of exploitation was more dependent upon the target species than on the total landings between systems; in other words, removals of species with higher trophic levels had a correspondingly greater effect on the percentage of primary production required (PPR) to sustain them. In these models, estimates of PPR are made for each trophic pathway, and energy flows are raised to primary production equivalents by means of methodology suggested by Ulanowicz (1995) and described in more detail in Christensen et al. (2000). The statistic of primary production required to support fisheries removals is thus a measure of the total amount of new production removed from exploited populations, scaled to the appropriate trophic level.

An example of how this index might be useful for comparative purposes is presented as figure 8. This figure shows total removals (landings and some measure of discards) in metric tons per square kilometer from three ecosystems in different time periods plotted with the estimated percentage of relative production necessary to support these landings (as above, the primary production raised to the equivalent trophic levels of the catches).

In the Eastern Bering Sea (EBS) models (Trites et al. 1999) there were massive harvests of long-lived, slow-growing predators, primarily baleen whales, sperm whales, walrus, and seals, with a corresponding low volume of landings in terms of tonnage but representing nearly all of the production at those trophic levels in that system. What this showed was essentially the "mining

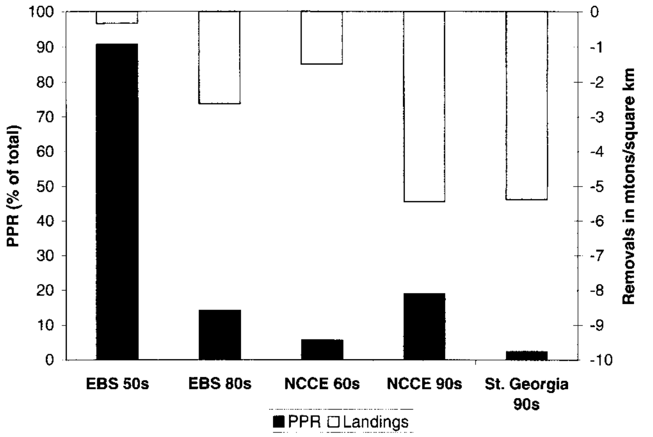

Figure 8. Fisheries removals (in metric tons/square kilometer) and percentage of primary production required (PPR) to sustain them, derived from five coastal ecosystem models. EBS = eastern Bering Sea; NCCE = northern California Current ecosystem; St. Georgia = Strait of Georgia.

out" of the biomass of higher trophic levels in the EBS during a period of intensive exploitation in the 1950s and 1960s. By contrast, in the 1980s the EBS supported the largest (by volume) fishery in the United States—the trawl fishery for walleye pollock—in addition to fisheries for Pacific cod, tanner crab, and many flatfish species. The removals (in t/km^2) increased substantially; however, due to the lower trophic levels of the target species, the percentage of system production that was removed annually declined considerably.

In the northern California Current, landings were relatively low in the 1960s, less than 1.5 t/km^2, and the corresponding percentage of primary production required to support those landings was on the order of 6%. By the 1990s, however, the total landings had increased substantially (see fig. 4; additionally, some groundfish landings had already peaked in the 1980s and dropped by the 1990s), to an average of nearly 6 t/km^2; this represented some 20% of the available production being removed by the fishery. By contrast, comparison with the (contemporary) Strait of Georgia model constructed by Pauly, Pitcher et al. (1998), removals were on the same magnitude between the NCCE and the Strait of Georgia in terms of tons per square kilometer, but because of the tremendous productivity and recycling of nutrients and energy in the Strait of Georgia, landings required a substantially greater percentage of the scaled production in the NCCE.

It is interesting to consider that the total removals per unit area, and the percentage of production accounted for in those removals, is greater in the NCCE than in the (contemporary) eastern Bering Sea. Whereas the latter is one of the most productive fishing grounds in U.S. waters, the immense area of this coastal shelf is what accounts for the tremendous volume of fisheries that it supports. While this construct of production required to support landings may seem vague, and is certainly fraught with major uncertainties about the real nature of the food web that supports these landings, we believe that this example illustrates the means by which simple ecological models may show the nature and magnitude of human-induced disturbances, and ultimately may provide a useful index or tool for scaling the extent and magnitude of human intervention in these complex ecosystems.

CONCLUSIONS

McEvoy (1996) suggested that successful fisheries management will require that managers and policymakers "cooperate with each stock's strategy for responding to the environment." Clearly, this environment is modulated by variability and change in climate as well as increasing measures of anthropogenic disturbance. We believe that the development and application of static and dynamic ecosystem models will ultimately reveal useful insights about how both climate and fishing affect NCCE structure and dynamics, and will provide valuable insight into system definition and behavior. Additionally, we hope to illuminate gaps in research or knowledge that create potential management limitations and increase uncertainty. Finally, we believe that the development of such models will lead to both static and dynamic visualizations that readily convey to managers and stakeholders the dynamics of this ecosystem and potential or probable effects of alternative management approaches. Ultimately, such efforts should lead to the development of more refined models to quantify the nature of ecological change in this system as a result of both climate effects and fishing, and will be useful as a framework for incorporating ecological considerations into fisheries management practices.

It is fair, however, to suggest that such insights are unlikely to lead to any meaningful short-term solutions to current crises in the management of northern California Current fisheries. The salmon crisis or the massive problems associated with effectively managing the groundfish fishery and the recovery of depleted populations can be addressed only by a massive change in the way in which large-scale system variability and human-induced impacts (both fishery and nonfishery related) are mitigated and managed in the future. The adoption of an "ecosystem-based approach" will result neither in obvious solutions to current crises nor in a substitute for more traditional means of assessing and managing fisheries. As McEvoy (1996) suggests, "If scientific fishery management could not predict or maintain the production of individual species, it seems a bit presumptuous to expect that we could now anticipate and direct the interacting components of an entire ecosystem."

Clearly, the adoption of a broader view of the interactions between fisheries (both their biological and human components) and marine ecosystems is necessary, and we must accept the dynamic and inherently unpredictable nature of entire systems and learn to operate within the bounds of uncertainty to ensure future sustainability. The nature of the coastal pelagics FMP is a step in such a direction, as is the movement toward using marine reserves to provide refugia for species as well as opportunities to assess how disturbed and undisturbed systems may differ in form and function. Equally necessary are basic reforms in the current approach to fisheries management away from traditional focused command-and-control practices. These changes are not mutually exclusive; both can and must occur if the resources and the communities which depend upon them are to persist in the future.

ACKNOWLEDGMENTS

We thank Kerim Ayden, Troy Buckley, Lorenzo Ciannelli, Elizabeth Loggerwell, and Julia Parrish for their discussions and assistance with the models; Anna Zagorska for proofreading early drafts; and Alec MacCall and one other reviewer for their attempt to force the authors to address critical shortcomings in this paper. Abstract

In this paper we present results from dynamic simulations of the Northern California Current ecosystem, based on historical estimates of fishing mortality, relative fishing effort, and climate forcing. Climate can affect ecosystem productivity and dynamics both from the bottom-up (through short- and long-term variability in primary and secondary production) as well as from the top-down (through variability in the abundance and spatial distribution of key predators). We have explored how the simplistic application of climate forcing through both bottom-up and top-down mechanisms improves the fit of the model dynamics to observed population trends and reported catches for exploited components of the ecosystem. We find that using climate as either a bottom-up or a top-down forcing mechanism results in substantial improvements in model performance, such that much of the variability observed in single species models and dynamics can be replicated in a multi-species approach. Using multiple climate variables (both bottom-up and top-down) simultaneously did not provide significant improvement over a model with only one forcing. In general, results suggest that there do not appear to be strong trophic interactions among many of the longer-lived, slower-growing rockfish, roundfish and flatfish in this ecosystem, although strong interactions were observed in shrimp, salmon and small flatfish populations where high turnover and predation rates have been coupled with substantial changes in many predator populations over the last 40 years.

1. Introduction

In the California Current, many fish populations and the communities that depend upon them are in a state of crisis. Many long-lived, slow-growing groundfish have become severely depleted due to overharvesting, and

obligatory rebuilding plans suggest that some stocks could take many decades to recover. The condition of several stocks is so poor that the Pacific Fisheries Management Council (PFMC) found it necessary in 2003 to close the majority of the continental shelf to most fishing, an action that has resulted in dramatic impacts to fishermen and fishing-dependent communities. Salmon crises, driven by a complex combination of natural and anthropogenic factors, have been ongoing in the Pacific Northwest for decades, although recent changes in ocean conditions have boosted production in some regions to record levels. Fisheries for highly variable coastal pelagic populations could be entering a new phase as well, as some stocks may have recently entered into a period of low productivity. Yet other fisheries, such as those for high turnover invertebrates such as Dungeness crab (*Cancer magister*) and pandalid shrimp (primarily the ocean shrimp, *Pandalus jordani*), have been highly variable over time, and in recent years have been thriving.

Historical management of these fisheries has generally been crisis-based rather than proactive. However there is a growing national and international recognition of the need to develop an ecosystem-based approach to fisheries management (EBFM) in response to the challenges and shortcomings of traditional resource management approaches in sustaining marine ecosystems (Botsford et al., 1997; EPAP, 1999; NRC, 1999; Pauly et al., 2002; Pikitch et al., 2004). The common threads of ecosystem-based management approaches involve taking a more holistic view of managing resources in the context of their environment. For marine fisheries, this implies greater consideration of the interactions between climatic and oceanographic processes, the connections and interactions between fished and unfished populations in the ecosystem, and the role of humans as both predators and competitors in such ecosystems. While efforts to develop an ecosystem focus in fisheries modeling and management are far from new, the desire to do so has increased as both stakeholder and public perceptions of fisheries have evolved from limitless frontiers to systems with limits and thresholds (Hanna, 1997; EPAP, 1999; NRC, 1999). Although the direct application of ecosystem modeling and management strategies in fisheries systems has historically been limited (Mangel et al., 2000; Goodman et al., 2002), the potential role of such approaches holds promise in the future of marine resource management. This paper uses a dynamic ecosystem model of the Northern California Current (NCC), a region of the larger California Current System (CCS), to improve our understanding of the relationships among physical, ecological and human (fisheries) processes in shaping the trajectories of commercially important populations of fish and shellfish. In particular, the model allows us to evaluate how conceptual and statistical relationships between climate and the commercially important biota in this ecosystem can be incorporated into a dynamic model and assessed against known or suspected trends in ecosystem behavior.

2. Data and methods

The California Current is essentially the eastern limb of the Central Pacific Gyre, and begins where the west wind drift splits into two broad coastal currents, the California Current to the south and the Alaska Current to the north, near the northern end of Vancouver Island. The location of the NCC relative to the large-scale circulation patterns and coastal domains of the northeast Pacific (Fig. 1, left-hand panel) is shown as adapted from Ware and McFarlane (1989), as is the general bathymetry of the area of the NCC modeled in this exercise (Fig. 1, right-hand panel). As there are really several major currents in the region, all of which vary in geographical location, intensity and direction with the seasons, this region is generally referred to as the California Current System (CCS, Hickey, 1979). In most cases, the shelf, slope and offshore regions of the California Current System have their greatest changes in physical and biological characteristics at major promontories along the west coast. These include Point Conception, Cape Mendocino, and Cape Blanco (US GLOBEC, 1994). The dynamics over the shelf are generally forced by regional wind fields, which tend to be equatorward in the spring and summer, and poleward in the winter. Spring and summer equatorward winds drive offshore Ekman transport of surface waters, which is balanced by the upwelling of deeper waters that tend to be cooler and nutrient rich. Although the scales of the wind fields tend to be large (100s of km), there are significant spatial differences over both alongshore and cross-shore directions, often related to the geographic barriers described earlier. The northern half of the CCS, the region of coastal ocean between Cape Mendocino and Vancouver Island, is often described as a zoogeographic transition between Californian and Aleutian biological provinces (Bottom et al., 1993). Although this entire area should rightly be referred to as the Northern California Current Ecosystem, the political boundary between the US and Canada (which runs

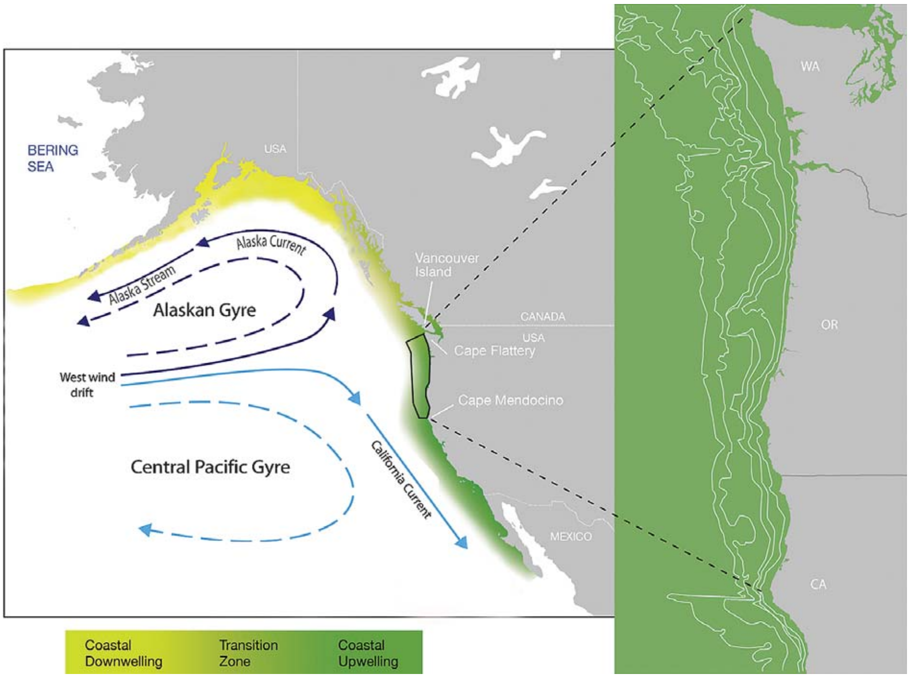

Fig. 1. Major current patterns and ocean domains of the Northeast Pacific and bathymetry (50, 100, 200, 500, 1000 and 2000 m contours) of the continental shelf and slope between Cape Mendocino and Cape Flattery.

southwest off of Cape Flattery, WA) has been used here as a northern boundary for the purposes of these modeling efforts, primarily due to data limitations.

The region modeled is the area between the nearshore and the continental slope to a depth of approximately 1280 m (typically 20–80 km offshore), as this represents the limits of available data from continental slope surveys and the approximate limits of most historical and contemporary fishing effort for trawl and fixed gear. Throughout this region, there are extreme gradients in physical conditions and biological communities between the highly energetic waters nearshore, and the cold, low oxygen waters of the continental slope. Although the true extent of the California Current itself is far seaward of these boundaries, and many important highly migratory species spend much of their lives outside this area, the shelf and shelf break waters represent most of the habitat for most resident groundfish species, and much of the range of Pacific hake (*Merluccius productus*), salmon (*Oncorhynchus* spp.), sardine (*Sardinops sagax*), mackerel (both *Trachurus symmetricus* and *Scomber japonicus*) and other migrants. This coastal margin also includes the regions of greatest biological production at lower trophic levels, and the greatest densities of migratory seabirds and marine mammals. Seabirds and marine mammals exemplify the problems associated with establishing boundaries around marine ecosystems, as some of the most ecologically important populations migrate from other ecosystems throughout the Pacific. For example, humpback whales (*Megaptera novaeangliae*) migrate north from the equatorial Pacific in summertime, northern fur seals (*Callorhinus ursinus*) migrate to the NCC from the Bering Sea during winter, and sooty shearwaters (*Puffinus griseus*) migrate to the NCC from the southern hemisphere.

The modeling framework employed in this paper is the Ecopath mass balance approach developed by Polovina (1984) and Christensen and Pauly (1992). Ecopath is currently available as part of a modeling package that includes a dynamic model, Ecosim (Walters et al., 2000), and a spatially-explicit dynamic model called Ecospace (Christensen and Walters, 2004a). Comparable software developed by one of the authors (K. Aydin) was also used for much of this work. The origins of the modeling approach can be traced back to Steele (1974), Laevastu and Favorite (1978), and deeper into the development of theory on thermodynamics, ecosystem structure and marine ecology (Margalef, 1963; Ryther, 1969; Odum, 1969). The resurgence in the popularity of these (and similar) modeling approaches is not necessarily explained in terms of an increased foundation of knowledge and data to parameterize such models, but rather to the present political interest in developing ecosystem-based fisheries management tools and insights. The approach used by Ecopath and Ecosim is but one of several potential modeling frameworks for investigating trophic interactions in large marine ecosystems. Most critical reviews of multispecies modeling approaches (such as multi-species biomass dynamics models, multi-species VPA, individual-based models, and others) agree that despite conceptual shortcomings and data limitations, ecosystem models have the potential to augment contemporary single-species models by confronting an array of interactions and dynamics that are more difficult to address with single-species models, such as competition, predation and environmental variability (Hollowed et al., 2000; Fulton et al., 2003; Plagányi and Butterworth, 2004). Such models have also been suggested as vehicles for qualitatively structuring ecosystem limitations for using quantitative information from single species stock assessments. Many criticisms of ecosystem modeling approaches are based less on the model structure, than on the misuse and misunderstanding of the model limitations, a characteristic shared with single-species models (Schnute and Richards, 2001). As Walters et al. (2005) suggest, no model can ever be expected to be a "complete" representation of a food web, particularly where size structured interactions and trophic ontogeny have the potential to lead to more complex ecological interactions than can be accounted for in simplistic models.

Ecopath is a steady-state model that emphasizes rates of production and consumption of marine populations. The model provides a template for integrating a wide range of biological and fisheries information from stock assessments, survey data, bioenergetics, food habits studies, and fishing mortality. The energetic accounting of the model also forces a critical evaluation of basic interspecific interactions, which in turn allows an evaluation of whether what is believed to be "known" about a system (from survey, stock assessment or other sources) "adds up" in a thermodynamic sense. The necessary assumption is that, over an appropriate period of time (typically one or several years), a mass-balance model can be generated to represent the basic trophic interactions between major ecosystem components. It is important to note that this need not constrain the model to equilibrium, but rather only to a thermodynamically consistent state. The equations are thermodynamically based, such that new production of any component is partitioned between consumption by predators, export from the system, yield to fisheries, and biomass accumulation or decline (the left hand side of Eq. (1), and consumption of prey by predators is partitioned into respiration, tissue production and egestion (the right hand side of Eq. (1). The main equation for the entire model is:

$$B_i\left(\frac{P}{B}\right)_i \mathrm{EE}_i + \mathrm{IM}_i + \mathrm{BA}_i = \sum_j \left(B_j \frac{Q}{B}\mathrm{DC}_{ij}\right)_j + \mathrm{EM}_i + C_i \tag{1}$$

where B is the standing biomass of a given group, i, and j represents all predators on i, P/B is the production to biomass ratio (typically in units of 1/year, and based on bioenergetic models, mortality rates or literature values), EE represents the ecotrophic efficiency of a component (essentially the fraction of new production that is passed up through the food web), IM and EM represent immigration and emigration used to account for model imbalances related to migration, BA is a biomass accumulation term used to reflect observed trends, Q/B is a consumption to biomass ratio (also in units of 1/year), DC is the proportional diet composition of predators j on prey i, and C is the catch by fisheries. Because the model is essentially a series of linear equations, matrix methods can be used to estimate one unknown for each component of the model. Typically the unknown to be "solved," or estimated, is the EE, or ecotrophic efficiency. However when biomass or P/B ratios are unavailable, this value can be specified at a predetermined level and the model can be balanced to estimate either the average biomass (B_i), the production to biomass ratio (P/B), or the consumption to biomass ratio (Q/B). Although the assumptions of constant transfer rates are unlikely to be met in reality (where the stochastic nature of population and biological rates would suggest that a range of values would be more appropriate), the static approach is useful from the standpoint of generating a "snapshot" of the mean state of the ecosystem during a particular time period or condition.

A mass balance model of the NCC representing the 1960s was developed by Field (2004), and detailed documentation of the derivation of model parameters and reviews of food habits studies are not included here for the sake of brevity. In general, stock assessments provide the most complete source of information on the abundance and productivity of roughly 15 commercially important stocks as far back as the 1960s. Stock assessments are reported in the Appendices to the Stock Assessment and Fishery Evaluation (SAFE) Reports published by the Pacific Fisheries Management Council (PFMC, 2002, 2003). Where stock assessments did not model population abundance as far back as the early 1960s, estimates of catches and the results of assessments were used to fit known biomass surplus production models (MacCall, 2002) to arrive at reasonable biomass estimates for the 1960s model. For most unassessed species and assemblages, survey results from triennial groundfish surveys conducted from 1977 through 2001 (e.g., Weinberg et al., 2002) and slope surveys done through much of the 1990s (e.g., Lauth, 1999) were used to develop abundance estimates (additional details of the survey history and potential shortcomings are summarized in Zimmerman et al., 2003). Catch and landings data are taken first from stock assessments (where available), from the Pacific Fisheries Information Network (PacFIN) database between 1981 and 2003, and from historical records compiled by Lynde (1986) between 1956 and 1980. Estimates of bycatch rates were obtained from stock assessments where available, or developed from the bycatch data collected during studies of shrimp and groundfish trawl fisheries in the mid-1980s (Pikitch et al., 1988).

Estimates of abundance and productivity for lower and higher trophic level model components (phytoplankton, zooplankton, benthic fauna, marine mammals, seabirds) were based on a compilation of survey estimates, literature values, or model estimates. Abundance and population rate data for top-level predators, particularly seabirds and marine mammals, were obtained primarily from NMFS Marine Mammal Stock Assessments (Carretta et al., 2002) and other sources (e.g., Briggs et al., 1992; Wahl et al., 1993). Estimates of abundance and productivity for lower trophic levels were based on literature values of standing stocks and population rates for populations within or near to the NCC where available (Robinson et al., 1993; Tanasichuk, 1998; Peterson and Schwing, 2003), but were more typically based on top-down balances. Food habits data from the NCC were available from a wide range of studies of groundfish and top-predator populations between 1960 and 2000; including over 30,000 stomach samples of groundfish, although many such studies were highly limited in space and time (Livingston, 1983; Brodeur and Pearcy, 1984; Buckley et al., 1999). Consumption-rate values for most commercially important species estimates were generated using weight-at-age data collected from the triennial surveys and a generalized version of the von Bertalanffy growth equation developed by Essington et al. (2001), and were typically based on literature estimates for lower and higher trophic levels (e.g., Hunt et al., 2000).

The final model includes 63 components; 21 of which are commercially significant species or stocks of fish or shellfish, 8 of which are aggregations (at the genus or family level) of commercially significant groups (e.g., salmon, skates), 11 of which are functional groups of top predators (seabirds and marine mammals), 4 of which are either producers (phytoplankton) or detritus (benthic, pelagic, fisheries offal), with the remaining 19 representing broad aggregates of zooplankton, benthic fauna, and non-commercial fishes. As such, the model emphasizes detail for mid-trophic level predators, in particular commercially important groundfish, for which considerably more data tend to be available. The model components and parameters for the 1960s model are provided (Table 1), as is the diet matrix developed for this model (Table 2). Additionally, we summarize the more significant taxa in the aggregated or functional groups in the model (Table 3) and provide full common and latin names for the species or stocks in the model (Table 4). We also present the steady-state model in a more graphical form (Fig. 2), consistent with the methods developed by Aydin et al. (2003).

The basic equations of the dynamic Ecosim model, and many of the associated assumptions and technical details, are developed in detail in Walters et al. (2000) and Christensen and Walters (2004a). Ecosim turns the energy flows of a given Ecopath model into dynamic, time-varying predictions by using coupled differential equations derived from the basic Ecopath equation (Eq. (1)), such that:

$$\frac{\mathrm{d}B_i}{\mathrm{d}t} = g_i \sum_j Q_{ji} - \sum_j Q_{ij} + I_i - (M0_i + F_i + e_i)B_i \tag{2}$$

where $\mathrm{d}B_i/\mathrm{d}t$ is the growth rate (in units of biomass) of the group i during the time interval $\mathrm{d}t$, g_i is the growth efficiency (defined as production, P, over consumption, Q), Q_{ji} represents predation by group i on group j, Q_{ij} represents predation on group i by group j, I_i is the proportional biomass immigration rate, $M0_i$ is the non-predation mortality, F_i is the fishing mortality rate, and e_i is the proportional emigration rate. More simply, the instantaneous change in biomass of a given group i is dependent upon the difference between the prey that i consumes (the Q_{ji}, multiplied by growth efficiency) and how much of that group is consumed by predators (the

See Table 3 for a description of the more significant taxa in the aggregated functional groups listed here, and Table 4 for the scientific names of the stocks or species listed here.

Q_{ij}), taking into account non-predation mortality ($M0$), fishing (F), immigration (I) and emigration (e). The differential equations are solved in Ecosim using either an Adams–Bashforth integration or a Runge–Kutta fourth-order routine (Walters et al., 2000). One of the more recent developments in Ecosim is the ability to handle ontogenetic shifts in life history characteristics with either "split-pool" juvenile and adult groups for model components, or multiple life history stanza models for species with more complex ontogeny (Christensen and Walters, 2004a). Although alternative versions of the NCC model were constructed with species-specific juvenile and adult pools, the lack of data on abundance, consumption, production and prey preferences made effective implementation of a split-pool or multi-stanza model unfeasible at the present time. Instead, juveniles of similar species have been pooled together, as rockfish, flatfish and roundfish juveniles, based on what predation could be reliably inferred from diet studies (where juveniles as prey are very rarely identified beyond genus or family level) and estimates from the literature and other models regarding plausible production and consumption rates.

The most important interactions in the dynamic model are the biomass flows between compartments, the consumption rates (Q_{ij}) themselves. These flows are calculated by the "foraging arena" concept (Walters and Juanes, 1993; Walters et al., 1997, 2000), which assumes a heterogeneous environment in which the biomass of a model component is partitioned into states vulnerable and invulnerable to predation. The transfer rate, v, between these two states in part determines whether control in the model is top-down (Lotka-Volterra), bottom-up, or intermediate. The non-vulnerable state is intended to represent mechanisms that prey use to avoid predation, such as daily vertical migrations or schooling; behaviors that can lead to strong competitive interactions between predators even when the biomass of prey is large. For example Bundy (2001) demonstrated a strong top-down effect of harp seals on cod when vulnerability parameters were set at either high (implying top-down control) or intermediate (default) values. When they were set to low (bottom-up) values, strong top-down effects did not occur. In this instance, high vulnerability is likely to be a reasonable assumption, particularly as marine mammals and other animals with high passive metabolism costs typically do not have the option of lowering consumption rates relative to prey availability. A low vulnerability implies weak top-down control on a prey biomass (closer to ratio-dependent predation rates), to the extent that control is bottom-up and production does not significantly increase with predator declines.[1]

Consumption is modeled in a manner that facilitates opportunities to manipulate consumption rates dynamically, such that the consumption rate of a prey i by a predator j (Q_{ij}) is determined by the equation:

$$Q_{ij} = \frac{a_{ij} v_{ij} B_i B_j T_i T_j S_{ij} M_{ij}/D_j}{v_{ij} + v_{ij} T_i M_{ij} + a_{ij} M_{ij} B_j S_{ij} T_j/D_j} \tag{3}$$

---

[1] Walters et al. (2000) suggest that modeling in a low vulnerability scenario is comparable to the compensatory responses considered in contemporary single-species management. While this is true, the nature of compensation in Ecosim comes from increased per-capita consumption (at the expense of other species) rather than from the increasing growth rates (and conversion efficiencies) of relatively younger fish as older individuals are removed from the population in a typical catch-at-age stock assessment model (Aydin, 2004).

See Table 3 for a description of the more significant taxa in the aggregated functional groups listed here, and Table 4 for the scientific names of the stocks or species listed here.

Table 3
Summary of the more significant species or taxa in aggregated functional groups

Phytoplankton	Functional group of all photosynthetic primary producers, diatoms generally dominate
Infauna	Functional group of polychaetes, bivalves, small crustaceans, and some echinoderms
Amphipods	Functional group of all gammarid, caprellid and hyperiid amphipods
Epibenthic	Functional group including many echinoderms (holothuroids, asteroids, ophiuroids), brachyurans, mysids, isopods, cumaceans, gastropods, and other organisms
Micro-zoop	Functional group of small heterotrophic zooplankton, primarily protozoans such as gymnodiniods, dinoflagellates, ciliates, and nanoflagellates
Copepods	All developmental stages of species in the subclass Copepoda
Euphausiids	All developmental stages of species in the order Euphaussiacea
Carniv-zoops	Functional group including pasiphaid, seregestid and other pelagic shrimps, chaetognaths, pelagic polychaetes, and the pelagic stages of many invertebrates, such as crab megalopae
Small jellies	Functional group of filter-feeding urochordate herbivores; salps, doliolids and larvaceans, as well as thecosome pteropods (such as *Limacina helecina*)
Large jellies	Functional group includes essentially all gelatinous carnivores, principally cnidarians (hydrozoans and scyphozoans), ctenophores and heteropods
Benthic shrimp	Functional group of benthic decapod shrimp (excluding *Pandalus jordani*) such as *Crangon*, *Eualus*, *Daridea*, and *Calocaris* species
Cephalopods	Functional group of cephalopods, such as *Loligo*, *Gonatus*, and *Octopus* species
Forage fish	Functional group of clupeids, osmerids and other taxa, including northern anchovy (*Engraulis mordax*), Pacific herring (*Clupea harengus pallasi*), eulachon (*Thaleichthys pacificus*), and whitebait smelt (*Allosmerus elongates*)
Mesopelagics	Functional group of mesopelagic taxa, such as California headlightfish (*Diaphus theta*), northern lampfish (*Stenobranchius leucopsarus*), and blue lanternfish (*Tarletonbeania crenularis*)
Benthic fish	Functional group, common families include eelpouts (Zoarcidae), snailfish (Cyclopteridae), poachors (Agonidae), and sculpins (Cottidae)
Macrourids	Functional group includes all grenadiers (family Macrouridae)
Mackerel	Includes jack mackerel (*Trachurus symetricus*) and Pacific mackerel (*Scomber japonicus*)
Salmon	Primarily Chinook and coho salmon (*Oncorhynchus tshawytscha* and *O. kisutch*)
Skates	Primarily *Raja* and *Bathyraja* species, such as big skate (*R. binoculata*), longnose skates (*R. rhina*) and black skate (*B. trachura*)
Dogfish	Primarily dogfish (*Squalus acanthias*), but includes cat sharks (*Apristurus* spp.)
Juvenile rockfish	All juvenile stages of *Sebastes* rockfish
Black rockfish	Primarily black rockfish (*Sebastes melanops*) but includes other common nearshore rockfish, such as blue (*S. mystinus*), China (*S. nebulosus*), and quillback (*S. maliger*)
Shelf rockfish	Based on PFMC designations, includes *Sebastes* species such as bocaccio (*S. paucispinis*), yelloweye (*S. ruberrimus*), chilipepper (*S. goodei*), and silvergrey (*S. brevispinus*)
Slope rockfish	Based on PFMC designations, includes *Sebastes* species such as aurora (*S. Aurora*), darkblotched (*S. crameri*), rougheye (*S. aleutianus*), sharpchin (*S. zacentrus*), and splitnose (*S. diploproa*)
Juvenile thornyheads	All juvenile stages of *Sebastolobus* species
Juvenile roundfish	All juvenile stages of sablefish, lingcod, and other commercially significant roundfish
Juvenile flatfish	All juvenile stages of Pleuronectiform fishes
Small flatfish	Functional group that includes most small flatfish, including sanddab (*Citharichthys* spp.), Slender sole (*Lyopsetta exilis*), butter sole (*Isopsetta isolepis*), and starry flounder (*Platichthys stellatus*)
Coastal sharks	Functional group includes soupfin (*Galeorhinus galeus*) and thresher sharks (*Alopias* spp.)
Shearwaters	Functional group primarily of *Puffinus griseus*, but including petrels (*Oceanodroma* spp.) and phalaropes (*Phalaropus* spp.)
Murres	Primarily common murre (*Uria aalge*), but including Cassin's auklets (*Ptychoramphus aleuticus*), Rhinoceros auklets (*Cerorhinca monocerata*), tufted puffins (*Fratercula cirrhata*) and other alcids
Gulls	Primarily *Larus* species, but including kittiwakes (*Rissa* spp.), northern fulmars (*Fulmarus glacialis*) and black-footed albatross (*Phoebastria nigripes*)
Toothed whales	Primarily harbor porpoise (*Phocoena phocoena*), Dall's porpoise (*Phocoenoides dalli*), and Pacific white-sided dolphin (*Lagenorhychus obliquidens*)
Sea lions	Primarily Steller sea lions (*Eumetopias jubatus*), but including California sea lions (*Zalophus californianus*) and northern elephant seals (*Mirounga angustirostris*)
Baleen whales	Primarily humpback whales (*Megaptera novaeangliae*), but including minke (*Balaenoptera acutorostrata*), fin (*B. physalus*), blue (*B. musculus*), and sei (*B. borealis*) whales

Table 4
Common and scientific names for specific species or stocks in the model

Common name	Scientific name
Pandalid shrimp	*Pandalus jordani*
Dungeness crab	*Cancer magister*
Tanner crab	*Chionoecetes tanneri*
Pacific sardine	*Sardinops sagax*
Pacific hake	*Merluccius productus*
Sablefish	*Anoplopoma fimbria*
Pacific Ocean Perch (POP)	*Sebastes alutus*
Canary rockfish	*Sebastes pinniger*
Widow rockfish	*Sebastes entomelas*
Yellowtail rockfish	*Sebastes flavidus*
Shortspine thornyhead (ssthorny)	*Sebastolobus alascanus*
Longspine thornyhead (lsthorny)	*Sebastolobus altivelis*
Lingcod	*Ophiodon elongates*
English sole	*Parophys vetulus*
Petrale sole	*Eopsetta jordani*
Rex sole	*Glyptocephalus zachirus*
Dover sole	*Microstomus pacificus*
Arrowtooth flounder	*Atheresthes stomias*
Pacific halibut	*Hippoglossus stenolepus*
Albacore	*Thunnus alalunga*
Orca	*Orcinus orca*
Sperm whale	*Physeter macrocephalus*
Harbor seal	*Phoca vitulina richardsi*
Fur seal	*Callorhinus ursinus*
Grey whale	*Eschrichtius robustus*

where a_{ij} is the search rate for prey i by predator j, v_{ij} is the transfer rate between the vulnerable (v_{ij}) and invulnerable prey behavior states,[2] B_i and B_j are the biomass of prey and predators, respectively, T_i and T_j represent the relative feeding time of prey and predators, respectively, S_{ij} is a user-defined seasonal or long-term forcing effect, M_{ij} is a parameter representing mediating forcing effects, and D_j represents the effects of handling time as a limit to consumption rate as a function of handling time. The values for search rates (a_{ij}) are inferred from a maximum consumption rate, $C^{\max}$. As with the vulnerability parameters, these parameters are difficult to estimate, measure or otherwise derive, although their influence on model dynamics is generally less than the influence of setting vulnerabilities. The general approach here has been to use default values unless otherwise noted.[3] Both S_{ij} and M_{ij} default to 1, but can be used to increase or decrease vulnerability with season, habitat change, climate or other factors.

Although this modeling framework was not originally developed to include biophysical processes, it is possible to drive productivity from the bottom-up with time series of either physical or biological data (Watters et al., 2003). Similarly, the ability to mediate the vulnerability of prey to predators dynamically is used to mimic some of the impacts of climate variability on the spatial distribution and production of some ecosystem components. For example, we can evaluate the extent to which forcing lower trophic level production with

---

[2] The vulnerability rates chosen by the user range in a continuum between 0 and 1, with 0 representing "bottom-up" control, 1 representing "top-down" control, and 0.3 for mixed control. The values used in the computations are rescaled such that the computational v_{ij} is equal to $\exp(2*[\exp(v_{ij}) - 1])$ where v_{ij} is chosen by the user.

[3] The default value for $C^{\max}$ is 2, which translates into the expectation that if predator j numbers were very high, their maximum consumption rates of prey i would be twice the (Ecopath) default value. Thus, as with vulnerability, the estimated values for $C^{\max}$ can have an influence on model dynamics, with a high ratio of $C_{ij}^{\max}$ to C_{ij} implying strong top-down control and a low ratio implying bottom-up control. Similarly, the maximum relative P/B was set to 2, the maximum relative feeding time to 2, the feeding time adjustment rate 0.5, the predator effect on feeding time to 0, the density dependent catchability to 1, handling time $(Q/B_{\max})/(Q/B_0)$ to 1000, and the fraction of "other" mortality sensitive to changes in feeding time to 0. This is consistent with other approaches to these parameters (Bundy, 2001; Cox et al., 2002), although Olson and Watters (2003) vary the fraction of other mortality sensitive to feeding time by trophic level, setting it to 0 for large predators, 0.5 for medium-size fishes and 1 for forage components.

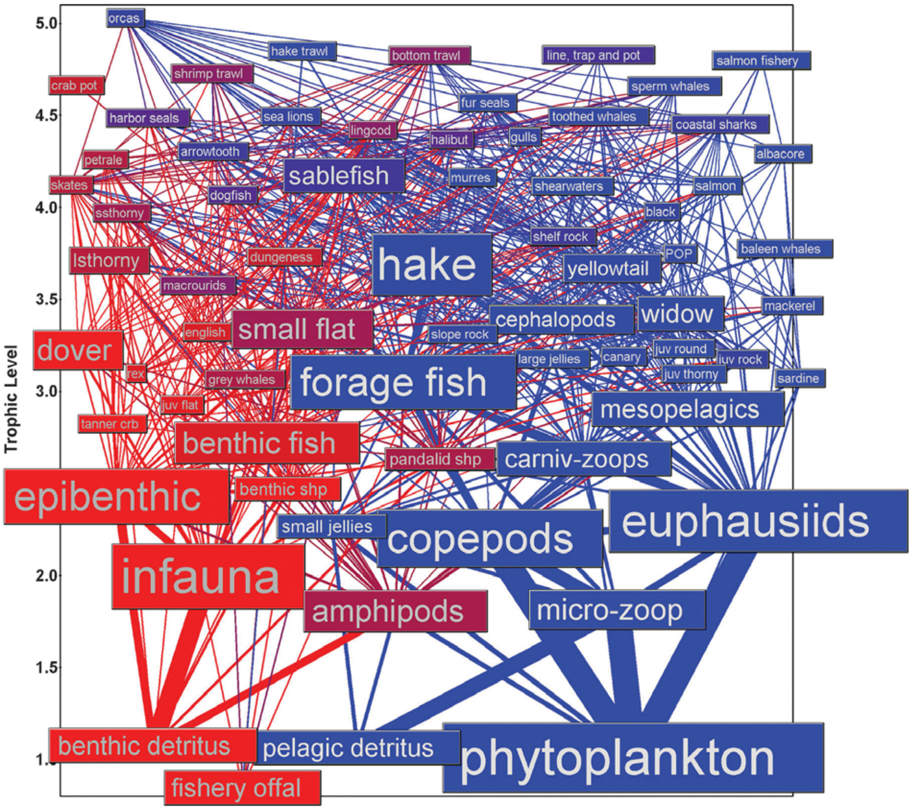

Fig. 2. The significant food web of the Northern California Current. Key taxa for functional groups are provided in Table 3. Common names and scientific names of species and stocks are given in Table 4. The estimated trophic level is along the *y* axis, the height of the boxes is scaled to the log of the standing biomass, the width of the bars represents biomass flux of prey to predators, and the colors represent the alternative energy pathways such that pelagic (primary production) energy pathways are shown in blue and the benthic (detrital loop) energy pathways are shaded in red.

physical indices improves the fit of model dynamics to the estimated or inferred trends from stock assessments and surveys relative to the fit obtained by running the model with no variability in bottom-up forcing. To attempt to validate the model performance, a series of simulations were run in which the 1960s model was projected to 2004. Fishing was represented by using fishing mortalities based on stock assessments and known catches (for hake and most groundfish), estimated changes in effort (for pandalid shrimp and Dungeness crab) and in one case a highly simplified assumption of constant fishing mortality (Pacific salmon) where attempting to estimate either fishing mortality or effort was impractical.

The model was run forward first under the assumption of a constant environment, then forced dynamically with several climate indices. A range of climate time series was tentatively explored as forcing functions, although only a subset are shown and discussed here. The indices discussed here include upwelling wind indices, indices of wind derived southward transport, the Pacific Decadal Oscillation (PDO) index, and an index of predicted Oregon coastal coho (*Oncorhynchus keta*) salmon survival (Logerwell et al., 2003). Upwelling wind indices were generated by the average of monthly offshore Ekman transport indices at 42, 45 and 48° N, as obtained from the Pacific Fisheries Environmental Laboratory (PFEL) Live Access Server (www.pfeg.noaa.gov). The southward transport and the PDO indices were chosen to represent the significance of large-scale environmental conditions on the abundance and dynamics of key predator stocks in the NCC; as discussed by Chelton et al. (1982). Transport estimates were averaged over a greater spatial area (36 to 51° N), with the expectation that this would better represent larger scale patterns of spatial distribution for migrant species. Similarly, the PDO is widely recognized to reflect patterns in SST variability, which in turn have been strongly linked to the production and distribution of salmon, hake, sardine and other species (Mantua et al., 1997;

Francis et al., 1998; Hare and Mantua, 2000; Swartzman and Hickey, 2003). Estimates of southward transport were obtained from PFEL, and the PDO was obtained from the JISAO Climate Impacts Group (www.cses.washington.edu/cig/). These indices are shown (Fig. 3) as either raw values (Logerwell index, PDO) or monthly standardized anomalies with monthly means removed and a 13 month running mean of average values (upwelling, transport).

The Oregon coastal coho marine survival index was developed by Logerwell et al. (2003) based on a conceptual model of the principal environmental processes thought to influence marine smolt-to-adult survival rates, as estimated by hatchery releases and adult returns in the coastal areas of the Pacific Northwest. The

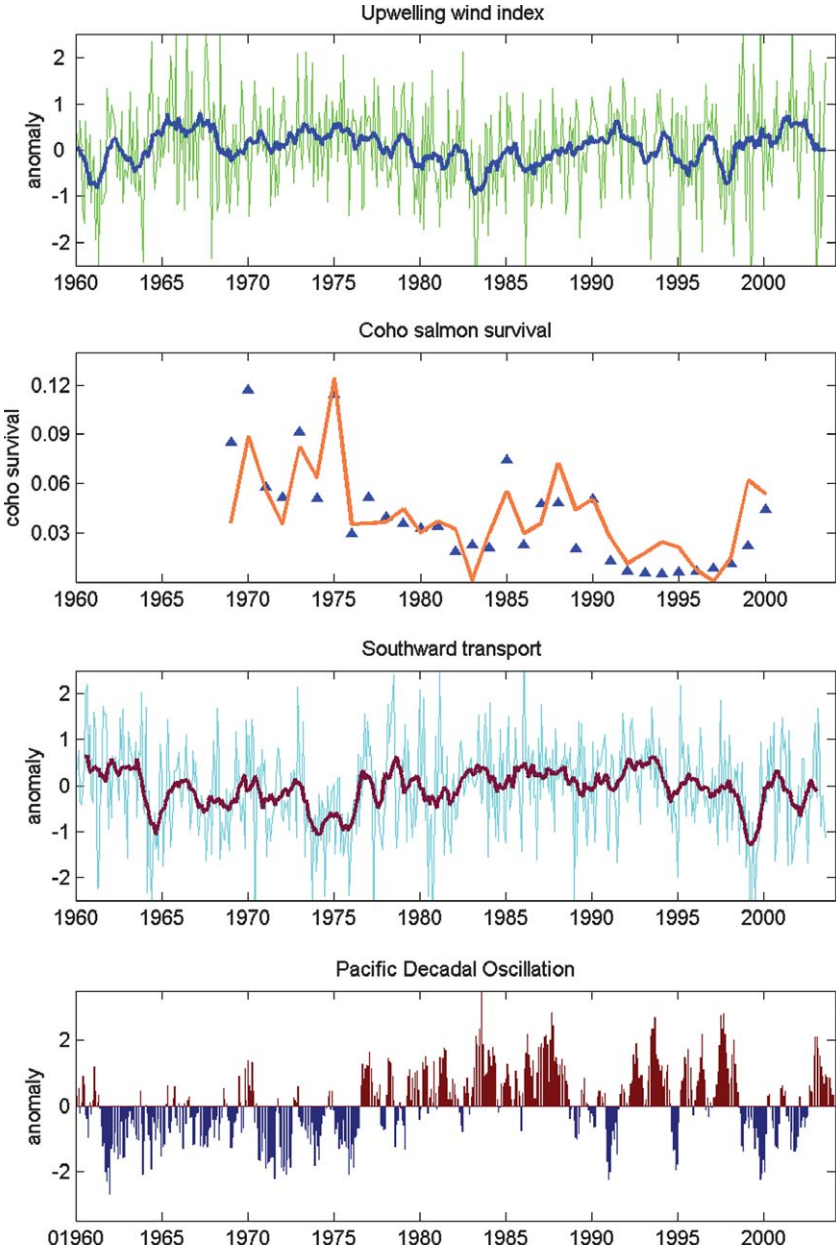

Fig. 3. Climate indices used to drive the dynamic model. From top to bottom, monthly anomalies of upwelling winds (from PFEG) with their 13-month running means, observed (points) and predicted (line) coho survival index from Logerwell et al. (2003), monthly anomalies of southward transport (from PFEG) with their 13-month running means, and the Pacific Decadal Oscillation (Mantua et al., 1997).

authors used a general additive model (GAM) to evaluate sequentially the non-linear relationships between ocean conditions and coho survival, including winter sea surface temperatures prior to migration (a "preconditioning" index), the date of the spring transition, relative sea level during the spring of smolt migration, and winter sea surface temperature the year after smolt migration. Their resulting model explains 75% of the variability in coho survival between 1969 and 2000, including both the monotonic declines in survival evident since the mid-1970s, and high interannual variability throughout the period of the study. The use of this index, hereafter referred to as the Logerwell index, is based on the assumption that the survival of coastal coho salmon is representative of system-wide variability in physical ocean conditions and lower trophic level productivity. In support of this argument is the observation by Peterson and Schwing (2003) of a strong relationship between coho survival and indices of the biomass of subarctic copepods off of the central Oregon coast.

All of the indices (with the exception of the Logerwell index, which is an annual index that begins in 1969) were converted to monthly standardized anomalies based on a climatology of 1950–1964, to set the baseline reasonably close to the mean of the starting period of the model runs. The climate indices were used here in two ways. The first, most straightforward way was as simple, "bottom-up" forcers of primary production over time. For the second way, indices were used as "top-down" forcing mechanisms that mediate the predatory impact (consumption), and consequently production pathways, of mid-trophic level consumers by altering the vulnerability of their prey to predation. The intent of this approach is to represent the effect of an increase in predator abundance (and thus predation) associated with changing spatial distributions of migrant species (hake, sardine and mackerel) during warm/low southward transport periods, as well as to reflect greater reproductive success of salmon, rockfish and other species during cool/high southward transport periods.[4] Although this is not strictly a "top-down" mechanism in the sense that it is driving changes in the very top of the food chain (marine mammals, seabirds, fisheries), it is driving massive changes in the dynamics of top piscivores and community behavior, by increasing the consumption (and consequently, the production) of select model components at the expense of others. A similar (although not identical) approach to forcing was used by Cury et al. (2000) as well as by Shannon et al. (2004) to simulate anchovy–sardine regime shifts in the southern Benguela (and other) ecosystems. In these instances, the vulnerability of the prey of small pelagic fishes (e.g., sardine and anchovy) was increased, while the vulnerability of these small pelagics to their respective predators was decreased, a mechanism they referred to as "middle-out" or wasp-waist forcing. As our mechanism varies from this in attempting to account for the ecosystem impacts of shifting distributions of higher trophic level predators, we will maintain the terminology of "top-down" climate forcing for the purposes of this paper.

This application of climate indices to drive the model is consistent with observations developed in the literature and observed in monitoring programs. For example, Dorn (1995), Ware and McFarlane (1995) and Swartzman and Hickey (2003) have all clearly demonstrated a positive relationship between sea surface temperature and the northerly extent of hake distribution, a characteristic shared by Pacific sardine and mackerel (Jacobson and MacCall, 1995; Emmett and Brodeur, 2000; McFarlane et al., 2002). Consequently, there is greater predation impact by hake and other coastal pelagics in such years, presumably to the detriment of other elements of the ecosystem. This impact can be represented by increasing the vulnerability of euphausiids, forage fish and other prey to predation by hake and other migrants during warm periods. By contrast, Mantua et al. (1997) showed that many west coast salmon populations are more productive during cooler conditions (negative phases of the PDO), and Hare and Mantua (2000) demonstrated that recruitment for many west coast groundfish stocks, particularly rockfish (*Sebastes*) species, responds similarly. Ralston (personal communication) has also demonstrated that rockfish reproductive success (as indexed by midwater trawl estimates of juvenile abundance) is extremely poor during periods of low transport in the California Current. Furthermore, Hare and Mantua (2000) as well as Hollowed et al. (2001) found that recruitment and productivity of many flatfish in the Gulf of Alaska seems to be greater during positive PDO conditions, and trends from assessments and surveys would suggest a similar relationship for NCC flatfish. Clark and Hare (2002) reported a strong relationship between Pacific halibut (*Hippoglossus stenolepus*) recruitment and the PDO throughout the range

---

[4] This is done by creating a dummy biomass pool in the model that is driven deterministically by the climate time series. This biomass pool in turn is used to "mediate" the vulnerability of prey to select predators, such that the value M_i in Eq. (3) in any given time step is equal to the value of the input climate time series (scaled between 0 and 2, such that a value of 1 would have no effect).

of halibut in the northeast Pacific. Although the Oregon and Washington halibut stocks are not independently assessed, the trends in survey, catch, and catch per unit effort data for halibut in the NCC are consistent with trends for the assessed stocks over the past 50 years.

The results from the dynamic simulations were averaged to annual values and compared with the data (annual values from stock assessment results, survey information and catches) for 24 of the model components most significant in commercial fisheries by using a negative log likelihood estimator. Negative log likelihoods for each simulation were generated by estimating the likelihood for each time series with a lognormal probability density function for each observation, and taking the negative log of that value. These values are summed across all years for each group, and across all groups to get a total negative log likelihood for the simulation. These results were further evaluated using Akaike Information Criteria (Akaike, 1992), in which the best fitting model is determined to be that which has the lowest AIC. The AIC is estimated as

$$A_i = -2\log L(\theta) + 2K \tag{4}$$

in which L is the likelihood function maximized over the vector of estimated parameters (θ) and K is the number of parameters. In this case, the number of additional parameters was assumed to be equivalent to the number of years of climate indices included in the model (relative to the baseline case of 0 for no climate). Although the climate indices themselves are not free parameters, but rather fixed values based on a priori assumptions of their significance to ecosystem dynamics, this approach to measuring the relative improvement in model fit among models of differing complexity is appropriate.

3. Results

Select simulation results are presented as Figs. 4–7. In these figures, the first panels show the 24 model components (all commercially important groups) that were used to estimate fits, all but three being assessment or survey abundance estimates. As abundance estimates do not exist for pandalid shrimp, Dungeness crab, or salmon, reported catches were compared to predicted catches for these groups. Total negative log likelihoods for the key model runs are also reported (Table 5). These include a run with no climate forcing, runs with a single bottom-up index, runs with a single top-down index, and runs with both bottom-up and top-down indices. The results demonstrate that adding some of the climate indices as a forcing factor improves the fit modestly to substantially, an obvious exception being the addition of upwelling as a bottom-up forcer. The resulting likelihoods and AIC criteria for four select runs are also provided (Table 6), and discussed in greater detail throughout the remainder of this section. Finally, we show that these results hold up consistently with similar relative likelihood settings (Table 7), regardless of whether the baseline vulnerability parameters are set at low (“bottom-up”) or high (“top-down”) values. Although we limit the remaining discussion to the simulations made with the default (“mixed”) vulnerability, confirmation that the results do not change significantly under alternative settings is critical in evaluating model behavior.

The first run (Fig. 4) is a baseline simulation with only fishing mortality and relative effort as forcing factors. In this scenario, fishing mortality is presumed to be the major driver of population change, consistent with the single species assessment results for these stocks. This is particularly true for longer-lived rockfish (*Sebastes* and *Sebastolobus* sp.), roundfish (sablefish, *Anoplopoma fimbria* and lingcod, *Ophiodun elongatus*) and Dover sole (*Microstomus pacificus*). Interestingly, there are also suggestions that the observed increases in flatfish such as English sole (*Parophrys vetulus*), rex sole (*Glyptocephalus zachirus*), and other small flatfish are associated with decreasing predation on these species by higher trophic level piscivores. The fit of Pacific hake is not as good as many of the other assessed species, which is not surprising given that hake are coastwide migrants in which recruitment is largely a function of processes that occur outside the NCC. While the fits to pandalid shrimp and Dungeness crab landings are not remarkably poor in light of the nature of the forcing function (units of effort), they do lack some of the highly variable patterns exhibited by these stocks in actual landings (and presumed abundance). Furthermore, the near tripling of salmon landings (which reflect an index of biomass, based on a constant mortality rate) seems unrealistic; this may reflect both the simplistic assumptions made with regard to harvest rate, as well as the inability of the model to account for other salmon population impacts (hydropower, hatcheries) and the complexity of salmon life history patterns.

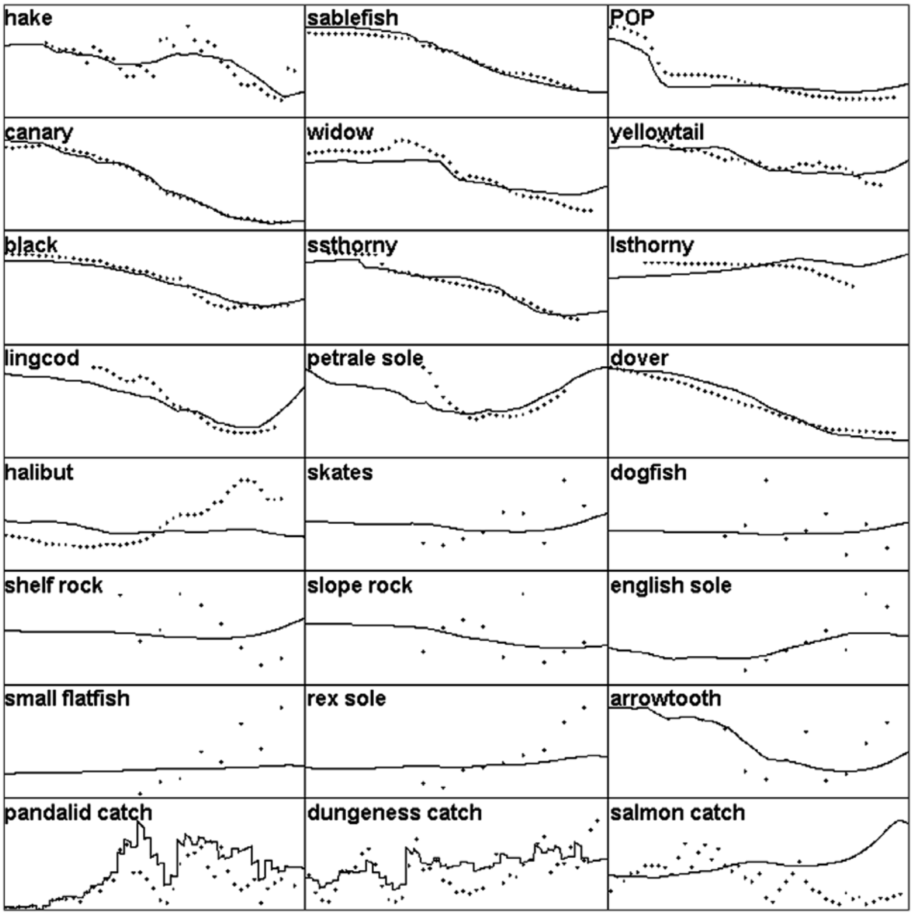

Fig. 4. Modeled population trajectories from 1960 to 2004 (solid lines) shown with stock assessment trends, survey indices, and landings (dotted lines) for commercially important species and functional groups, with no environmental forcing. Time (1960–2004) is along the *x* axis, relative or absolute biomass is along the *y* axis.

If we run the model with bottom-up forcing, the predicted time series run with the upwelling index has a poorer fit to the reference data (Table 5). Given that the wind-driven upwelling index excludes many factors relevant to productivity (such as ocean temperature, depth of the mixed layer, and nutrient concentrations), this result is not surprising. However, running the model with the Oregon coho survival index (Fig. 5) improves the fit substantially, and the AIC would suggest that this model is better supported by the data (Table 6). Much of the improvement in likelihood is observed in the more dynamic indices for shrimp, crab, salmon and lingcod. With top-down (but no bottom-up) forcing, southward transport improves the fit (Table 5), but the improvement is not sufficient relative to the AIC. Running the model with the PDO as a top-down forcing mechanism (Fig. 6) improves the likelihood substantially (to −389), and the resulting AIC suggests that this model is actually the most appropriate given the data. Running the model with the PDO as a bottom-up forcing mechanism (not shown) slightly decreases the fit relative to running the model with no climate forcing (to −320). Interestingly, when the model is run with both PDO and coho survival together as top-down and bottom-up respectively (Fig. 7), the overall negative log likelihood is improved (−374) relative to when the model is run with coho survival (bottom-up) alone, yet less than when the model is run with the PDO (top-down) alone. However the improvement is not adequate relative to the AIC, suggesting that the two-index model is a poorer fit than using either index independently.

With respect to other elements of the ecosystem, the top three rows of Fig. 8 show the behavior of a subset of 9 model components as “indicators” of how different trophic levels behaved throughout the simulation.

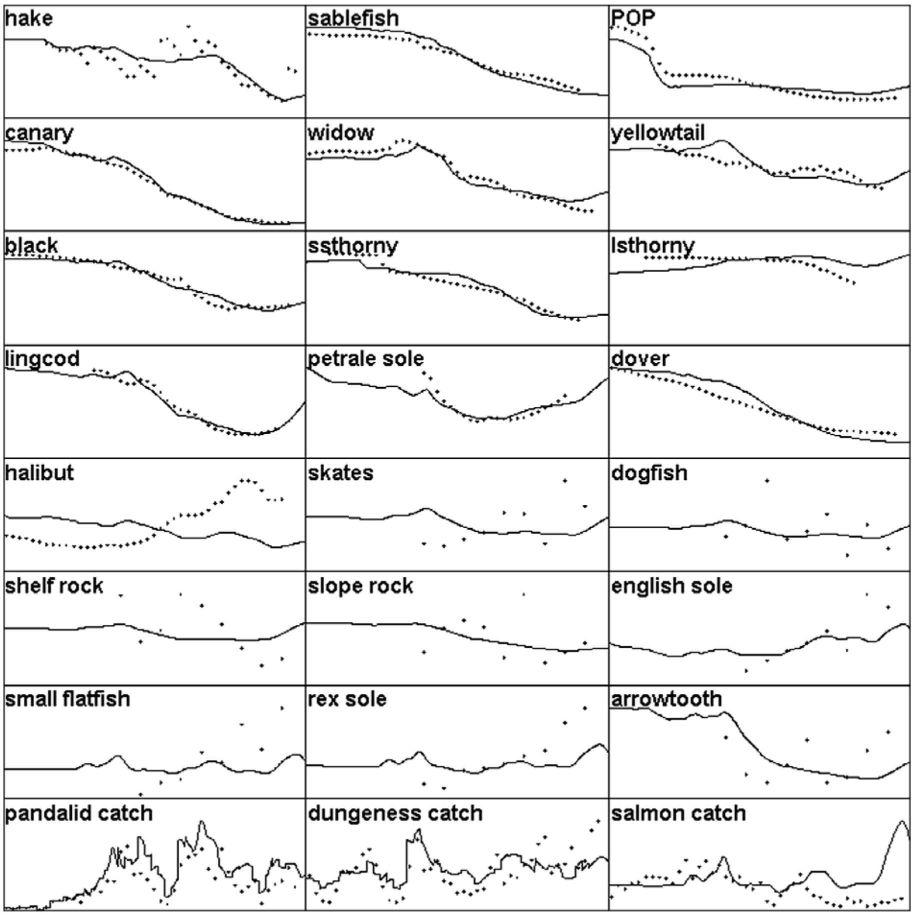

Fig. 5. Modeled population trajectories (as in Fig. 4) with "bottom-up" environmental forcing driven by the OPI coho survival predictive index. Time (1960–2004) is along the x axis, relative or absolute biomass is along the y axis.

This figure is shown for informative purposes only, to provide the reader with a sense of the scale of variability produced by the model for high turnover species (such as copepods, euphausiids and forage fish), as well as low turnover species (such as pinnipeds and baleen whales). Note that the high-turnover groups were not used in the fitting process, due to a lack of appropriate abundance data. Instead, select indices of relative abundance from a range of sources were shown for scale only. For example, model estimates of copepod biomass were shown with recent (1996–2003) relative biomass estimates by Peterson and Schwing (2003), and simulation estimates of euphausiid abundance were shown with the model estimates from the La Perouse Bank region over a similar time period by Robinson and Ware (1999). For forage fishes, abundance estimates (which are presumably uninformative) from the triennial groundfish trawl survey are shown for scale, for sardines the most recent coastwide stock assessment trend is shown for scale (Conser et al., 2002). For harbor seals (*Phoca vitulina richardsi*), counts reported in Carretta et al. (2002) are included for scale. For sea lions (including both *Zalophus californianus* and *Eumetopias jubatus*), pup counts from southern rookeries of California sea lions, where the population growth is considerably greater than that observed in the NCC, are shown for scale. Finally, point estimates of the number of California Current-wide humpback whales (*Megaptera novaeangliae*) from Carretta et al. (2002) are shown for scale for baleen whales. This illustrates the range of population behavior being produced by the model for both lower and higher trophic levels, as well as highlights that the model is able to allow known trends for top predators such as marine mammals to be incorporated into the model dynamics. Equally important is the point that the model is unable to replicate trends in coastal pelagic species such as sardine, where population changes of several orders of magnitude have

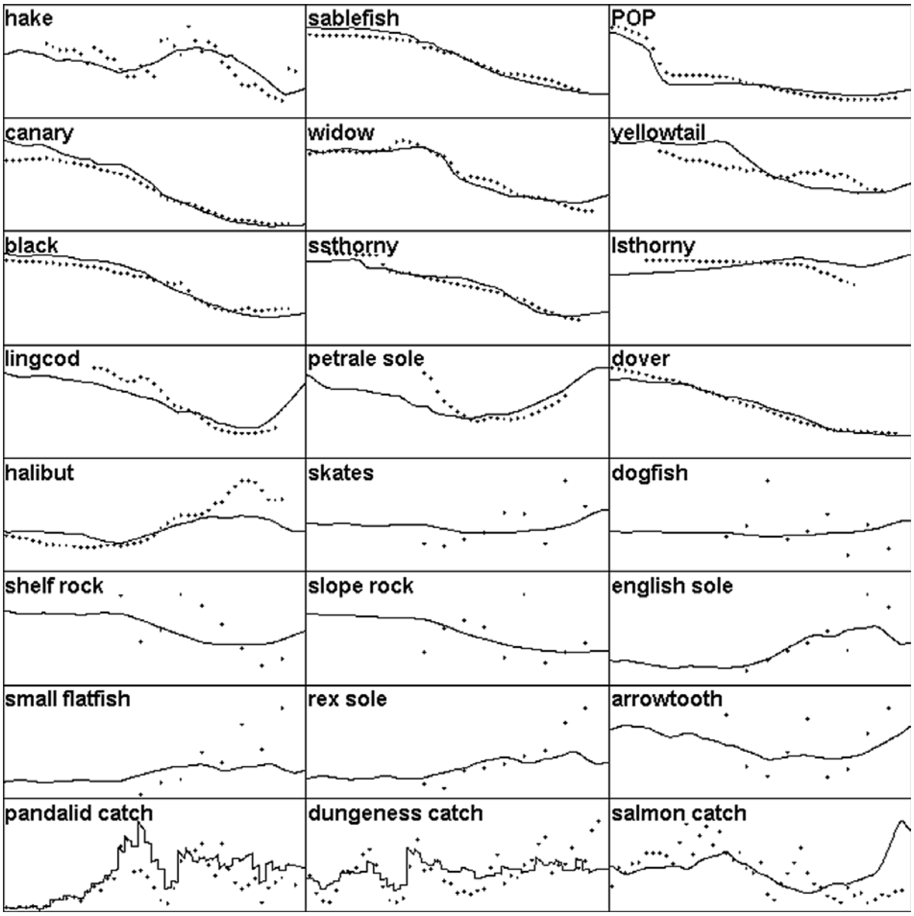

Fig. 6. Modeled population trajectories (as in Fig. 4) with "top-down" environmental forcing based on PDO mediation on the vulnerability of prey to key predators. Time (1960–2004) is along the *x* axis, relative or absolute biomass is along the *y* axis.

occurred over an extremely short time period. Note that neither the trends and "observations" shown at the top of Fig. 8, nor the observed and predicted catches from the bottom, were included in estimating likelihoods for evaluating improvement in model behavior. Instead, they are shown solely for informative purposes.

The bottom panels (Fig. 8) show observed and predicted catches for the 21 model components for which biomass estimates were used to estimate the model fit. Note that the "observed" catches here represent only reported landings for unassessed species (they include assessment estimates of discard mortality plus catches where available). Consequently, the often significant discrepancies between the observed and predicted landings in the unassessed groups (shelf and slope rockfish, small flatfish, rex sole, arrowtooth flounder, skates and dogfish) are partially explained by the catches of those species being forced by bycatch ratios relative to total landings by gear type. These bycatch ratios were estimated based on observed bycatch rates (relative to total catch) from the Pikitch et al. (1988) study, which were incorporated into the catch composition of the fishing fleets at the beginning of the simulation. For most species, it is clear that predicted catches are very similar to observed catches, which is not surprising given that simulations are run with fishing mortality rates based on the assessments themselves. For several, such as small flatfish, rex sole, skates and dogfish, "catches" are substantially higher than landings, reflecting the low retention and high discard rates observed for many of these groups. Interestingly, catches and reported landings for some of these groups, dogfish and skates in particular, do seem to converge in later years. This is a period in which limited fishing opportunities and developing markets for these species appear to have led to increased retention, and consequently an increase in reported landings.

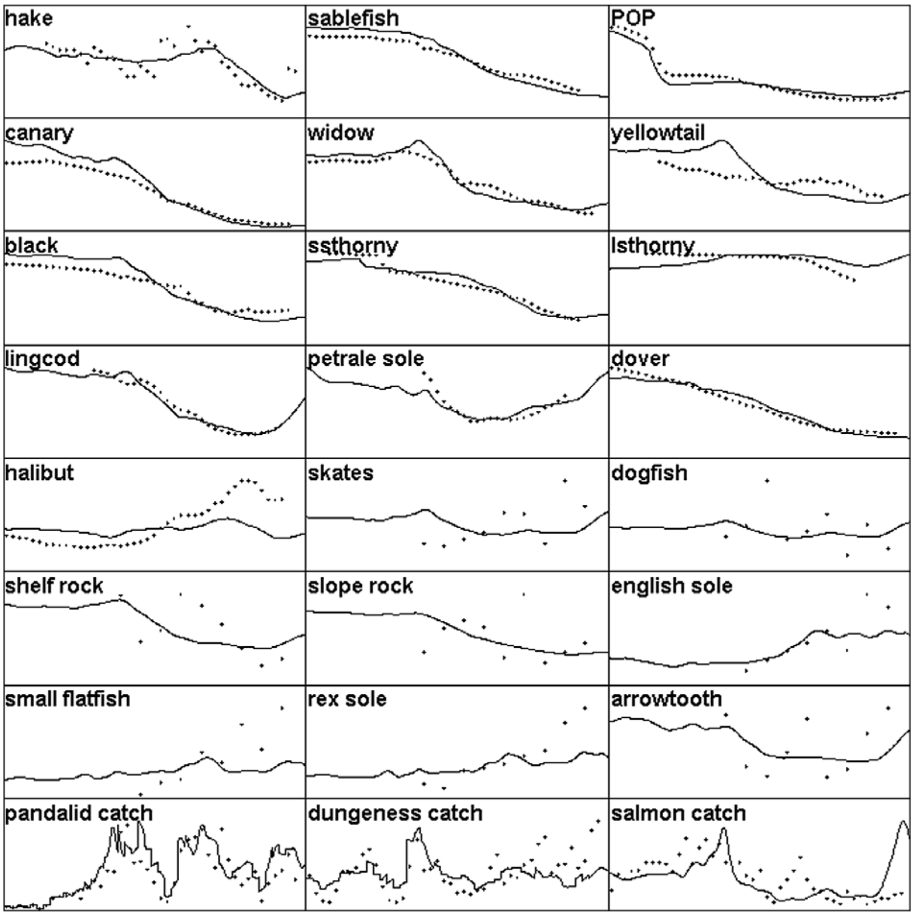

Fig. 7. Modeled population trajectories (as in Fig. 4) with a combination of "bottom-up" forcing from the OPI coho survival index and "top-down" forcing with PDO mediation on the vulnerability of prey to key predators. Time (1960–2004) is along the *x* axis, relative or absolute biomass is along the *y* axis.

Table 5
Total negative log likelihood estimates of simulations under alternative climate forcing scenarios

Bottom-up climate	Top-down climate		
	None	PDO	Transport
None	−329	−389	−337
Upwelling	−192	−210	−197
Coho index	−369	−374	−365

Table 6
Total negative log likelihoods, and the AIC for each of four key models when each year with a climate index is treated as a free parameter

	No climate	Logerwell index	PDO	Logerwell and PDO
Total negative log likelihood	−329	−369	−389	−374
Number of new parameters		33	45	78
Akaike Information Criteria	−658	−671	−688	−592

The final result relates to model estimates of the potential top-down consequences of changes in the abundance of marine mammals in the NCC. Over the last four decades, many populations of California Current pinnipeds, cetaceans, and even some seabirds have increased substantially, following nearly two centuries of

Table 7
Total negative log likelihoods for the four most significant runs under alternative vulnerability assumptions

		No climate	Logerwell index	PDO	Logerwell and PDO
$v = 0.1$	(bottom-up)	−166	−285	−301	−307
$v = 0.3$	(mixed)	−329	−369	−389	−374
$v = 0.5$	(top-down)	−313	−339	−397	−354

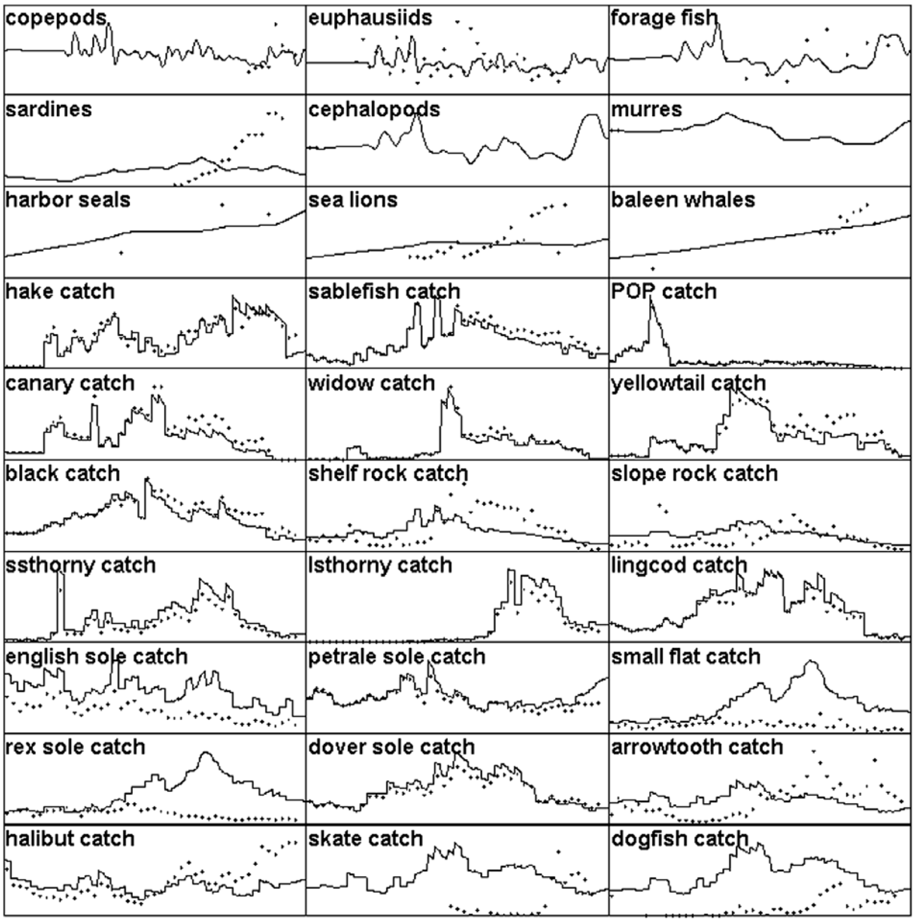

Fig. 8. Modeled population trajectories of lower and higher trophic level components (top nine panels) and catches of key species (bottom 21 panels) with a combination of "bottom-up" forcing from the OPI coho survival index and "top-down" forcing with PDO mediation on the vulnerability of prey to key predators. Time (1960–2004) is along the x axis, relative or absolute biomass is along the y axis.

often intensive hunting and culling (Scheffer and Slipp, 1944, 1948; Ainley and Lewis, 1974; Cass, 1985; Clapham et al., 1997). Food habits, based principally on studies from the 1960s, show that rockfish and other commercially important groundfish make up a modest, but significant, proportion of most pinniped diets (Fiscus and Baines, 1966; Perez and Bigg, 1986; NMFS, 1997). Although the relative impact of marine mammal predation on forage fish, cephalopods, and other lower trophic level groups seems to be fairly low in contrast to that of other predators, pinnipeds represent a greater fraction of mortality on commercially important stocks of roundfish, rockfish, flatfish, hake and sardine. For example, Fig. 9 shows the total (modeled) biomass of all stocks of *Sebastes* rockfish in the NCC over the last 42 years, along with model estimates of the total sources of mortality for these stocks. As fishing mortality increased dramatically in the 1980s, the model suggests declines in piscivore (principally sablefish, lingcod, and halibut) predation and increases in marine mammal

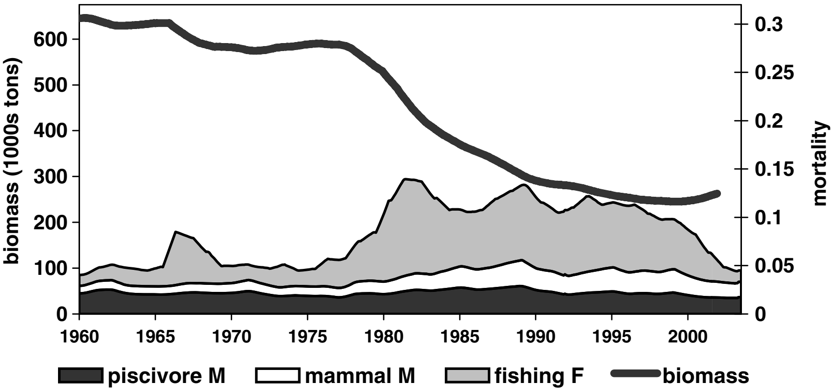

Fig. 9. Model estimated changes in natural mortality (predation) rates from marine mammals and piscivorous fish, relative to fishing mortality for all *Sebastes* spp.

(principally pinniped) predation. Yet rockfish stocks were declining over this period, and pinniped populations increasing, which implies that there was a significant decline in the relative consumption of rockfish (the fraction of rockfish in pinniped diets) over this period. With declines in many of these species, particularly rockfish, the model would suggest a shift in diet composition away from groundfish in favor of forage fish, flatfish, and cephalopods, as the total natural mortality to rockfish from pinnipeds would have increased if the diet composition had remained constant. This too is consistent with studies of California Sea Lions that suggest food habits tend to be temporally dynamic and related to the relative availability of prey (Lowry et al., 1991; Lowry and Carretta, 1999). Although the high sensitivity of marine mammal consumption estimates to Ecosim model parameters makes any such estimates highly questionable (Mackinson et al., 2003), in general the model suggests that the direct top-down impacts of marine mammal population growth on rockfish (and perhaps other commercially species) are likely to be negligible, at least in more northern waters where pinniped population growth is relatively moderate.

Finally, we consider a visual image of the results of the dynamic model. Fig. 10 shows the significant food web of the NCC (as in Fig. 2), with changes in biomass in 2002 relative to starting (1960) conditions represented by color. Red boxes indicate model elements that have declined relative to their starting values, green boxes indicate elements that have increased (flows between boxes are modeled the same way). The end year, 2002, was chosen to represent a year of high (above average) productivity, such that the forage groups at the base of the food web are relatively abundant. A number of commercially important species are green as well, including salmon, shrimp, sardine and many flatfish; observations consistent with recent record runs of salmon, catches of shrimp and crab, and production of forage fish. As discussed above, many marine mammals (harbor seals, sea lions, and baleen whales) have increased in abundance over this period as well. However much of the upper-middle level of the food web, in particular many groundfish, are slightly to very red, representing the observation that a very significant fraction of this low-turnover biomass has been removed by fishing. Clearly, many stocks in this ecosystem no longer fill the functional role that they used to, and although the potential consequences to ecosystem function and stability are difficult to estimate, their potential role in stabilizing ecosystem variability by virtue of their former high abundance and longevity has arguably been undermined (Apollonio, 1994).

4. Discussion

It is perhaps counterintuitive, that the "top-down" climate forcing scenario improves the model fit slightly more than the "bottom-up" scenarios. For the PDO in particular, it is difficult to imagine that the impacts are restricted to top-down influences on the distribution and abundance of predators, when there are clearly processes that are more "bottom-up" in nature associated with the PDO mode of variability. For example, Peterson and Schwing (2003) show that changes in both zooplankton community composition and biomass appear to be linked to changes in the PDO, indicating that the PDO has a major influence on secondary

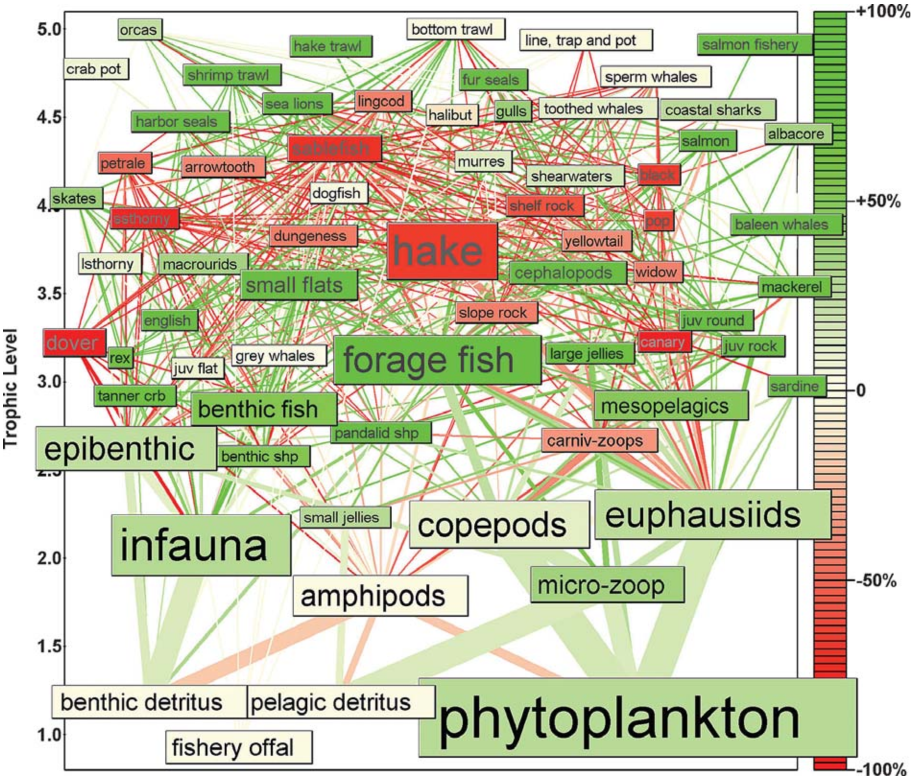

Fig. 10. The significant food web of the NCC (as in Fig. 2), with estimated changes in relative biomass, biomass flows and catches between 2002 (assuming above average primary and secondary production) coded in color as a percentage change from baseline starting values (1960).

production throughout the California Current. Zooplankton is the major food source for many groundfish and for most forage fish, and forage fish in turn comprise at least 10% of the diet for 24 of the components in the model, and over 50% for five of the components. Yet the poor response of the model to direct forcing by the PDO suggests that this influence is complex and non-linear, and the effects may be better quantified by accounting for a variety of physical factors simultaneously, as was done in the coho survival index. Consequently, a scenario that includes both bottom-up and top-down forcing is more consistent with what is known about the system. This is particularly true given the magnitude of bottom-up variability suggested by not only coho survival, but by observations on the interactions between local and basin-scale forcing, and the observed year-to-year variability in secondary production throughout the California Current (Chelton et al., 1982; McGowan et al., 1998; Robinson and Ware, 1999). Another problem is the lack of appropriate time series. If adequate data on the relative abundance and productivity of lower trophic model elements (zooplankton, forage fish, cephalopods) existed with which to compare model behavior, it might be expected that bottom-up forcing could result in significantly better model performance by fitting higher frequency variability. Similarly, because of a lack of age structure in this model, an autocorrelated climate forcer such as the PDO may better represent long term changes in abundance resulting from high frequency variability in recruitment for long-lived species. For those the impacts of climate on abundance and productivity are cumulative over longer time scales. Although the model and the model results discussed here are based on incomplete data, and are highly dependent on simplifying assumptions regarding ecosystem structure and physical dynamics, the results are consistent with what is known about the interactions between the biota in this ecosystem and their environment.

That much of the variability observed in single species models and dynamics can be replicated in this multi-species modeling approach is both encouraging and informative for two key reasons. The first is that model performance can be improved significantly when climate is introduced as a driving force, which is consistent with the observation that climate forcing has been shown to be a critical factor in determining the productivity and dynamics of many individual species in this ecosystem. Secondly, such convergence implies that there are few strong interspecific interactions (predation, competition) between most of these species that might have led to trajectories diverging from those suggested by single species assessments. This is somewhat intuitive for many of the rockfish, roundfish and longer-lived flatfish, where low natural mortality rates are indicative of low predation rates and relatively weak trophic interactions. Stronger interactions were observed in species such as shrimp, salmon, and small flatfish, where high turnover and high predation are coupled with substantial changes in many of their key predators (hake, sablefish, marine mammals) over the last 40 years. For example, the model fit to observed landings of pandalid shrimp improved significantly with both bottom up forcing (consistent with Hannah, 1993) and top-down forcing, consistent with literature describing strong interactions between shrimp and Pacific hake (Gotshall, 1969; Rexstad and Pikitch, 1986; Hannah, 1995). In the case of shrimp in particular, the relative improvement in fit was actually greatest when both the bottom-up (Logerwell) and the top-down (PDO) indices were used to drive the model. This suggests (perhaps not surprisingly) that both bottom-up and top-down factors are of great importance to shrimp abundance and productivity. In a similar modeling exercise focused on Pacific hake, Agostini (2005) used the model described here to assess the direct impact of increasing or decreasing hake biomass on other elements of the ecosystem. Her results suggest that most elements of the model (particularly pandalid shrimp, rockfish, salmon, seabirds and marine mammals) benefited from a reduction in hake biomass as a result of increases in the availability of forage fish and other prey.

Some of the stronger interactions suggested by the model were among several of the slower growing species: sablefish (*Anoplopoma fimbria*), shortspine thornyhead (*Sebastolobus alascanus*), and longspine thornyhead (*S. altivelis*). Several authors have noted that thornyheads are an important prey item of sablefish (Laidig et al., 1997; Buckley et al., 1999), and both sablefish and shortspine thornyheads appear to represent the most significant (known) sources of predation for longspine thornyheads. The baseline model suggests that natural mortality (predation) rates for longspine thornyheads have fallen by nearly fourfold over the past forty years, coincident with the declines in predator abundance (Field, 2004). Since this has been associated with an increase in catches of longspines from the late 1980s to the late 1990s, the increased fishing mortality may have been largely offset by declines in predation mortality. Moreover, total mortality has declined to very low levels in recent years associated with reductions in fishing effort. While the 1996 stock assessment, assuming a constant natural mortality rate, predicted declines in longspine abundance beginning in the early 1990s, the reductions of their major predators suggest that the biomass should have been largely stable, or increasing (as suggested by Figs. 4–7). The lack of any discernable trend in the slope survey data, except for a possible increase in abundance in recent years, lends support to this potential interaction.[5] At a minimum, this is a consideration that could be taken into account, qualitatively if not quantitatively, both in stock assessments and in future consideration of the impacts of fishing on community structure.

It must be acknowledged that the aggregation of many species and assemblages, and lack of size, age, and ontogenetic life history structure in the model may mask additional potentially significant interactions. For example, Yoklavich et al. (2000) show dramatic changes in the community composition of heavily fished rocky reef habitats, where piscivorous species such as lingcod, bocaccio, yelloweye, and cowcod (*Ophiodon elongates*, *Sebastes paucispinis*, *S. ruberrimus*, and *S. levis*, respectively) have been substantially depleted (all of these species are currently listed as overfished by the Pacific Fisheries Management Council). In these reefs, the abundance of smaller, faster growing, and less commercially important species such as greenstripe, rosethorn, splitnose, and pygmy rockfish (*S. elongates*, *S. helvomaculatus*, *S. saxicola*, and *S. wilsoni*, respectively) was considerably greater. By contrast, isolated and presumably lightly fished reefs with higher concentrations of piscivorous species were associated with much lower concentrations of such smaller, planktivorous species. Similarly, Walters and Kitchell (2001) demonstrated the potential for strong interactions among the adults of higher trophic level piscivores and their prey, such that adults crop down forage species that may be potential predators or competitors of their own juveniles, with non-linear negative impacts on piscivore stocks when

---

[5] Based on the data collected on Alaska Fisheries Science Center West Coast Slope Surveys in Lauth (1999, 2000a,b), as well as unpublished data from the Northwest Fisheries Science Center, Fisheries Resource Analysis and Monitoring Division slope surveys conducted between 1998 and 2004 (Helser et al., NWFSC, unpublished manuscript).

adult abundance is reduced by fishing. Despite the recognized importance of trophic ontogeny in these and other species in the NCC, the lack of adequate abundance and age or size-specific diet data for most species makes modeling such potential interactions extremely challenging.

Future modeling efforts will benefit greatly both from assessing ecosystem behavior under a range of modeling approaches, as well as from integrating traditionally distinct modeling approaches to couple more realistic physical forcing mechanisms with multispecies and ecosystem interactions across multiple trophic levels. For example Fulton et al. (2004) found that combining hydrographic and biological submodels that incorporated functional groups and processes into reasonably complex food webs resulted in the ability to replicate the behavior of a large, temperate bay ecosystem in South Australia. In another example, Aydin et al. (2005) linked a food web model based on Ecopath with Ecosim with nutrient–phytoplankton–zooplankton (NPZ) model to drive seasonal variability in production and a bioenergetics model for pink salmon (*Oncorhynchus gorbuscha*), illustrating the significance of seasonal and ontogenetic prey switching for this key species in the Alaskan subarctic gyre ecosystem. As baseline knowledge and modeling abilities increase, the integration of multiple modeling approaches is likely to hold considerably more promise for successfully identifying the processes and mechanisms of ecosystem change in the future than any individual modeling approach alone. In achieving such objectives, the results of this paper should be considered a stepping-stone, rather than an end product.

Perhaps the most vexing characteristic of the Ecosim model is that model behavior is constrained by equilibrium processes, such that a perturbed model will always return to equilibrium, following the removal of perturbations such as changes in fishing mortality or bottom up forcing (given sufficient time). Although this is not entirely true when modeling under very high vulnerability scenarios, which can lead to erratic and at times chaotic behavior (users are cautioned against setting vulnerability values too high), even then the usual result is a return to starting conditions after long time periods. Walters et al. (2000) identified this as a weak, albeit necessary, characteristic of the model, particularly as this equilibrium generally precludes the possibility of prey switching by predators. Hollowed et al. (2000) noted that these constraints reduce the utility of such models in evaluating the consequences of species outbreaks, as well as the introduction of exotic species. Similarly, Rice (2001) attacks this stability by arguing that an alternative form of interaction, which he describes as scramble competition, occurs when resource availability changes abruptly for reasons other than usage by consumers, and when all individuals simultaneously experience either a sudden shortage or a sudden abundance of food or other resources. Such variability is often an integral feature of coastal upwelling ecosystems, for example, which are characterized by variability in physical conditions and productivity over multiple time scales. By driving population dynamics with climate information both from the bottom-up and the top-down, we begin to move slowly away from such equilibrium assumptions. However, the model by design has retained its equilibrium qualities, such that all species will eventually return to their starting values if perturbations (changes in bottom-up productivity, fishing) are removed; a quality that could be unrealistic in the face of possible "flips" of ecological states.

The need to move beyond traditional equilibrium-based approaches in both modeling and management has been well recognized for decades, yet because such movement pushes us into unfamiliar territory, there remains substantial reluctance to proceed (Gunderson et al., 1995; Levin, 1998; Rice, 2001). For example, Holling and Meffe (1996) argue that the key to maintaining resilience in natural resource management is to facilitate existing processes and variability, rather than attempt to alter and control them, and McEvoy (1996) advises that "the best that fisheries managers can do is to monitor and adjust the interaction between a volatile ecology, a creative economy, and society's understanding and control as they go along." From a socio-ecological perspective, Berkes et al. (2002) argue that resilience is a function of the livelihood security of stakeholders (be they individuals or groups), as defined by entitlements and access to resources. For example, Hanna (1992) found that the diversification of fishing strategies between groundfish, shrimp, and crab, benefited fishermen in the NCC by virtue of reducing the variability of landings and earnings during changes in resource abundance, suggesting that socio-ecological resilience is in part dependent upon access to a range of resources.

Pikitch et al. (2004) have reiterated the often-made point that there remains a need to derive and develop community and system-wide standards, reference points, and control rules analogous to single species criteria, particularly evaluations of ecosystem productivity relative to the requirements of other ecosystem components and removals by fisheries. Quantitative ecosystem models offer a valuable vehicle for doing so (Pauly et al., 1998; Jarre-Teichmann and Pauly, 1998; Fulton et al., 2005). Furthermore, where trophic interactions between exploited species seem clear, dynamic modeling can offer valuable information regarding the likely or potential trade-offs between harvest strategies, and provide a template to evaluate both the magnitude and some measure of reasonable consequences of removals of either predators or prey in the system of interest (Christensen and Walters, 2004b; Walters et al., 2005).

Although quantitative modeling of significant trophic interactions in the NCC may not lead to substantive changes in harvest or management strategies in the near term, it may enhance understanding of variations in population trends, and will contribute to a more holistic understanding of ecological connections and interactions. By far the most important feature of these models is that, if based on reasonable knowledge and presented with appropriate skepticism, they serve as a stimulus and focus for initiating dialogues and discussions with regard to both past ecosystem dynamics and plausible ecosystem futures. Ecosystem models can complement the insights gained from single species models through a more holistic evaluation of past and current abundance and productivity, and offer a means to evaluate plausible expectations of future system trade-offs among management decisions. Admittedly, however, the challenges of distilling the insights gained from these simulations into concrete management advice remain substantial.

Acknowledgements

Early drafts of this manuscript were greatly improved by comments received from Vera Agostini, E.J. Dick, Xi He, George Hunt, Alec MacCall, Dave Preikshot, Thomas Wainwright and one anonymous reviewer. Special thanks also go to Troy Buckley, Lorenzo Ciannelli, Dave Fluharty, Sarah Gaichas, Don Gunderson, Jodie Little, Ivonne Ortiz, Are Strom, and Anna Zagorska for their help, support, and critical reviews of this effort over time. Financial support was provided by Washington Sea Grant and the NCEAS Working group on Fisheries and Climate, support for the first author was also provided by the NMFS Southwest Fisheries Science Center. Many individuals provided us with critically important data, insights, and comments over the years, including Dave Colpo, William Daspit, Nancy Friday, Robert Hannah, Thomas Laidig, Bob Lauth, Yong Woo Lee, Pat Livingston, Elisabeth Logerwell, Nick Lowry, Julia Parrish, Bill Peterson, Steve Ralston, Rolf Ream, Bruce Robson, Cynthia Suchman, John Wallace, and Mark Wilkins. The views expressed herein are those of the authors, and do not necessarily reflect those of NOAA nor those who provided data and insights relevant to these efforts. This paper is NMFS Santa Cruz Lab contribution #280.

Why is the Northern End of the California Current System So Productive?

BY BARBARA M. HICKEY
AND NEIL S. BANAS

ABSTRACT. Although scientists have long believed that, in an eastern boundary current system, alongcoast wind stress is responsible for the upwelling of deep nutrients that initiates phytoplankton blooms, the California Current System (CCS) presents a challenge to this idea. Seasonally averaged chlorophyll concentrations are several times higher along the Washington/southern British Columbia coast than off northern California, where alongcoast wind stress is several times greater. The high chlorophyll concentration is reflected in higher trophic levels, such as zooplankton and fish density in the northern CCS. This article discusses potential reasons for this apparent paradox. The analysis suggests that the northern CCS has several mechanisms that can produce upwelled nutrient concentrations comparable to those in regions with much greater wind stress, including a persistent nutrient supply through the dynamics of the Strait of Juan de Fuca and local upwelling enhancement by submarine canyons. Large-scale upwelling resulting from coastal-trapped waves forced in the areas with stronger wind stress is also likely an important factor, as is iron input by the Columbia River. In addition, in contrast to other parts of the CCS, the high-productivity northern latitudes have numerous physical features that give phytoplankton blooms time to develop fully and to be retained on the shelf, including wide shelves, coastlines without large capes, a large bank, wind intermittency, and density fronts related to the Columbia River.

DOES PRODUCTIVITY DIFFER ACROSS REGIONS IN THE CALIFORNIA CURRENT SYSTEM?

Overall biological productivity in the California Current System (CCS), a system of currents that flow along the western boundary of the United States and southern Canadian Pacific coast (Figure 1), is generally attributed to seasonal upwelling of nutrient-rich deep waters to the continental shelf, as in other eastern boundary systems (Hill et al., 1998). This upwelling is caused primarily by the stress of winds blowing equatorward on the ocean's surface next to the coastal boundary. When the deeper water with higher nutrient concentration upwells, phytoplankton in the upwelling layers are exposed to light and begin to grow, resulting in a "bloom" (a high concentration of phytoplankton) (MacIsaac et al., 1985). It might be expected that overall productivity along any eastern boundary coast would be correlated with the strength of the alongcoast wind stress at a given location. In the CCS, this relationship does not hold: seasonally averaged coastal chlorophyll concentrations increase fivefold from northern California to southern Vancouver Island, counter to the magnitude of the alongshelf wind stress, which decreases by a factor of eight over this region (Figure 2; see also Hickey and Banas, 2003; Ware and Thomson, 2005). High chlorophyll concentrations in the northern CCS are reflected in higher trophic levels, such as zooplankton biomass and fish stocks ("bottom-up control"), in the Washington/British Columbia region (Ware and Thomson, 2005; Figure 3).

One important oceanic difference among regions in the CCS is the degree of influence of freshwater (i.e., water input by rivers and estuaries and energetic tidal currents associated with these features; Figure 1). These freshwater sources affect stratification, light, circulation, nutrient supply, and phytoplankton retention in coastal waters. Juvenile salmon are generally more highly concentrated in regions affected by river plumes (Figure 4). The distribution of the annual return of bird colonies to sites along the Washington coast suggests that birds may find areas most influenced by freshwater most attractive. Near the Juan de Fuca Strait, as well as farther south near the plume from the Columbia River, colonies returned in most years studied (80–100% colony return; Figure 5). This paper explores the potential causes of the large-scale alongcoast chlorophyll gradient in the CCS in light of two recent observational programs that studied the regions most influenced by freshwater: River Influences on Shelf Ecosystems (RISE, a Coastal Ocean Processes [CoOP] project) focused on the Columbia River; and Ecology and Oceanography of Harmful Algal Blooms Pacific Northwest (ECOHAB PNW) focused on the Strait of Juan de Fuca effluent.

Barbara M. Hickey *(bhickey@u.washington.edu) is Professor, School of Oceanography, University of Washington, Seattle, WA, USA.* **Neil S. Banas** *is Oceanographer, Applied Physics Laboratory, University of Washington, Seattle, WA, USA.*

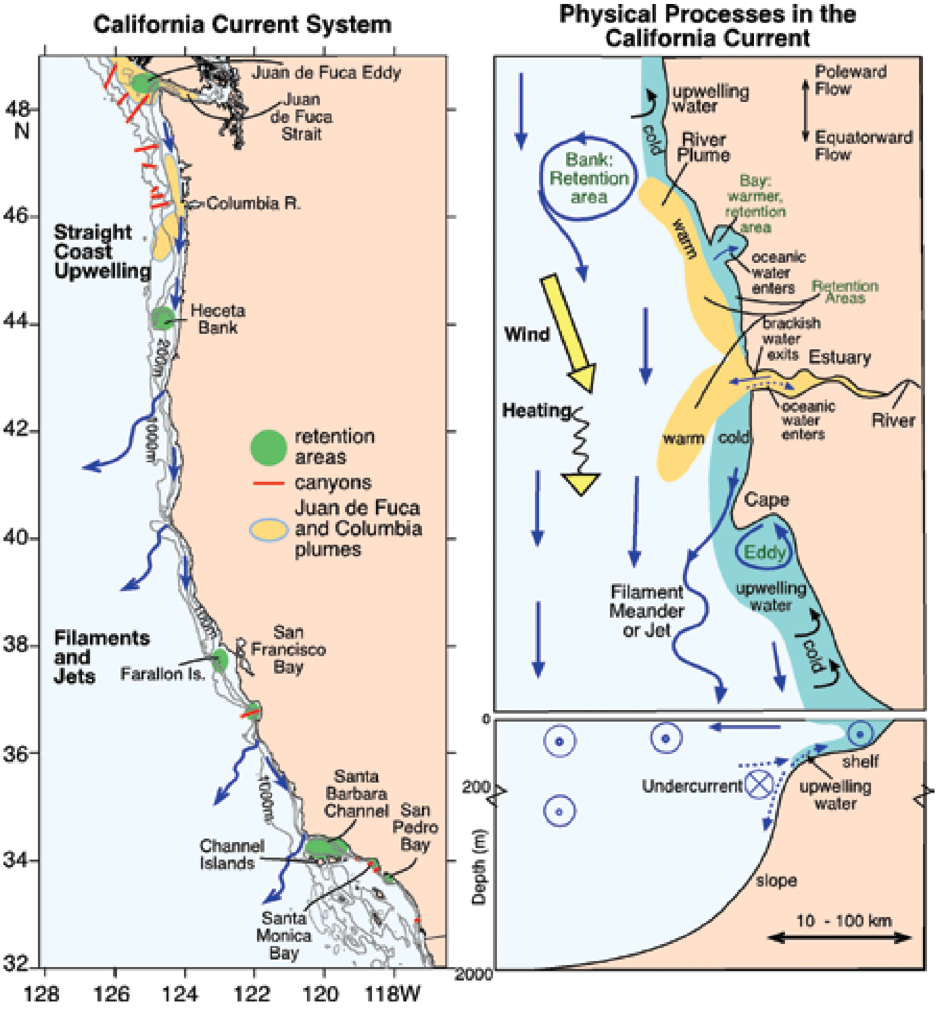

Figure 1. Primary physical processes in the California Current System (CCS) in summer. (Left) A map of the CCS with bottom topography and typical surface currents (blue arrows), showing the location of submarine canyons (red), regions with longer than average residence times (green, "retention areas"), and primary sources of freshwater (yellow, the Strait of Juan de Fuca and the Columbia River). The Columbia River plume is depicted in the bi-directional pattern frequently seen in the summer season. Regions where upwelling is primarily two dimensional ("straight coast upwelling") are differentiated from those farther south that are more three dimensional ("filaments and jets"). (Right) A cartoon showing typical circulation patterns for an arbitrary subregion of the CCS in plan view (upper) and cross section (lower). In the cross section, circles with dots indicate equatorward flow; circles with crosses indicate poleward flow. Retention areas over banks, behind capes, and within bays and estuaries are noted in green text. Upwelling water next to the coast is shown as darker blue. Note that river plumes are generally warmer than coastal waters in summer.

THE CCS AND LOCAL WIND-DRIVEN UPWELLING

The California Current is a ~ 1000-km-wide, sluggish current that forms the eastern limb of the North Pacific gyre, spanning the Pacific coast from ~ 20°N to ~ 50°N (Hickey, 1979, 1998). Superimposed on that mean flow, narrower equatorward jets induced by the equatorward alongshelf wind stress develop seasonally on the shelf, spreading seaward over the shelf and slope as the season progresses (Strub and James, 2000). Isopycnals begin to tilt upward toward the coast following the "spring transition" (Huyer et al., 1979; Huyer, 1983; Strub and James, 1988), resulting in the upward movement of deeper, nutrient-rich water, and this upward movement continues throughout the season (Hickey et al., 2006) (Figure 1). Thus, nutrients, which have higher concentrations deeper in the water column, are lifted to upper layers of the continental shelf where they can be used by phytoplankton. Recent measurements show that in addition to vertical movement of nutrients due to upwelling, vertical mixing can enhance nitrate flux into the euphotic zone by as much as 25% (Hales et al., 2005). A poleward undercurrent (the "California Undercurrent") develops over the continental slope as upwelling continues (Figure 1, lower right panel). The development of the undercurrent is important in that once it is present, flow in the bottom boundary layer (~10 m from the bottom) changes from onshore (in which it can provide nutrient-rich water to the shelf) to offshore (in which it can remove nutrient-depleted water from the shelf).

These seasonal patterns are interrupted or their amplitudes modified at intervals of 2–20 d when the wind along the shelf reverses direction (Hickey, 1998; Barth et al., 2007). The frequency of interruption changes significantly along the coast, from almost no interruptions (i.e., steady equatorward winds) off California to frequent interruptions off Washington (Figure 6d, showing the percentage of days with equatorward winds as a function of latitude). The seasonal coastal jet over the middle and outer shelf and upper slope rarely

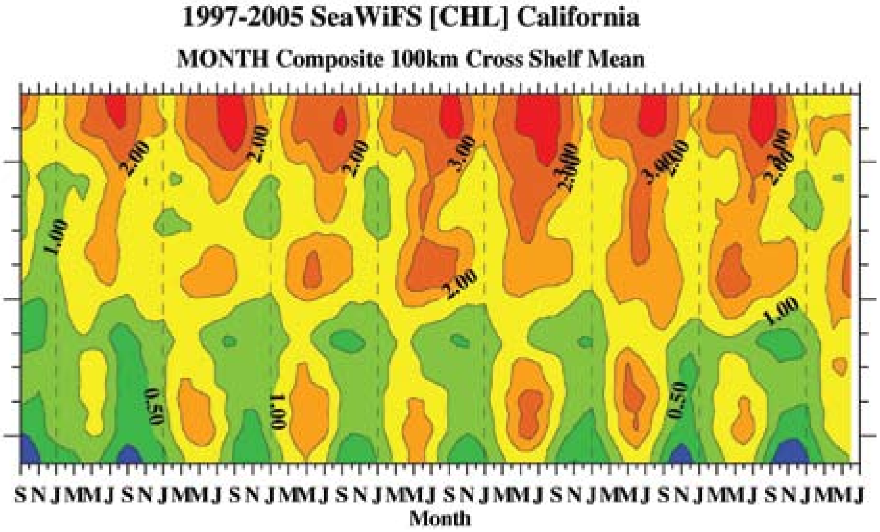

Figure 2. Seasonal and interannual variation of coastal chlorophyll concentration versus latitude in the CCS. Data were derived from several years of SeaWiFS satellite data and averaged from the coastline seaward to 100 km. This averaging distance captures the majority of seasonal chlorophyll variability (Henson and Thomas, 2007). The figure depicts the strong latitudinal gradients that are the focus of this paper: higher chlorophyll concentrations are observed in the northern CCS. Contours are 0.25 (dark blue), 0.5, 1.0, 2.0, 3.0, and 5.0 (red) mg chl m^{-3}. Maximum chlorophyll is located well north of the Columbia River entrance, and the Strait of Juan de Fuca has a low particulate load, so that coastal particulates are not expected to have significantly biased these patterns. The patterns as well as magnitudes in the northern CCS (3–6 mg m^{-3}) are consistent with extensive historical in situ chlorophyll measurements (Landry et al., 1989). *Figure courtesy of Andrew Thomas, University of Maine; see also Legaard and Thomas, 2006*

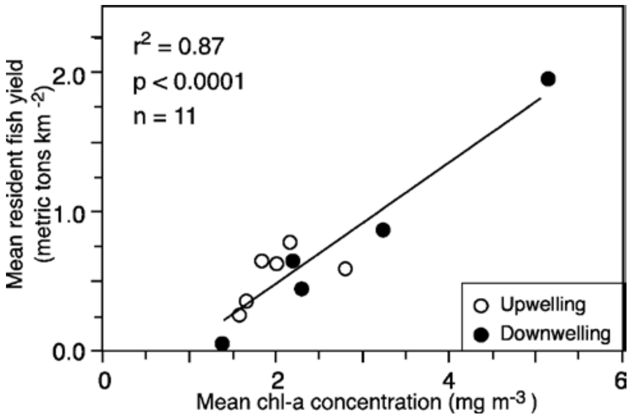

Figure 3. Demonstration of large-scale "bottom up" trophic linkage. The mean annual chlorophyll *a* concentration and the long-term annual yield of resident fish are strongly correlated along the British Columbia coast. Solid circles denote upwelling periods. Open circles denote downwelling periods. *Figure adapted from Figure 2 in Ware and Thomson (2005)*

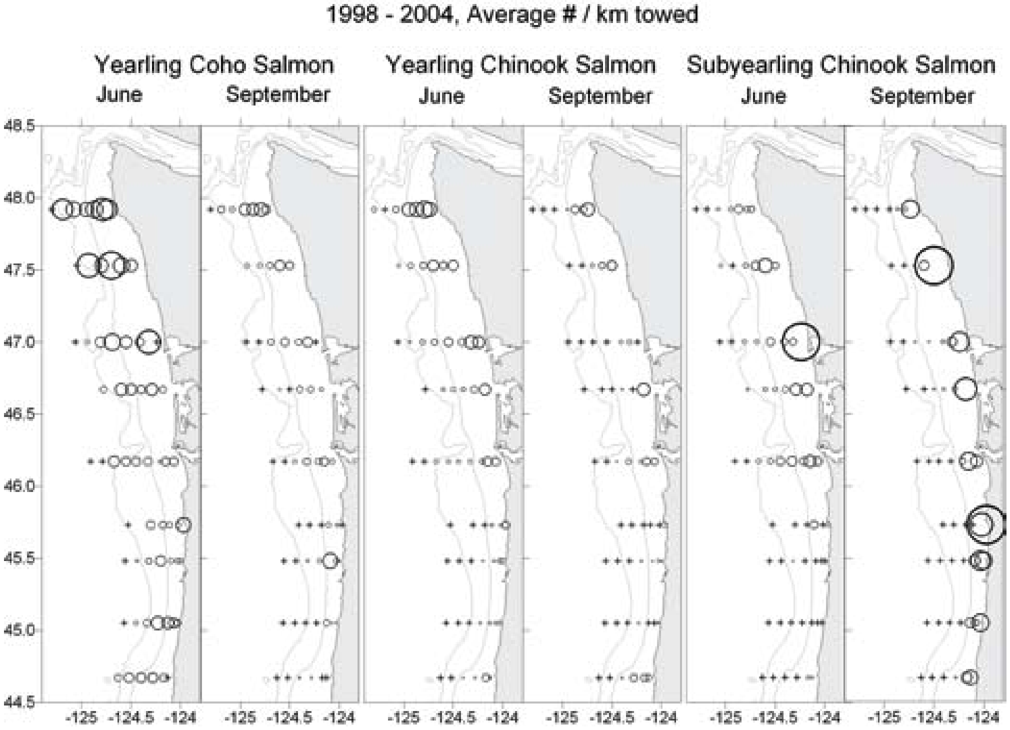

Figure 4. Average number of juvenile salmon per km towed during seasonal cruises over a six-year period. The fish were using a 100-m-long NORDIC 246 Rope Trawl with a 20 m x 30 m mouth opening. The size of the circles is proportional to the number of fish caught per km towed. The largest circle indicates >26 fish per km; the + sign indicates that no fish were caught in the tow. The illustration indicates that most young salmon prefer more northern habitat; in particular, they prefer the region north of the Columbia River entrance (just north of 46°N), a region frequently occupied by the Columbia plume in spring and early summer. Fall Chinook are an exception. *Figure courtesy of Bill Peterson and Ed Casillas; data in part from Fisher et al. (2007)*

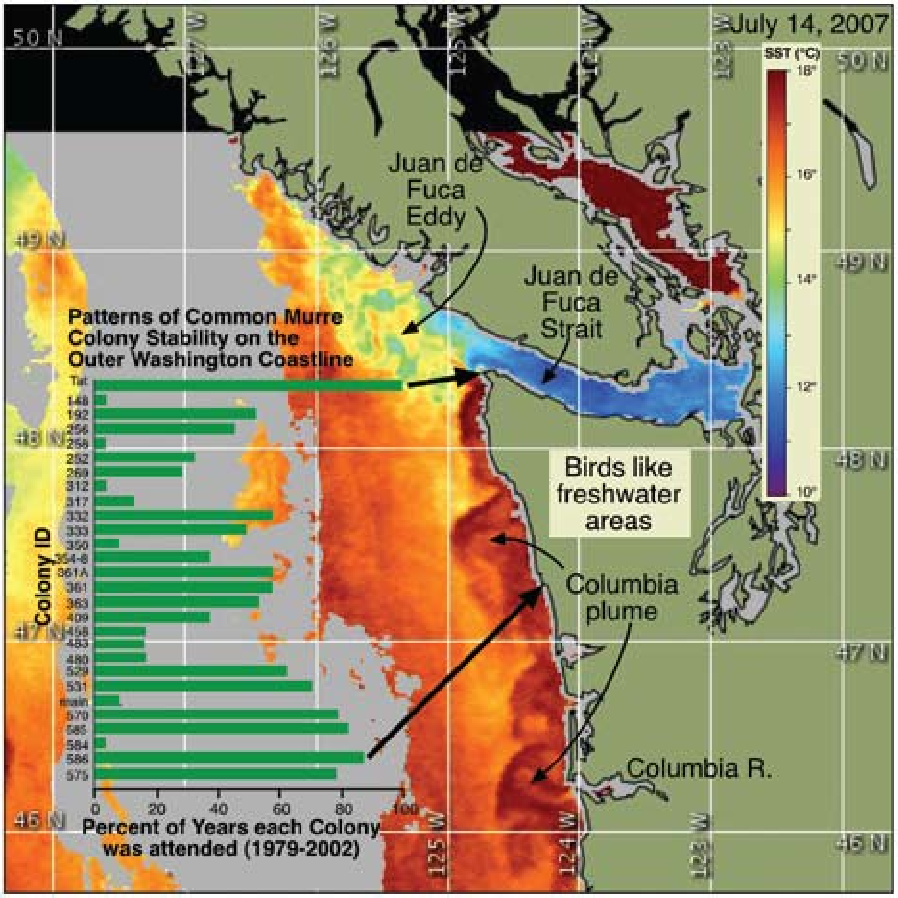
Figure 5. Patterns of colony stability for the Common Murre along the northern Washington coast (data are from the region between the black arrows), plotted on a satellite-derived image of sea surface temperature for July 4, 2007. The freshwater plume from the Strait of Juan de Fuca is seen as a cold feature emanating from the Strait; the plume from the Columbia River is seen as a warm feature all along the Washington/Oregon coast. The Columbia River plume on this date extends much farther along the coast than is typical for this month. The highest percent of colony occupation occurs near or at the two ends of the region sampled, suggesting a relationship between colony stability and location of freshwater plumes. Satellite AVHRR data are from the NOAA Coastwatch program. *Unpublished bird colony data courtesy of Julia Parrish and the US Fish and Wildlife Service, Washington Outer Coast Refuge*



reverses direction from equatorward to poleward during the upwelling season (Huyer et al., 1979; MacFadyen et al., 2008), although its amplitude is modified by local wind dynamics. The jet is controlled by pressure differences due to sloping isopycnals and sea surface height, and the Coriolis force (Earth's rotational tendency). In contrast, currents on the inner shelf (~ 30 m bottom depth or less), which are controlled by surface and bottom friction, reverse from equatorward to poleward a few hours after the wind reverses. In the northern reaches of the CCS, much of the variability in alongshelf currents over the middle and outer shelf is a result of propagating disturbances generated by winds south of a given location (Battisti and Hickey, 1984). Near the sea surface and near the seafloor at all locations across the shelf and slope, friction is also important. Surface frictional currents change direction from onshore to offshore when winds change from poleward ("downwelling-favorable") to equatorward ("upwelling-favorable").

If winds blow equatorward along a straight coastline, at equilibrium, the depth at the source and the amount of upwelled water should be roughly proportional to the strength and duration of the winds divided by the Coriolis parameter (two times Earth's rotation rate times the sine of the latitude) and density (Hill et al., 1998). As mentioned above, alongshelf winds are not constant along the coast: maximum wind stress magnitude occurs off northern California and the alongcoast difference between Washington (~ 48°N) and northern California (~ 42°N) is about a factor of eight (Figure 6a). The factor of eight might possibly be mitigated in northern latitudes by the duration of upwelling winds if those winds were more persistent. But in spring off the Washington coast, upwelling winds typically occur only one-half to two-thirds of the time, and actual downwelling winds also occur (Figure 6d).

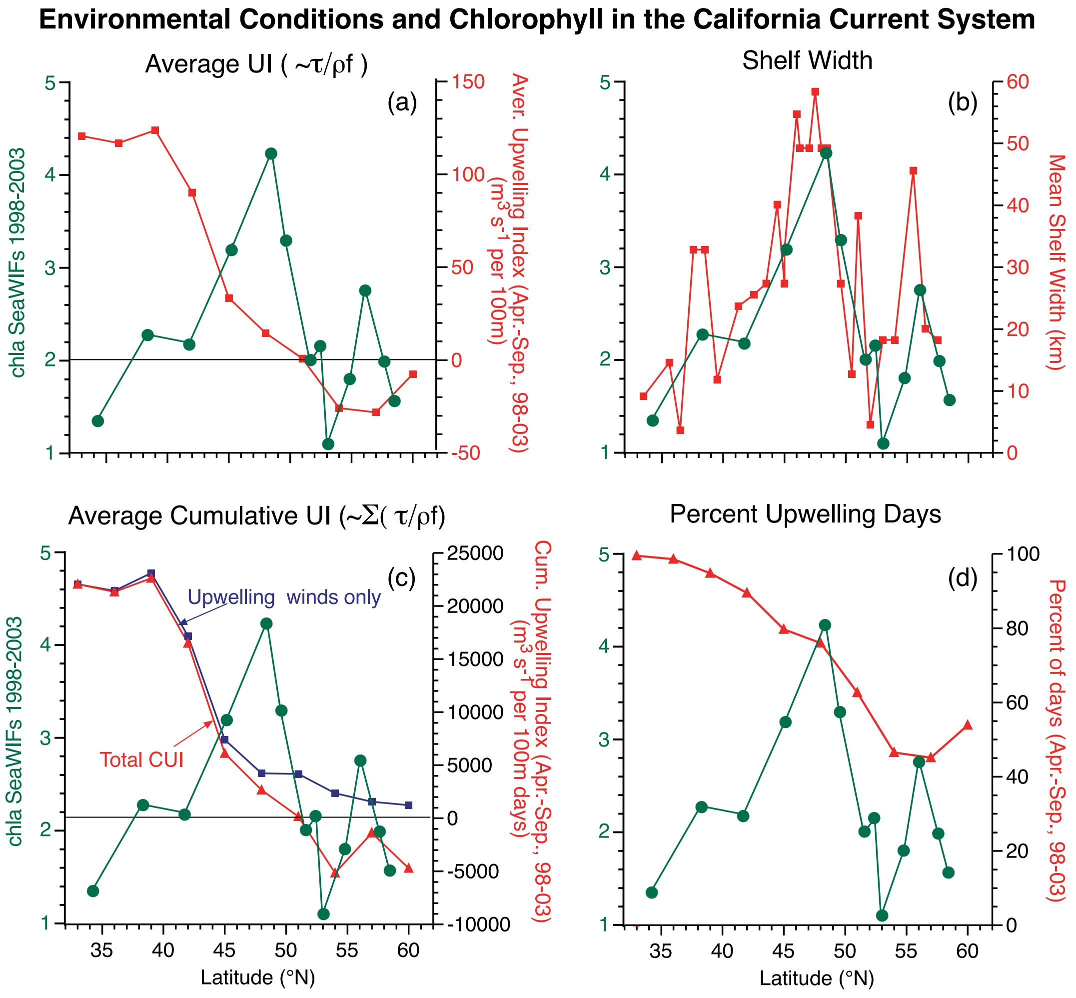


Figure 6. Mean chlorophyll concentration along the coast (from Ware and Thomson, 2005) and (a) Spring-to-summer average (Apr. 1–Sep. 30, over 1998–2003) coastal upwelling index (Bakun, 1973); (b) shelf width averaged manually over one-degree intervals; (c) spring-to-summer average cumulative coastal upwelling index for all winds (CUI) and for just upwelling winds; and spring-to-summer average percentage of days with upwelling-favorable winds. The figure shows that chlorophyll concentration is a maximum at mid latitudes, in a region of declining upwelling wind stress magnitude (panels a and c) and increasing degree of upwelling intermittency (panel d). The alongcoast chlorophyll pattern is well correlated only with shelf width (panel b).

IS NITRATE SUPPLY FOR PRIMARY PRODUCTIVITY SIMILAR OVER THE CCS?

In spite of these alongcoast differences in wind forcing, nitrate supplied to the sea surface is indeed similar over the CCS from California to Vancouver Island. (In the CCS, nitrate, silicate, and phosphate have very similar spatial and temporal seasonal patterns as shown in Figures 1.14–1.22 in Landry et al. [1989]. We use "nutrients" to describe the macronutrients nitrate, nitrite, silicate, and phosphate; we use "nitrate" to describe nitrate and nitrite together.) Values of 20–25 µM nitrate are typically reported in waters upwelled to the surface over the inner shelf by early summer (see MacFadyen et al., 2008, for Washington/Vancouver Island values; see Huyer et al., 2005, for central Oregon and northern California). Minimum temperatures of shelf bottom water over this latitudinal range are essentially identical as well (Geier et al., 2006).

HOW IS NITRATE SUPPLY ABLE TO OVERCOME A FACTOR OF EIGHT DIFFERENCE IN WIND STRESS OVER THE CCS?

Remote Wind Forcing

Seasonal changes in water properties can propagate poleward from the region where winds caused the disturbance ("remote wind forcing") as a baroclinic (density-related) wave (McCreary et al., 1987). In support of this model-generated idea, observational studies have attributed the spring transition in part to remote wind forcing (Strub et al., 1987; Hickey et al., 2006). Analyses of seasonal changes in the northern CCS in 2005 provide convincing evidence that remote wind forcing continues to be important for large-scale upwelling of water properties in the northern CCS throughout the upwelling season (Hickey et al., 2006; Pierce et al., 2006).

Still, these analyses provide, at most, a partial answer to the question. Although remote wind forcing might be sufficient to ensure that the source depth of water that upwells to the northern shelves is similar to that in regions with stronger and more persistent local wind forcing, this mechanism does not necessarily result in delivery of the deeper water and associated nutrients to the euphotic zone where the nutrients can be used by the phytoplankton. Figure 6d shows that local upwelling winds are intermittent at northern latitudes and thus isopycnals are upwelled to the surface near the coast only intermittently. Also, the presence of large amounts of freshwater increases stratification at northern latitudes much of the time, further inhibiting upwelling (Hickey et al., 2005). Fortuitously, the northern CCS has other mechanisms, such as estuarine and tidal dynamics, that help move nutrients to the euphotic zone.

Major estuaries and associated river plumes in the CCS occur in its northern end (Figure 1). River plumes can alter nutrient supply as a *conduit* of land-derived nutrients from watersheds to the ocean, like the Mississippi River. Alternately, they can act as a *facilitator*, entraining coastal upwelling-derived nutrients into the euphotic layer and distributing them out over the continental shelf or slope in the plume (Figure 7). The northern CCS has two

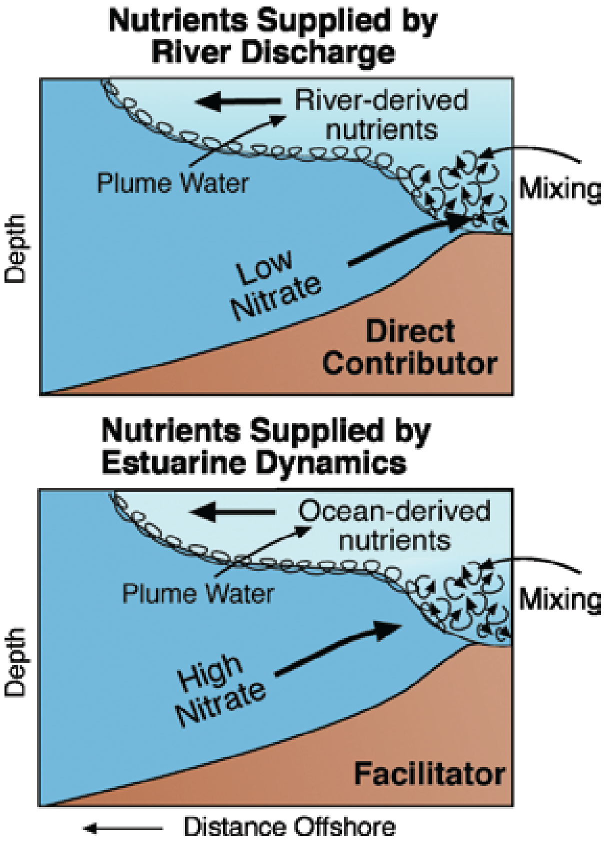

Figure 7. Cartoon depicting how freshwater plumes (lighter blue) interact with the coastal ocean (darker blue). Fresher water may contain land-derived nutrients (plume as "conduit"), such as occurs generally with the Mississippi River plume. Alternately, if upwelling is occurring, the intense mixing with ocean water near the plume lift-off region mixes nutrient-rich upwelled water into the plume, which then carries the rich water seaward (plume as "facilitator").

massive freshwater sources: the effluent from the Strait of Juan de Fuca, whose freshwater originates in the Fraser River and the rivers of Puget Sound, and the Columbia River, the second largest river in the continental United States. The Columbia outflow is half an order of magnitude smaller than the outflow from the Strait of Juan de Fuca (1.4 x 10^4 m^3 s^{-1} vs. 10^5 m^3 s^{-1}; Hickey et al., 1991, 2008). However, the salinity deficit of the freshwater transferred to the coastal ocean is much larger than that of the strait (~ 10–20 vs. 31.5 practical salinity units [psu]; Hickey et al., 2005, 2008); thus, effects of the Columbia River on local stratification and circulation (but not necessarily on macronutrients) can exceed those of the strait. During the delayed spring transition of 2005, relatively high values of chlorophyll were observed in the vicinity of both these freshwater features, in contrast to other regions (Figure 8d).

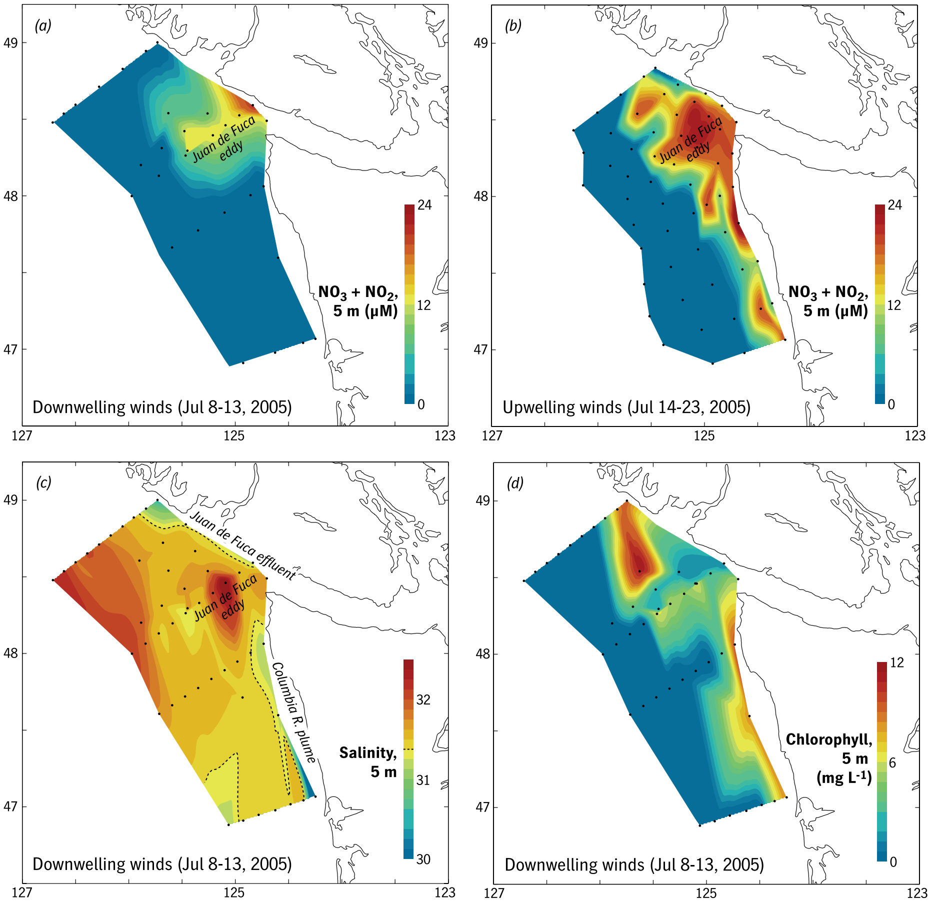

Figure 8. Upper panels compare contoured maps of nitrate plus nitrite during downwelling-favorable (a) and subsequent upwelling-favorable (b) winds along the southern Vancouver Island/Washington coast at a depth of 5 m. Station locations are indicated with black dots and no smoothing has been done. The contrast between the nitrate supply along the open coast, which disappears during periods of downwelling winds, and in the Juan de Fuca region, where supply is governed by estuarine/strait dynamics, is shown explicitly. In addition to a more persistent nutrient supply, the nutrients are transported offshore by the strait effluent and the offshore Juan de Fuca eddy, a distance several times greater than by wind-driven transport in the coastal upwelling zone. Lower panels compare 5-m salinity (c) and chlorophyll *a* (d) during a period of downwelling in early July 2005. Chlorophyll concentration is elevated in the two regions most influenced by freshwater (dark blue areas, offshore of the strait and in the Columbia River plume) even though winds were downwelling-favorable. Nitrate concentration remained high offshore of the strait as shown in Figure 8a. This was the period of delayed upwelling when chlorophyll, primary productivity (Kudela et al., 2006), and other marine populations (e.g., Mackas et al., 2006; Newell and Cowles, 2006) failed in some regions. *Unpublished nitrate and chlorophyll-a data from Bill Cochlan, San Francisco State University, ECOHAB PNW program. See MacFadyen et al. (2008) for more details.*

The Juan de Fuca Strait Outflow

Nutrients exiting the Juan de Fuca Strait are essentially all derived from the same water source that is upwelled in the rest of the CCS (Mackas et al., 1980). The water is drawn up the Juan de Fuca canyon and enters the strait to compensate for the loss of mass of the outflowing water, because the strait is an estuary. This nutrient-rich water is subsequently entrained into outflowing strait water and thus provides a massive, relatively steady nutrient source to the northern CCS (Mackas et al., 1980; Denman et al., 1981; MacFadyen et al., 2008). The difference between nitrate supplied by straight-coast, wind-driven upwelling and by the Juan de Fuca Strait can be seen by comparing surface nitrate during a period of downwelling and subsequent upwelling (Figures 8a and 8b). Nitrate continues to emerge from the strait but is absent along the coast during the period of downwelling winds (see also MacFadyen et al., 2008). The Juan de Fuca region has three other unique advantages as a nutrient source over regions supplied by upwelling along a straight coastline. First, its strong currents transport nutrients offshore at least four times farther than water upwelled at the coast (~ 60 km vs. 15 km offshore). Second, it retains them locally due to the

Table 1. Order of magnitude estimates of nitrate input to the southern Vancouver Island/Washington shelf by a variety of sources.

Type of Upwelling	Spring (Apr–Jun) x 10^9 kg	Full Season (Apr–Sep) x 10^9 kg	Comments
Strait of Juan de Fuca	0.2 0.3	0.5 0.6	Strait alone Doming enhancement added
Coastal	0.2	0.4	WA coast
Canyon Enhancement	0.2–0.5	0.2–0.5	No input after undercurrent develops; H = 10m
Columbia, Downwelling (conduit)	0.02	0.02	Input only in spring
Columbia, Upwelling (facilitator)	0.02	0.04	Mean value from Bruland et al., 2008

Juan de Fuca eddy (Figures 1 and 8), a major topographic feature in this area (see later discussion of retention). These physical advantages are enhanced by diminished utilization by phytoplankton as water emerges from the strait (MacFadyen et al., 2008). The source waters for phytoplankton in the strait are always deep (100–200 m) so that plankton density is low, in contrast to phytoplankton upwelled close to the coast on the wide, highly retentive northern shelves. While transiting the strait, phytoplankton are light limited due to vigorous vertical mixing, so that growth is minimal. Thus, several days are required to initiate blooms that significantly draw down nutrients. The third advantage is that because the outflow from the strait occurs over the upper 100 m (Hickey et al., 1991), high nutrient concentrations (nitrate > 25 µM; MacFadyen et al., 2008) are provided much deeper in the water column than occurs with the ~ 10–20-m-thick offshore surface Ekman layer produced by wind-driven upwelling. Local usage of these nutrients usually depletes the upper 10 m of the water column. However, the remainder of the water column is exported equatorward to Washington and Oregon in the coastal jet, providing a rich source of nutrients to the ecosystems of those shelves.

To obtain an order of magnitude seasonal estimate of nitrate input by the Strait of Juan de Fuca, we used a flux of 50 kg nitrate s^{-1} (Mackas et al.,1980). The flux was multiplied by the appropriate number of days in the April to June period (spring) and for the full April through September upwelling season (upper value in Table 1). As the season progresses, doming beneath the Juan de Fuca eddy is itself a source of upwelling to the base of the pycnocline (MacFadyen et al., 2008). To include that effect, estimates were increased by 25%, using the estimates of cross-isopycnal nitrate flux derived from microstructure measurements off Oregon (Hales et al., 2005) (lower value in Table 1).

For comparison, we estimated nitrate contributed by upwelling due to local winds along the Washington coast by assuming a two-dimensional balance such that the wind-driven offshore flux in the surface layer is balanced by an onshore upwelling flux (as in Denman et al., 1981). A cumulative upwelling index was used to compute the mass input over spring alone and over the full season (as seen in Figure 6). Following Hickey et al. (2006), only upwelling-favorable wind stress values were included because wind reversals do not appear to reverse currents in the bottom boundary layer over the middle and outer shelf. The upwelling distance used was the entire coast from the Columbia River to the Strait of Juan de Fuca. For a conservative estimate, the upwelling nitrate concentration was assumed to be 30 µM (see nitrate time series in Hickey et al., 2006).

Results show that in spring, nitrate supplied by outflow from the ~ 20-km-wide Strait of Juan de Fuca contributes roughly the same (or more) nitrate to the 220-km-long southern Vancouver Island/Washington shelf as local coastal upwelling, a doubling of available nitrate. The significance of nitrate output by the strait is consistent with Crawford and Dewey (1989), who showed that the strait was the dominant source of nutrients for the Vancouver Island coast.

Nitrate provided by the strait is thus substantial, and would allow phytoplankton to continue blooming when nitrate is depleted in regions without this alternate nitrate source, as occurs during periods of persistent downwelling winds such as in spring 2005.

The Columbia River Plume

The Columbia River plume was historically reported to be oriented southwest of the river mouth in summer (Barnes et al., 1972). However, recent work shows that the plume is present more than 50% of the time north of the river mouth, and frequently has branches both north and south of the river mouth at the same time in summer (Figure 1) (Garcia-Berdeal et al., 2002; Hickey et al., 2005, 2008). The plume from the Columbia River can be both a nutrient conduit and a facilitator (Figure 7). Most nutrients derived from local watersheds are used inside the Columbia River estuary in the summer growing season and are not exported out to the continental shelf (Conomos et al., 1972). However, in spring and early summer during periods of high rainfall, moderate concentrations of nitrate (~ 5–18 μM) can be supplied directly to the coastal ocean (Bruland et al., 2008). This nutrient supply may help sustain local ecosystems during periods of weak or no upwelling, or late transitions to spring conditions, as occurred in 2005 (Figure 8d).

Significant entrainment of shelf water occurs where the plume separates from the bottom (the plume "lift off" region) and exits the river mouth, and also occurs just inside the estuary (Figure 7) (McCabe et al., 2008; Bruland et al., 2008). If upwelling has been occurring on the nearby shelf, the nutrient-rich upwelled shelf water is mixed or entrained into the outflowing Columbia River water, similar to the process that entrains much deeper nutrients into Juan de Fuca Strait. Model results (Banas et al., in review; MacCready et al., 2008) suggest that the amount of nitrate mixed into the coastal water exceeds that which would be upwelled by wind-driven upwelling along a coast without a plume or an estuary. This result is captured in a plot showing the difference in total nutrients (biomass plus nitrate) as well as nitrate and chlorophyll maps on selected dates between two model runs, one with, and one without the Columbia River estuary and its plume (Figure 9). During a period of weak or intermittent upwelling (July 12–18), nitrate is much higher near the river mouth when the riverflow and estuary are included in the model (Figure 9d); total nitrate shows a ~10 μM increase in the plume area throughout this period. The enhanced nitrate supply is due to a combination of freshwater and tidal dynamics; note the smaller, corresponding positive anomaly in nitrate at the mouth of the estuary just north of the Columbia estuary (Figure 9d, July 18), which has strong tides but negligible summer river input (set to zero in the model).

During the modeled downwelling event July 18–20 (Figure 9a), the excess plume-facilitated nitrate supports a phytoplankton bloom near the Columbia mouth and along the Washington coast (Figure 9b, July 20), whereas in the no-river case, nitrate and biomass both decline quickly during downwelling (Figures 9b and 9d, July 20). These plume effects are strongest under weak-to-moderate upwelling; during periods of strong, sustained upwelling-favorable winds (July 21–26), the plume is blown offshore and southwest, and nitrate supply varies little between model cases (Figure 9d, July 26).

The presence of a river plume over a shelf does not always increase local nitrate or total nutrient supply. The increased stratification can impede upwelling of new nitrate from deeper layers (Hickey et al., 2005), as shown in model runs. During weak, variable upwelling (July 12–17), the plume partially caps nutrient supply and reduces primary production along the Washington coast in comparison with the no-river case, causing a deficit in biomass (Figure 9b, July 14) and total nitrogen (Figure 9c).

For comparison with other sources in Table 1, seasonal nitrate input by the Columbia River plume was estimated both for downwelling-favorable winds, in which entrainment into the plume was ignored but watershed-derived nitrate exiting the estuary was counted, and for upwelling-favorable winds, in which riverine nitrate was assumed to be zero but the nitrate from upwelled water on the shelf is mixed or entrained into the outward moving plume near its lift off location. Ranges for nitrate obtained on RISE cruises were taken from Bruland et al. (2008): 5–18 μM in river water during downwelling periods and ~ 20 μM in plume water during upwelling periods. Values were multiplied by the typical spring riverflow (~ 10^4 m^3 s^{-1}) and by the number of days of downwelling or upwelling, respectively. Because river input of nitrate only occurs under substantial storms, we assumed that no direct river contribution occurs after June.

Perhaps surprisingly, nitrate supply

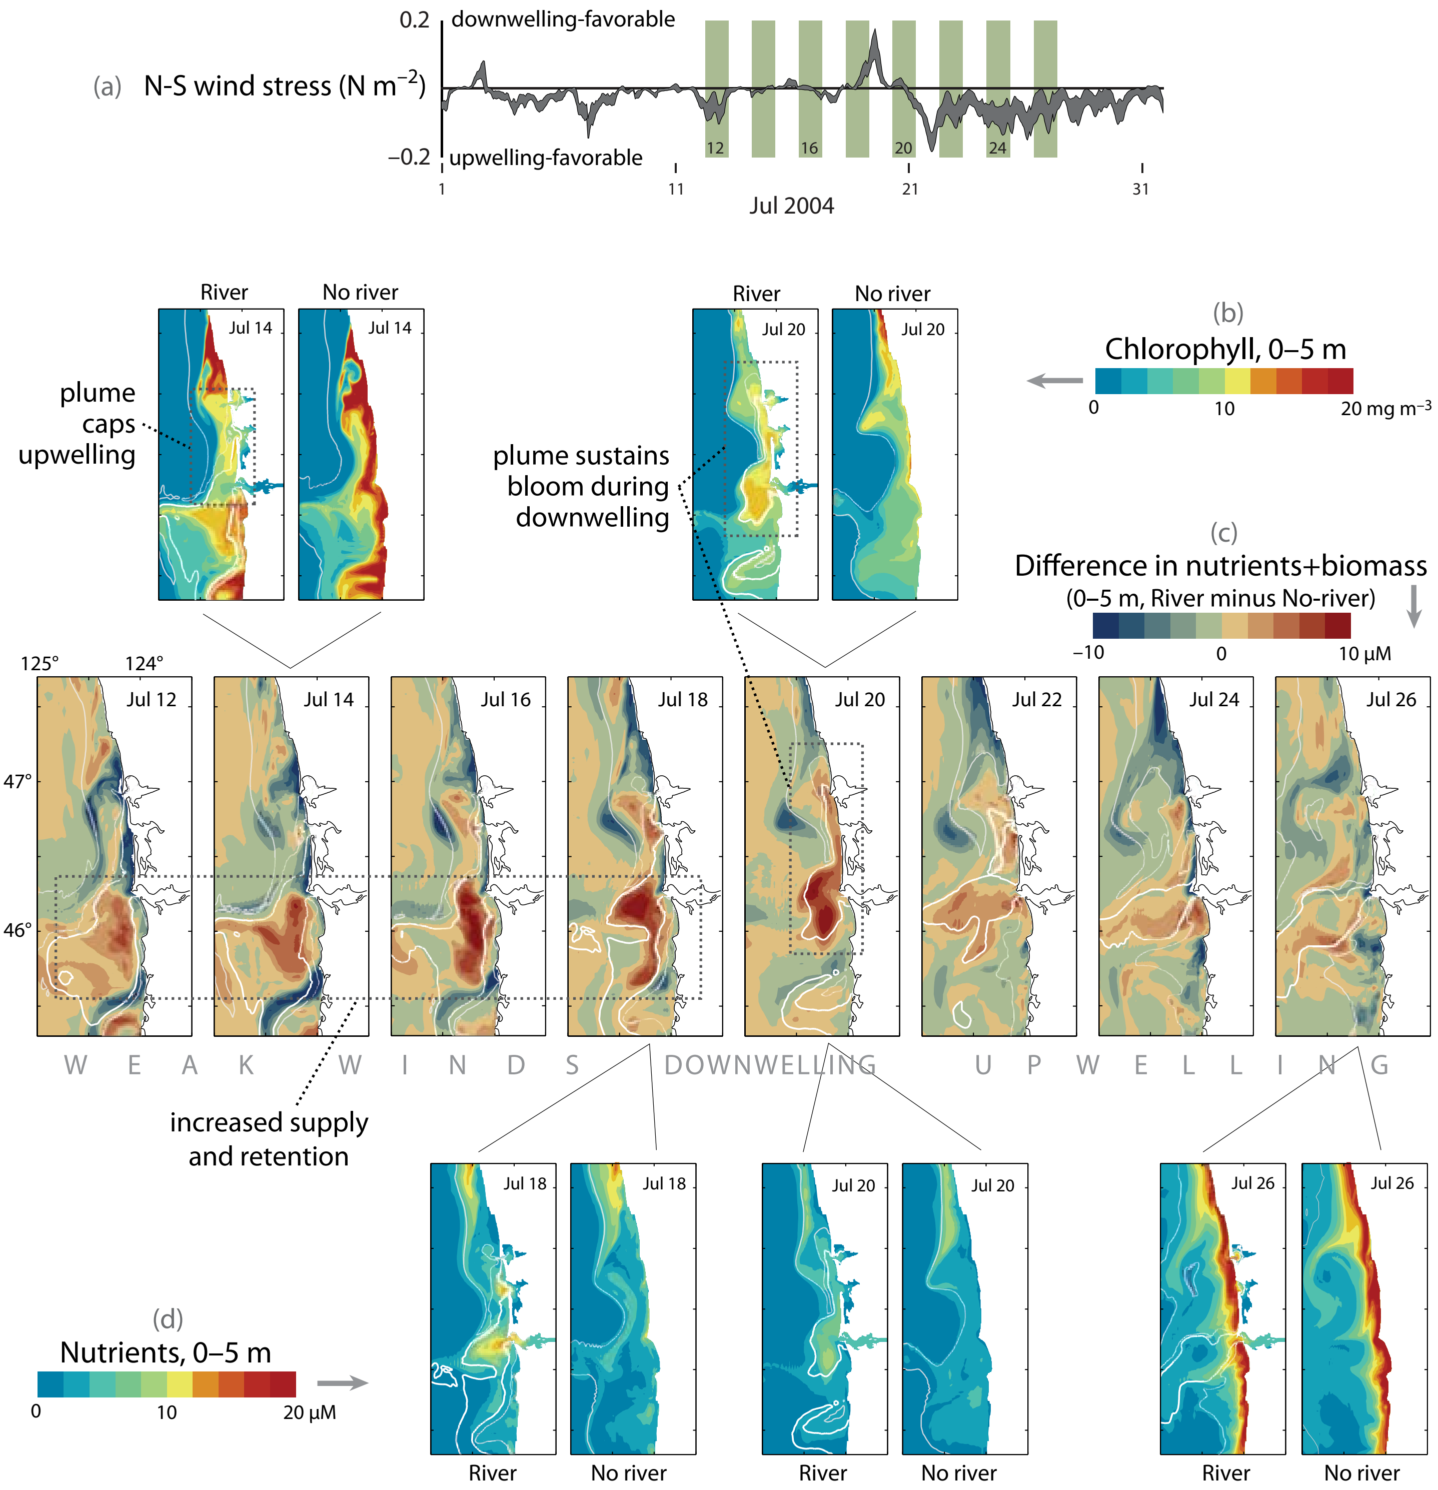

Figure 9. Timeline of nutrients and biomass in the surface layer (0–5-m average) from July 2004, from an ecosystem model case (see Banas et al., in review; MacCready et al., 2008) with the Columbia River plume included ("River"), and a "No-river" case in which riverflow = 0 and the Columbia River estuary and Washington small bays are replaced with an unbroken coastline. River nitrate is set to zero. Each snapshot is a 25-h tidal average. Contours of salinity are shown in white (thicker, 30 practical salinity units [psu]; thinner, 31.5 psu) to mark the location of the plume. North-south wind stress is given in (a). The main timeline (c) shows the difference between model cases in nutrients + biomass (both in nitrogen units); snapshots of chlorophyll (b) and nutrients (d) are also shown to highlight key features. During weak, variable upwelling (July 12–17), the plume partially caps nutrient supply and primary production along the Washington coast, causing a deficit in biomass (b, July 14). At the same time, however, the plume also causes increased supply and retention of nutrients in the plume south of the river mouth during this period (c, July 12–18; d, July 18). During the downwelling event July 18–20 (a), the excess plume-derived nutrients support a phytoplankton bloom near the Columbia mouth and along the Washington coast (b, July 20), whereas in the no-river case, nutrients and biomass both decline quickly during downwelling (b, d, July 20). These plume effects are strongest under weak-to-moderate upwelling: during strong, sustained upwelling (July 21–26), the plume is blown offshore and the nutrient supply varies little between model cases (d, July 26).

by the Columbia River and its plume, both as a conduit from the river itself and as a facilitator of upwelling-supplied nitrate, is an order of magnitude smaller than that from all other sources (Table 1) for the region as a whole. If we restrict our attention to the river mouth, the nitrate supplied by mixing of upwelled water into the plume at lift off (Bruland et al., 2008) suggests a half order of magnitude enhancement over straight coast upwelling (2.5 vs. 0.5 kg s^{-1}, for a Columbia River mouth width of 4 km). This estimated enhancement is also consistent with patterns shown in Figure 9. The small overall contribution of the Columbia River in comparison with, for example, the Strait of Juan de Fuca, is due primarily to the small river and plume volumes, in comparison to the other sources. Still, despite the relatively small contributions on a seasonal basis, the Columbia River can be important as a local source during periods of downwelling or weak upwelling winds.

Iron is vital for phytoplankton blooms in an upwelling system, and iron supply may contribute to productivity differences along the CCS (Chase et al., 2005). Recent measurements indicate that even off the Oregon coast, phytoplankton growth is not iron limited (Chase et al., 2005), although iron can be a limiting nutrient off California (Hutchins and Bruland, 1998). RISE studies show that iron is never limiting on the Washington coast (Bruland et al., 2008). Not only is the plume from the Columbia River heavily laden with iron, but iron from the Columbia plume is also deposited in sediment along both the Washington and Oregon coasts. The iron-laden sediment can be mixed into bottom water and thus added to the already nitrate-rich water.

Submarine Canyons

Like river plumes, submarine canyons are not distributed uniformly over the CCS—the majority of canyons occur in the northern CCS (Figure 1). Upwelling is enhanced on the southern sides of these canyons (Allen, 1996; Hickey, 1997; She and Klinck, 2000), forced by the cross-shelf pressure gradient associated with the equatorward flowing coastal jet. This enhancement would not be expected once the poleward undercurrent sets up seasonally. Although the water originating in canyons does not break the sea surface locally, this upwelled water moves onshore in the bottom boundary layer over the shelf as it moves equatorward in the shelf jet (Crawford and Dewey, 1989). This water reaches the coast at some location south of a particular canyon, where it would require local wind forcing to upwell it into the euphotic zone.

We estimated the seasonal contribution by submarine canyons to nitrate over the shelf bottom using results in Hickey (1997) to scale the thickness (~10 m), temperature (7–7.5°C), and velocity (~ 10 cm s^{-1}) of the upwelling layer. Temperature was converted to nitrate (~ 35 μM in this temperature range) using a relationship obtained from multiple ECOHAB PNW and RISE cruises ($r^2 = 0.8$). The length of the downstream (equatorward) side of each canyon was measured manually. To provide a range of possible input, estimates were made for two coastline intervals: all canyons between 46°N and 50°N, and canyons south of Juan de Fuca canyon only (Juan de Fuca canyon is open ended and thus has unique canyon dynamics). Input was estimated to occur only from April to June, before the poleward undercurrent develops, and only during upwelling periods, because the currents that impinge on the canyon at canyon depth may reverse to poleward during downwelling events (Hickey, 1997). Therefore, resulting values were multiplied by the average number of days of upwelling in each month.

Results suggest that in spring, nitrate supplied to the shelf bottom due to upwelling enhancement by canyons is roughly the same as (or more than) the amount that local coastal upwelling supplies to the southern Vancouver Island/Washington shelf (Table 1). The canyon enhancement is also comparable to the nutrient supply by the Strait of Juan de Fuca.

IS RETENTION/CONCENTRATION OF PHYTOPLANKTON A MAJOR FACTOR IN EXPLAINING ALONGCOAST PRODUCTIVITY STRUCTURE?

The preceding discussions demonstrate that the northern CCS has delivery methods to the euphotic zone that ensure nutrient concentrations required for primary production at levels similar to other areas in the northern CCS. But chlorophyll concentrations at the sea surface are about five times higher in the northern CCS than off northern California (Figure 2). This observation suggests that retention of phytoplankton blooms plays an important role in producing alongcoast chlorophyll patterns. Indeed, the northern CCS is endowed with a massive eddy persistently supplied with nutrients, retentive river plume fronts, a coastline with no major promontories such as cause offshore jets and meanders farther south in the CCS

(Strub et al., 1991; Barth and Smith, 1996), and wide shelves (see Figure 1).

Surface drifters deployed in summer in the high-chlorophyll northern end of the CCS under a variety of wind conditions (Figure 10) demonstrate that the Washington shelf is indeed extremely retentive to surface water movement. There is little evidence of offshore movement in surface Ekman layers during periods of upwelling-favorable winds; drifter pathways, once free of the Juan de Fuca eddy at the northern end, are controlled primarily by the baroclinic coastal jet. In this region, fronts from the Columbia River are common (Hickey et al., 2005), and these fronts are generally oriented along the shelf. In general, water is retained on the Washington shelf for at least 10 days under moderate upwelling wind conditions (MacFadyen et al., 2008).

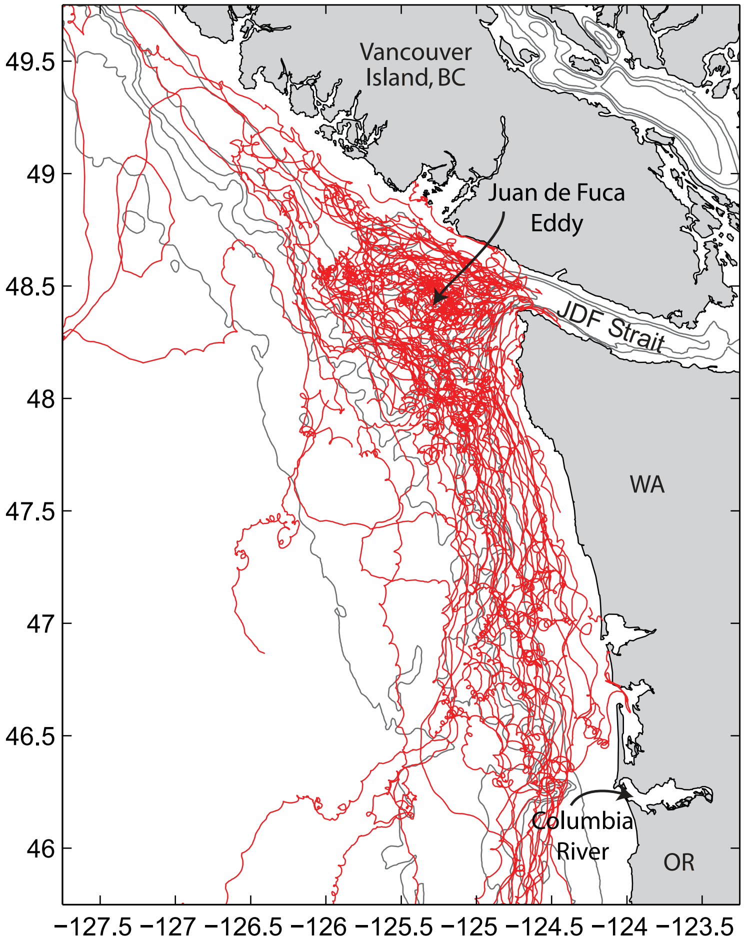

Figure 10. An illustration of particle retention on the southern Vancouver Island/Washington coast. Tracks of 68 surface drifters deployed in summer 2003–2006 during the ECOHAB PNW study. Most drifters were deployed in the Juan de Fuca eddy, the region with dense tracks just offshore of the Strait of Juan de Fuca. Contour intervals are 100, 150, 250, 500, 1000, and 2000 m. Drifters show little evidence of offshore transport in the surface frictional layer. Transit time from the eddy to the Columbia mouth is about 10 days in moderate upwelling winds. Few drifters leave the shelf; the few exceptions occur at the northwest end of the region under downwelling wind conditions, or at the south end of the region where drifters encountered the plume from the Columbia.

Retention is particularly long (up to 32 days have been observed) just offshore of the Strait of Juan de Fuca, in the Juan de Fuca eddy (Figure 10; Freeland and Denman, 1982; MacFadyen et al., 2005, 2008; Foreman et al., 2008). Although bloom concentration is important, we note that bloom maintenance during retention is perhaps more important—blooms require an ongoing source of nutrients in order to maintain high chlorophyll concentrations. The Juan de Fuca eddy region has an almost steady supply of nutrients, as noted previously. Escape from the eddy occurs primarily under upwelling-favorable wind conditions; in the near surface frictional layer, the geostrophic constraint is broken by frictionally dominated currents. Filaments with high chlorophyll have been observed emanating from the eddy region equatorward along the outer Washington shelf and slope along pathways like those shown in Figure 10 (MacFadyen et al., 2008; Trainer et al., in press). The Juan de Fuca eddy region likely provides much of the chlorophyll observed on the Washington shelf. Just below the surface layer, nutrients follow pressure surfaces, flowing generally equatorward in the shelf break jet whether winds are upwelling- or downwelling-favorable. These waters provide a high-nutrient environment that can sustain subsurface phytoplankton blooms, features commonly observed on the Washington shelf (Landry et al., 1989). They also are likely the source of waters upwelled along the

Washington/Oregon coasts in later parts of the upwelling season.

Heceta Bank, off central Oregon, is another retentive region in the northern CCS (Gan and Allen, 2005) where chlorophyll concentrations are relatively high (Landry et al., 1989; Spitz et al., 2005; Henson and Thomas, 2007). Although Heceta Bank and the Juan de Fuca eddy region may have similar retentive properties, Heceta Bank does not have the persistent strait-generated nutrient supply of the more northern feature.

The Columbia River plume also plays a significant role in retention on the southern Washington/northern Oregon shelf. Drifter pathways become more convoluted at about the latitude of the Columbia River mouth, a result of eddies spun off from the recirculating region near the mouth and offshore-tending fronts due to the southwest Columbia plume that develops during periods of upwelling-favorable winds (Figure 10; Banas et al., 2008). Model results (Figure 9) show that the plume can concentrate both nitrate and biomass, thus retaining the total resource over the shelf in a localized area much longer than if no plume were present. This concentration effect occurs during periods when winds change intermittently from downwelling- to upwelling-favorable.

Comparison of modeled surface particle tracks with and without a river plume included shows that surface particles originating on the inner shelf can be episodically retained on the inner shelf in the presence of the Columbia plume (Figure 11). At other times in the upwelling-downwelling cycle, the plume appears to enhance cross-shelf export instead (Banas et al., 2008). Model

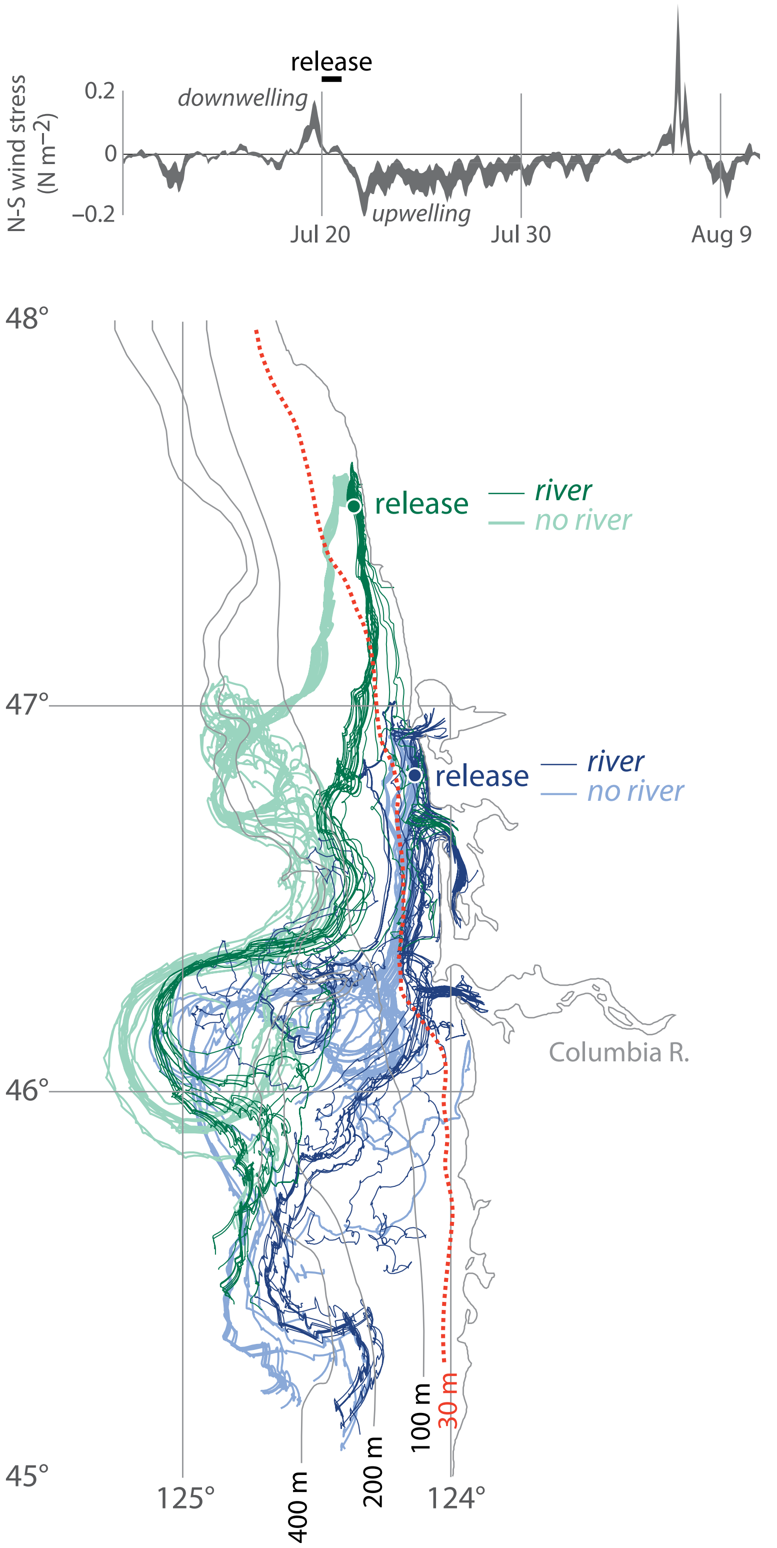

Figure 11. An example of nearshore retention caused by a river plume. The fate of water found on the Washington inner shelf during the onset of a sustained upwelling event, July 20, 2004, shown for two model cases: a base case with the Columbia River included (darker lines) and a case in which the Columbia is turned off and the estuary replaced by unbroken coastline. Particles were released at two locations (47.5°N, 46.83°N) over 25 h on July 20 and tracked using surface velocity fields for 20 d. During this transition from downwelling to upwelling, particles are retained on the inner shelf (landward of the 30-m isobath, dotted red line) several days longer in the presence of the plume.

studies also suggest (Banas et al., 2008) that interactions between the plume and variable winds episodically retard the equatorward advection of biomass from the Washington shelf, so that the plume acts as a retention feature in an alongcoast sense as well. Note that all these types of plume-driven retention occur in part as a result of wind intermittency: if the winds were upwelling-favorable only, we would expect the plume to result in excess offshelf transport to the southwest. Nevertheless, as downwelling-favorable winds occur over 30% of the time in this region in an average year (Figure 6d), inner shelf retention of phytoplankton, and resulting changes of patterns of microzooplankton, have important effects on the local ecosystem.

Last, we note that chlorophyll concentration is strongly related to shelf width along the coast (Figure 6b). The width of the shelf decreases equatorward from ~ 60 km at more northern latitudes to ~ 10 km off much of California (Figure 6b). Data in Lentz (1992) and in Hickey (1989) show that wind-driven flow in the near surface layers is similar at most locations: ~ 0.1 m s^{-1}. As winds blow harder, mixed layer depth increases (Lentz, 1992) and flow is distributed over a greater vertical distance. Thus, for the same wind stress along the coast, the residence time of material on the shelf should vary linearly roughly with shelf width. For a typical wind stress, surface residence time would be a week off the Washington coast, but one or two days off northern California in regions with a straight coastline; again, northern regions are favored for bloom retention.

OTHER ISSUES AFFECTING ALONGCOAST CHLOROPHYLL CONCENTRATIONS

Shelf Shape and Depth of Upwelled Water

In general, shelves are broader and flatter at northern latitudes (Figure 6b); note that width and steepness are strongly correlated by their geology. Allen et al. (1995) show that the depth from which shelf water is derived during upwelling depends critically on bottom slope and the width of the shelf. Over steeper shelves (e.g., off California), much of the flow that compensates for the wind-driven offshore flow in the surface frictional layer (the "return flow") originates from the central water column rather than from the bottom boundary layer. Because nutrients increase with depth in the water column, water originating deeper in the water column would tend to have higher nutrient concentrations than that originating from shallower depths. We might therefore expect water upwelled in the compensating flow over broader, steeper shelves (such as occur off Washington and southern British Columbia) to originate deeper and thus to have higher nutrient concentration than upwelled water over narrower, steeper shelves (such as occur off much of Oregon and California). Although the Allen et al. (1995) modeling result described above suggests a mechanism to help explain the correlation between shelf width and chlorophyll seen in Figure 6b, the modeled cross-shelf circulation pattern is not supported by field observations. In particular, the majority of the return flow in upwelling regions occurs well above the bottom boundary layer independent of shelf morphology as shown by Smith (1981) for both the CCS and the Peruvian upwelling systems. Off the Washington shelf, the strongest return flow is typically observed at a depth of about 10–15 m (Hickey, 1989).

Bloom Time Scales Versus Wind Intermittency

Intermittency is a critical component of resulting biological patterns. Off central California, maximum phytoplankton productivity is observed when wind variability matches phytoplankton bloom time scales, with three to seven days of relaxation being optimal and diatoms dominating the population (Wilkerson et al., 2006; Botsford et al., 2006). When winds are stronger, new production is less than the theoretical maximum, consistent with substantial export from the shelf as well as increased mixed layer depth and reduced light exposure (Dugdale et al., 2006). Stronger winds reduce transit time across the shelf to fewer than five days so that blooms cannot fully develop before they are exported offshelf and coastal waters are increasingly influenced by detritus (Kudela et al., 2006). Because the duration and strength of upwelling-favorable winds decreases poleward over the CCS (Figure 6d), wind time scales again are most optimal for growth in the northern CCS.

SUMMARY AND DISCUSSION

Chlorophyll concentration along the CCS is strongly correlated with shelf width (Figure 6b). If retentive banks are included in the wide shelf category, shelf width likely is more important overall than river plumes for retention in the northern CCS, and comparable in effect to the absence of large coastal promontories. Yet no chlorophyll would collect on a wide shelf if the appropriate nutrients were not available to fuel a bloom. Thus, in addition to a wide shelf and no large capes, to attain high productivity, nutrients must be upwelled onto the northern CCS shelf in concentrations comparable to or exceeding those in the central and southern CCS. Moreover, those nutrients need to be injected into the euphotic zone to be used by the phytoplankton, and ultimately, to affect higher trophic levels.

The discussion presented in this article suggests that these two requirements are met by different processes in the northern and southern CCS. Upwelling of deep isopycnals occurs in all parts of the CCS to distances more than 100 km from the coast and depths greater than 200 m from the sea surface. In northern latitudes, this large-scale upwelling is likely forced at least in part by the winds off northern California, with the disturbance traveling poleward as a wave, and is enhanced by submarine canyon upwelling. Nutrients upwelled into bottom waters by these processes as well as by local wind upwelling are moved into surface layers by estuarine dynamics and enhanced tidal mixing near estuaries, each of which inputs nitrate at levels comparable to local coastal upwelling. The Strait of Juan de Fuca and canyon upwelling provide nitrate at levels comparable to or exceeding that of local wind-driven coastal upwelling, almost an order of magnitude greater than nitrate supplied by the Columbia River plume. The nutrient supply from the strait is more persistent, extends farther offshore, and extends deeper in the water column than nutrients supplied by traditional coastal upwelling. However, during periods with significant downwelling, contributions from the Columbia River supply sufficient nitrate to fuel the ecosystem until upwelling conditions return. Off northern and central California, where upwelling-favorable winds are strong and persistent, upwelling forced by local winds near the coastline brings the needed nutrients to the euphotic zone. Our recipe for understanding and/or modeling the CCS ecosystem includes the following as essential elements:

- The Strait of Juan de Fuca with its tidal dynamics and its freshwater
- The Columbia River with its tidal dynamics, nutrients, and freshwater
- Submarine canyons with high topographic resolution
- Alongcoast wind structure to capture remote wind forcing

These conclusions can be used to speculate on potential effects of global warming in the northern CCS. For example, as air temperature rises, we might expect less riverflow in both the Fraser and Columbia Rivers, because the summer effluent in both rivers is derived from snowmelt. A decline in Fraser River outflow would cause a decline in the outflow from the Strait of Juan de Fuca, and hence a decline in turbulent mixing in the strait. Both effects would suggest a decline in nutrient supply to the northern CCS and perhaps a decline in the strength of the eddy offshore of the Strait of Juan de Fuca, hence less local retention of both nutrients and phytoplankton. Thus, the upstream source of nutrients and phytoplankton for the Washington/Oregon shelf could be substantially diminished. Weaker Columbia River outflow would cause the Columbia plume to contribute less to both nutrient supply and retention on the Washington shelf, reducing its usefulness as a buffer for the local ecosystem during spring periods of intermittent winds.

A final caveat: our predictions are based on the best existing information and synthetic knowledge. These predictions should be viewed only as a beginning. Much work clearly remains to be done to provide a more realistic basis for predicting changes in the productivity of the CCS over the next several decades.

ACKNOWLEDGEMENTS

Barbara Hickey would particularly like to thank one of her mentors, Joe Reid, who suggested that much of this material, the content of an invited Sverdrup Lecture at an Ocean Sciences meeting, should be written up as a paper. We would also like to thank several colleagues who generously shared data or figures that helped make many important points: Bill Cochlan at San Francisco State University provided nitrate and chlorophyll data for Figure 8; Parker MacCready graciously provided the Columbia River plume region hydrodynamic model underlying results shown in Figures 9 and 11. Andrew Thomas at the University of Maine provided satellite-derived chlorophyll data and Figure 3; Julia Parrish at the University of Washington and the US Fish and Wildlife Service, Washington Outer Coast Refuge provided the bird colony figure (Figure 5). Bill Peterson and Ed Casillas at the National Ocean and Atmospheric Administration (NOAA) and Joe Fisher at Oregon State University graciously provided the juvenile salmon distributions (Figure 4). Nancy Kachel assisted in analysis and figure graphics; Susan Geier assisted in editing; Amy MacFadyen provided the drifter track figure. This analysis was supported by grants to B. Hickey from NSF and from the Center for Sponsored Coastal Ocean Research of NOAA: OCE-0239089 (NSF), the Coastal Ocean Processes RISE project; NA17OP2789 (NOAA) and OCE-0234587 (NSF), ECOHAB PNW; OCE0001034 (NSF) and NA17RJ1232 (NOAA), GLOBEC Northeast Pacific CCS. Drifter, nitrate, and chlorophyll data were collected under the ECOHAB PNW grants. Support for Banas was provided by the RISE grant component to Parker MacCready. This is contribution #41, 23, 300, and 609 of the RISE, ECOHAB PNW, ECOHAB and GLOBEC programs, respectively. The statements, findings, conclusions, and recommendations are those of the authors and do not necessarily reflect the views of NSF, NOAA, or the Department of Commerce.

EXECUTIVE SUMMARY

(1) The California Current Large Marine Ecosystem (CCLME) spans approximately 3,000 km of latitude from northern Vancouver Island, British Columbia, Canada to Punta Eugenia, Baja California, Mexico.
(2) Based on latitudinal variation in physical forcing and biological communities, 3 "eco-regions" can be defined within the CCLME. We present preliminary evidence of linkage and interconnections among eco-regions ("sub-ecosystems"). In no one eco-region are all biological indicators available for ecosystem-based approaches to management.
(3) Herein, we present select biological observations as indicators of ecosystem state at multiple time scales.
(4) Based largely on NOAA's previous sentinel species program, we compiled time-series representing ecosystem "productivity". We have not attempted to integrate these indicators in this report.
(5) In recent years, the CCLME experienced unusual "ocean climate" as shown by the Pacific Decadal Oscillation index (PDO) and multivariate El Niño/Southern Oscillation index (MEI). There have also been obvious changes in the seasonal cycle of upwelling in the northern and central eco-regions.
(6) This variation in ocean climate has led to significant changes in food webs, as shown by: (i) higher copepod diversity and lower copepod and euphausiid (krill) biomass, (ii) reduced market squid (*Loligo opalescens*) abundance, and (iii) reduced and/or altered distribution and abundance of northern anchovy (*Engraulis mordax*), Pacific sardine (*Sardinops sajax*) and a suite of age-0 rockfish (*Sebastes* spp.).
(7) Vertebrate predators responded to these changes in the food web. Coho salmon (*Oncorhynchus kisutch*) survival has been very low and many seabirds experienced below normal breeding success, with unprecedented breeding failures of the dominant planktivorous species (Cassin's Auklet, *Ptychoramphus aleuticus*) in 2005 and 2006.
(8) Recent observations are best viewed in the context of long-term ecosystem fluctuations. Since the late 1980s/early 1990s, there have been signs of increasing system variability, diminishing ecosystem productivity, and declines in species with "sub-arctic" bio-geographic affinities. Some top predators are showing opposing changes. There has been increasing production of a dominant marine mammal (California sea lion, *Zalophus californianus*) and apparent decreasing production of large predatory fishes (e.g., Pacific hake *Merluccius productus*).
(9) The causes of these changes are not well understood, but possible mechanisms of change include (a) increased ocean stratification which may limit the efficacy of upwelling and primary productivity, (b) reduced advection and transport of cold, sub-arctic water and organisms to the ecosystem, or (c) ecosystem effects due to other human activities such as fishing.

INTRODUCTION

What is an Integrated Ecosystem Assessment?

An Integrated Ecosystem Assessment (IEA) is a dynamic, decision-support tool for management of living marine resources. Fluharty et al. (2006) include the following specific objectives for IEAs to be developed for each large marine ecosystem (LME) in the U.S.:

- To compile relevant data sets for the ecosystem (e.g., physical oceanography, atmospheric, climatological and weather observations, human use patterns and statistics, abundance and distribution of biological resources),

- To report on current conditions and trends in relevant data time series of physical, biological and human uses,

- To synthesize time series data to link important ecological outcomes to changes in relevant climate and human use drivers (i.e., forecasting),

- To evaluate data time series; provide suites of key indicators of ecosystem state (status); propose reference levels for safe and for desired states of the ecosystem,

- To forecast relationships between state indicators and pressure indicators (e.g., pollution, climate change, fishing-related removals, coastal development, etc.) to inform management, and

- To provide periodic ecosystem assessment updates to inform managers, stakeholders and the public on the state of the ecosystem.

For the California Current LME (CCLME), there are many physical and biological components that warrant observation and understanding, from a mechanistic perspective, to derive factors affecting key ecosystem form, function, and control, and the population dynamics of the top vertebrate marine predators (fish, seabirds, sea turtles, and marine mammals) of significant management concern. In this document, we present records (time-series) of key biological organisms, describe these data in the context of recent and long-term changes in the ecosystem, identify apparent gaps in knowledge, and outline possible future directions for CCLME IEA development. We emphasize that this *initial* [biological indicator] approach to development of a CCLME IEA should be complemented by other approaches (e.g., ecosystem modeling) and that the indicators shown herein are not comprehensive. Nonetheless, we suggest that the species and parameters selected are useful for understanding the population biology of species of management concern, and are therefore of great value to state and federal authorities in the CCLME.

The California Current Large Marine Ecosystem: Form, Function, and Controls

The CCLME is a large, dynamic and spatially heterogeneous marine environment in the eastern North Pacific Ocean off the west coast of North America (Duda and Sherman 2002). It spans nearly 3,000 km of latitude, from approximately the northern tip of Vancouver Island, British Columbia, Canada to Punta Eugenia, Baja California, Mexico (Figure 1). Several major physical oceanographic processes, all linked to variability in atmospheric circulation and the flow of dominant currents in the region, determine ecosystem form and function. These include *local effects* through coastal upwelling, effects of meso-scale structures (e.g., fronts and eddies) formed by jets and meanders of upwelling plumes and the California Current itself, and influences of *basin-scale* winds on sub-arctic and sub-tropical water mass intrusions. From an oceanographic perspective, the CCLME is under influence from the northern and western Pacific, as well as the tropical eastern North Pacific.

Atmospheric Considerations

The strength and juxtaposition of the North Pacific High relative to the Continental Low in summer and Aleutian Low in winter determines the phasing and amplitude of winds which force coastal upwelling and the strength of the California Current (Hickey 1979, Chelton et al. 1982). However, winds, currents, and upwelling within the CCLME are not homogenous; there is substantial latitudinal variation in physical forcing mechanisms. In the north, the CCLME is dominated by strong seasonal variability in winds and upwelling, whereas in the south there is less of a “seasonal cycle” in these parameters, meaning that winds and upwelling are more constant.

Habitat Considerations

There are numerous regions of elevated primary and secondary productivity, including seamounts, capes and coastal promontories (Figures 1 and 2). These highly productive “hotspots” offer favorable habitat for juvenile salmonids, and serve as spawning and feeding grounds for important small pelagic fish such as sardines, anchovies, and smelts. These also provide dynamic locations for trophic interactions, including foraging opportunities for a diverse, abundant suite of vertebrate predators. Many of these species are highly-migratory, visiting the CCLME from breeding grounds in Alaska (e.g., fur seals, northern fulmars), Baja California (e.g., gray whales), the Western Pacific (e.g., bluefin tuna, leatherback turtles), and as far as the southern hemisphere (e.g., several shearwaters and petrels). These living marine resources support vast societal interests, including commercial and recreational fishing and ecotourism.

Variability

Despite being diverse and productive, the CCLME is highly variable. Natural variability is exemplified by the Pacific Decadal Oscillation (PDO; Figure 3) and the El Niño/La Niña phenomena (Figure 4). These basin-scale environmental fluctuations have significant physical oceanographic (Bograd et al. 2003) and ecological effects, altering primary productivity and food webs (zooplankton: McGowan et al. 2003, Brinton and Townsend 2003; forage fish: Chavez et al. 2003). This variation in turn affects top predators (Ainley et al. 1995, Veit et al. 1997, Sydeman and Allen 1999, Sydeman et al. 2001, Hyrenbach and Veit 2003). Therefore, temporal environmental variability presents a fundamental challenge to management as population changes must be viewed from the perspective of normal ecosystem fluctuations (Botsford et al. 1997).

Human Impacts

Anthropogenic stressors, such as fishing, coastal development, pollution and global climate change affect the CCLME. These human impacts may act synergistically with natural ecosystem variability if they occur at the same time and place. For example, the west coast population of Pacific sardine (*Sardinops sagax*) was driven to low levels (and economic extinction) by extensive fishing during a period of adverse climatic conditions for this species (Chavez et al. 2003). Thus, understanding the potential interactions between natural and anthropogenic impacts is central for management of the CCLME.

Sub-ecosystem structure

The California Current is formed as the eastern leg of the North Pacific Gyre. The intensity of the transport in the California Current varies by season, year, and decade. It fluctuates, in part, relative to the position and strength of the North Pacific Current/West Wind Drift, which traverses the sub-arctic North Pacific Ocean and bifurcates between southern British Columbia and northern Oregon into the Alaska Current and California Current. While Washington and southern British Columbia may be considered a “transition zone,” we define the northern boundary of the CCLME as the northern tip of Vancouver Island, B.C., due to frequent upwelling along this section of the coastline in spring and summer (Allen et al. 2001, Whitney et al. 2005). Based on physical and biological attributes, U.S. GLOBEC (1992) subdivide the CCLME into three distinct “eco-regions” or sub-ecosystems: (1) southern British Columbia, Washington and Oregon to Cape Blanco; (2) Cape Blanco, southern Oregon, to Point Conception, California; and (3) southern California and Baja (Figure 5). Due to seasonal and longer-term climate variability, it is recognized that the boundaries of these broad eco-regions are dynamic and shift under varying oceanographic conditions.

RESULTS

Long-Term Research in the CCLME

Several long-term research projects investigating the CCLME have been conducted, with coverage spanning the entire ecosystem and 3 eco-regions (Table 1); at least three projects have over 20 year of data (Figure 2, Goericke et al. 2007). Data from several of these projects will be shown and discussed.

Recent Status of the CCLME

Basin-scale environmental indices

The PDO index (Figure 3) and Multivariate El Niño index (MEI; Figure 4) have both been in a positive (i.e., warm eastern North Pacific) state more or less continuously since late 2002. From late 1998 to early 2002, these indices were negative after nearly a decade in the 1990s of consistently positive anomalies.

Temperature and Upwelling

According to many studies, sea-surface temperature (SST) in the CCLME has increased by 0.5^{o}C to 1.0^{o}C over the past 50 years. Upwelling, however, has been variable, with an apparent general increase in NOAA's west coast upwelling index (Schwing and Mendelssohn 1997). Interannual variability in upwelling has been substantial, especially in recent years. In 2005, upwelling was delayed and/or interrupted and sea surface temperatures (SST) were ~2˚-6˚C warmer than normal (GRL 2006). In 2006, weak upwelling was noted in the central eco-region, while strong upwelling occurred in the north. The situation in the southern eco-region was different in both years, as average upwelling and SST was apparent (Peterson et al. 2006).

Zooplankton

Biologically, these unusual oceanographic conditions resulted in numerous changes in key ecosystem indicators. Off Oregon, copepod species richness was elevated with below-average abundance of northern-boreal species, particularly in 2005 (Figure 6). Copepod biomass in 2005 was the lowest on record, whereas it returned to near average in 2006 (Figure 7). It is hypothesized that when advection of waters from the Gulf of Alaska is strong, northern-boreal copepods are more abundant, copepod biomass is higher, and copepods species richness declines (Figure 8). These conditions apparently favor a more productive sub-arctic ecosystem off Oregon.

Off southern California, the seasonally-derived "small plankton volume" index (copepods and euphausiids) based on the California Cooperative Oceanic Fisheries Investigation (CalCOFI) program (Figure 2c) was slightly (though not significantly) below average in 2005 or 2006 (Figure 9). Average or slightly elevated zooplankton biomass was noted in the southernmost limits of the CCLME, off Baja California, in these years as well (Peterson et al. 2006).

The abundance of the euphausiid *Thysanoessa spinifera* in the diets of fish off Vancouver Island, Canada, was also below average in 2005 and 2006 (and continuing during winter 2007; Figure 10). Similarly, the abundance of euphausiids in the diet of a planktivorous seabird (Cassin's Auklet, *Ptychoramphus aleuticus)* off central California was anomalously low in 2005 (Figure 11). These euphausiids are keystone species in the coastal food webs of the CCLME.

Squid

Market squid (*Loligo opalescens*) in the southern eco-region were below-normal in 2005 and 2006 as evidenced by both landing data and California sea lion (*Zalophus californianus*) diet (Figure 12).

Forage fish indices

Northern anchovy (*Engraulis mordax*) and Pacific sardine egg counts in spring (April) 2005 and 2006 were very low, especially in comparison with 2001 – 2003 period (Figure 13). The relative increases and decreases in anchovy versus sardine eggs between years may be attributed to temperature and upwelling (Lluch-Belda et al. 1991, Jacobson and MacCall 1995).

The abundance of juvenile age-0 rockfish (*Sebastes* spp.) was exceptionally low in 2005. Essentially, complete recruitment failure in the central eco-region was observed (Figure 14). Juvenile rockfish were also conspicuously absent from the diet of a piscivorous seabird (Common Murre, *Uria aalge*) in 2005 and 2006 (Figure 15).

Vertebrate predators

Coho salmon (*Onchorhynchus kisutch*) returns to hatcheries (the Ocean Production Index [OPI]) were below average in 2005 and 2006 (Figure 16), pointing to poor ocean conditions in 2004 and 2005, the years of ocean entry. These years, though demonstrating reduced returns, were not as poor as during the mid 1990s (Peterson and Schwing 2003). Juvenile coho salmon growth off of the west coast of Vancouver Island in 2005 was the lowest on record since 1998 (DFO 2006).

Breeding success for most seabirds in the central eco-region was below average in 2005 and 2006, including complete breeding failure by the obligate planktivore (Cassin's Auklet) in both years (Sydeman et al. 2006, Figure 17). The two most common euphausiid species, *Euphausia pacifica* and *Thysanoessa spinifera*, were found in anomalously low proportions in Cassin's Auklet diet in 2005 (Figure 11).

The abundance of California sea lions (indexed by the anomaly in pup production from a rookery in the Channel Islands) was high and continuing an increasing trend since the mid 1980s (Figure 18), with the exception of the 1998 El Niño/Southern Oscillation (ENSO).

DISCUSSION

Up-scaling

There are regional differences within the CCLME in climate forcing and ecosystem response (Figures 5 and 19). Therefore, an assessment of the southern California Current region (eco-region 3) may vary from that for the northern California Current (eco-region 1). When considering an overall IEA for the CCLME, it may prove most useful to evaluate each eco-region/"sub-ecosystem" separately. But, in no single region are all the physical, chemical, and especially biological attributes available for comprehensive analyses. Therefore, to understand ecosystem form, function, and control, we must combine information between regions.

A simple mechanistic example for co-variation

The northern CCLME is dominated by strong seasonal variability in winds, temperature, upwelling, and plankton production. In addition to weak, delayed or otherwise ineffectual upwelling, warm-water conditions in this region could result from either onshore transport of offshore subtropical water or northward transport of subtropical coastal waters (Figure 8). Low copepod species richness and high abundance of northern-boreal copepods (Figure 6) is apparently associated with cold, sub-arctic water masses transported to the northern CCLME from the Gulf of Alaska. Therefore, copepod community composition may be used as an indicator of this physical oceanographic process.

Preliminary evidence suggests co-variation between eco-regions. When fatty, sub-arctic northern-boreal copepods are present in the northern CCLME during cool-water conditions, the productivity of the planktivorous Cassin's Auklet, in the central sub-region, increases (Figure 19a). Conversely, when the less fatty subtropical copepods dominate the system in warm-water years (i.e., a higher southern copepod Index), Cassin's Auklet breeding success is reduced (Figure 19b).

Area-based management?

As noted previously, there are regional differences in oceanography and biology. Moreover, within each region, there are differences in habitats that may be related to bathymetry and geology (Figure 20). Understanding the relationships between topography, oceanography, and species distributions will promote better management of CCLME resources spatially, as well as temporally. The relationships between bottom topography and ecosystem productivity are not well known, but so-called "benthic-pelagic" coupling is likely to be important for top predators. Identification and assessment of locations of high trophic interaction may be key to future management and conservation decisions in the CCLME.

Effects of global warming?

Ocean temperatures have increased, and are likely to continue to increase for the foreseeable future. Land is expected to heat faster than the ocean and these contrasts in temperatures may result in higher wind speeds (Bakun 1990, Snyder et al. 2003). Warmer waters are also increasing stratification (Roemmich and McGowan 1995, McGowan et al. 2003). The effects of stronger winds and increased stratification on upwelling, temperature and primary productivity in the CCLME are not well known (but see Schwing and Mendelssohn 1997, Mendelssohn and Schwing 2002), but clearly will have ecosystem consequences.

The timing of the seasonal cycle of productivity is changing (GRL 2006). Just as terrestrial biological systems are experiencing earlier phenology (IPCC 2007), we may observe an earlier (or later) start to the upwelling season in the CCLME, and this may vary by eco-region. If upwelling occurs earlier, we may observe an earlier seasonal cycle, from earlier phytoplankton blooms, to earlier peaks in zookplankton abundance. In contrast, as noted previously, if the efficacy of upwelling is weakened and/or delayed by increased water stratification, the seasonal cycle of different organisms may be offset, leading to mismatches between trophic levels in the abundance or availability of prey.

With these contrasting scenarios in mind, the potential for increased variability in the CCLME is probable. A more volatile climate with more extreme events will impact biological systems of the CCLME. Notably, by 2030, the minimum value of the PDO is expected to remain above the mean value for the 20th century. In addition, evidence of variability and declines in biological systems in the CCLME since ~1990 has already been shown. Such changes and others (e.g., range shifts in species' distributions) are likely to continue.

Data gaps and some future directions

We have many gaps in the long-term datasets that need to be identified and filled. For example, there has been extensive work in Monterey Bay, California on changes in phytoplankton community structure (e.g., a ratio of diatoms to dinoflagellates), and new work is commencing in Oregon (B. Peterson, personal communication). The ratio of diatoms to dinoflagellates appears to be an important index for food web development. Having this type of information available for other locations in the CCLME would be extremely valuable.

The species and parameters we have chosen are representative of different trophic levels, and known to be linked by trophic relationships, and have been considered in other ecosystem reports (Peterson et al. 2006, Goericke et al. 2007). No doubt, there will be other variables to consider, but this suite of parameters will be critical to any IEA developments for this system.

Importantly**,** we have not addressed the human dimension (fishing, development, pollution, etc.) on ecosystem dynamics. As intended, this report has focused on long-term observations (Table 1) and some key biological indicators. We have not considered socio-economic data and other human-related data, though this has been put forth as key to the IEA concept overall (Fluharty et al. 2006). Incorporating this information could advance an IEA for the CCLME.

One of the goals of IEA is to forecast future conditions for the ecosystem under consideration. This is difficult, but it is essential to consider how to best develop forecasting capabilities. Part of the solution may be to integrate, statistically, what is known and previously summarized. Integration of these indicators is therefore a primary goal of future IEA developments, which should also include modeling components. Coupling complementary field observations with spatially explicit ecosystem modeling, while beyond the scope of this document, is clearly needed to answer key ecological and management questions as well as to evaluate the efficacy of various CCLME monitoring programs.

Table 1. Summary of select long-term (10 years or longer) research projects of the CCLME.

Project name and coordinators	Region	Years covered	Description
Line P, Department of Fisheries and Oceans Canada (DFO) & others	1	1949 – present	Oceanographic sampling began on ships used for enhanced weather forecasting off British Columbia, Canada. Since then, vessels from the DFO have followed the same ~1,500 km cruise track from Vancouver Island (48.51°N, 124.81°W) to Ocean Station Papa (50.0°N, 145.0°W) 2-3 times each year (Figure 7a). Hydrography, nutrients and lower trophic level productivity is measured. Seabirds and marine mammals are also surveyed.
Rockfish Recruitment Survey, NOAA-NMFS-SWFSC & others	2	1983 – present	NOAA-NMFS and other collaborators have conducted annual surveys in the greater Gulf of the Farallones (Monterey Bay to Bodega Bay) region off central California (Figure 7b). Hydrography and estimates of recruitment for young-of-the-year (age-0) *Sebastes* are priories for this survey. Seabirds and marine mammals are also surveyed.
CalCOFI, NOAA-NMFS, California Department of Fish and Game, Scripps Institution of Oceanography & others	3	1949 – present	The California Cooperative Oceanic Fisheries Investigations (CalCOFI) has been monitoring ecosystem dynamics since 1949. In its current form, the CalCOFI survey grid consists of six parallel transects, ranging in length from 470 (northernmost) to 700 (southernmost) km (Figure 7c). This study area encompasses over 300,000 km^2 of the Pacific Ocean, ranging from 30° to 35° N, and seaward from the southern California coast to 124° W. Hydrography and icthyoplankton surveys are priorities for this program. Seabirds and marine mammals are also surveyed.
Southeast Farallon Island Seabird Ecology, U.S. Fish and Wildlife Service & PRBO	2	1971 – present	The Farallon Islands National Wildlife Refuge, managed by United States Fish and Wildlife Service (USFWS), host the largest marine bird and mammal colonies in the contiguous United States. Under contract with USFWS, PRBO Conservation Science monitors and studies the ecology of 12 seabird species and 5 pinniped species at this site. Daily measurements of SST, salinity, and weather are also made.
Channel Islands Seabird Ecology, Channel Islands National Park, California Center Environmental Studies	3	1968 - present	The California Center for Environmental Studies initiated research on Brown Pelicans (*Pelicanus occidentalis*) in the Channel Islands in the late 1960s. In 1985, the Channel Islands National Park initiated long-term studies of a variety of seabirds at Santa Barbara, Anacapa, and Prince (San Miguel) islands. This time series (not illustrated in this report) shows substantial interannual variability in seabird productivity and trends related to both the recovery of seabirds from DDT contamination of the marine environment and climate variability and change.
Vancouver Island Zooplankton, Department of Fisheries and Oceans, Canada	1	1979 - present	Since 1979, Fisheries and Oceans Canada has measured zooplankton and hydrographic conditions on the Vancouver Island continental margin. The zooplankton time series (not illustrated in this report) shows very strong interannual variability in community composition. Large copepods have shown strong shifts of the seasonal life history timing, becoming progressively earlier from the late 1970s to the present, with variation.
Newport Hydrographic Line, NOAA-NMFS-NWFSC	1	1996 – present (1969-1973)	Biweekly surveys of this line are conducted off Newport, Oregon. Priorities for this survey include hydrography and zooplankton (copepods and euphausiids). This time series augments similar data collected along the same transect in 1969-1973. Seabird observations have recently been added to this program.
Oregon and Washington	1	1998 - present	Hydrography, nutrients, chlorophyll-a, zooplankton and pelagic forage fish are sampled at six stations along each of eight

Forage Fish, NOAA-NMFS			transects ranging from Newport, Oregon to the Washington-Canadian border.
Winds to Whales – Monterey Bay, UC Santa Cruz	2	1996 - present	This interdisciplinary project organized by the Center for Integrated Marine Technologies (UCSC-CIMT) collects data on physical (winds, currents, SST), chemical (nutrients, trace metals, etc.) and biological (phytoplankton, zooplankton, marine mammals, etc.) processes in nearshore Monterey Bay.
Monterey Bay Time Series, Monterey Bay Aquarium Research Institute	2	1989 - present	Monthly shipboard surveys conducted to collect data on physical, chemical and biological properties in Monterey Bay. In1997, the surveys were conducted quarterly and became known as the Studies of Ecological and Chemical Responses to Environmental Trends (SECRET) project.
Tatoosh Island Seabird Ecology, University of Washington	1	1990 – present	Studies of the breeding success and diet of seabirds that inhabit Tatoosh Island, WA, focused on Common Murre (*Uria aalge*), began in 1990.
Triangle Island Seabird Ecology, Canadian Wildlife Service and Simon Fraser University	1	1994 - present	Studies of the breeding success and diet of the seabirds that inhabit Triangle Island. Focus on Rhinoceros Auklet (*Cerorhinca monocerata)* and Cassin's Auklet (*Ptychoramphus aleuticus*). Studies complement previous work conducted by CWS at this site in the late 1970s.
Groundfish Surveys, NOAA-NMFS-NWFSC & Fisheries and Oceans Canada	1	1977 - present	Triennial midwater/acoustic surveys of groundfish, with an emphasis on Pacific hake, are conducted from central British Columbia (Dixon Entrance) to central California (Monterey Bay). Measurements of hydrographic conditions and abundance of fish are priority measurements.

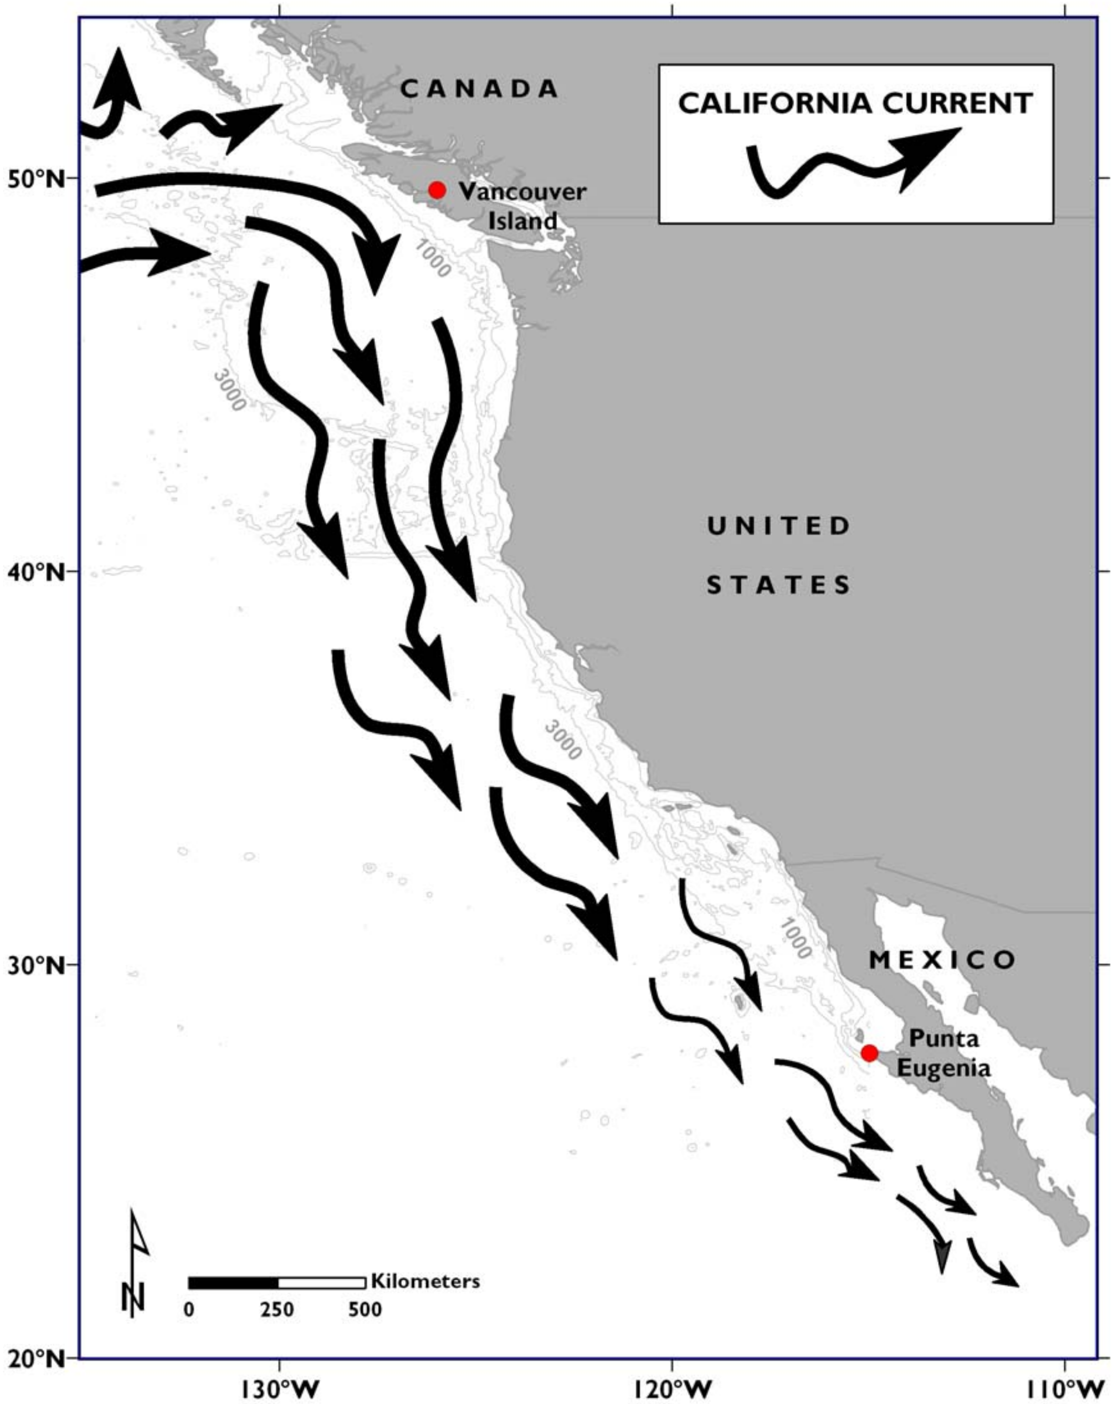

Figure 1. Conceptual map of the California Current Large Marine Ecosystem (CCLME). The geographic scope of this IEA is from Vancouver Island, Canada to Punta Eugenia, Mexico and offshore. Mangroves are found south of Punta Eugenia, but not to the north. The North Pacific Current (West Wind Drift) splits into the California Current and Alaska Current roughly at Vancouver Island.

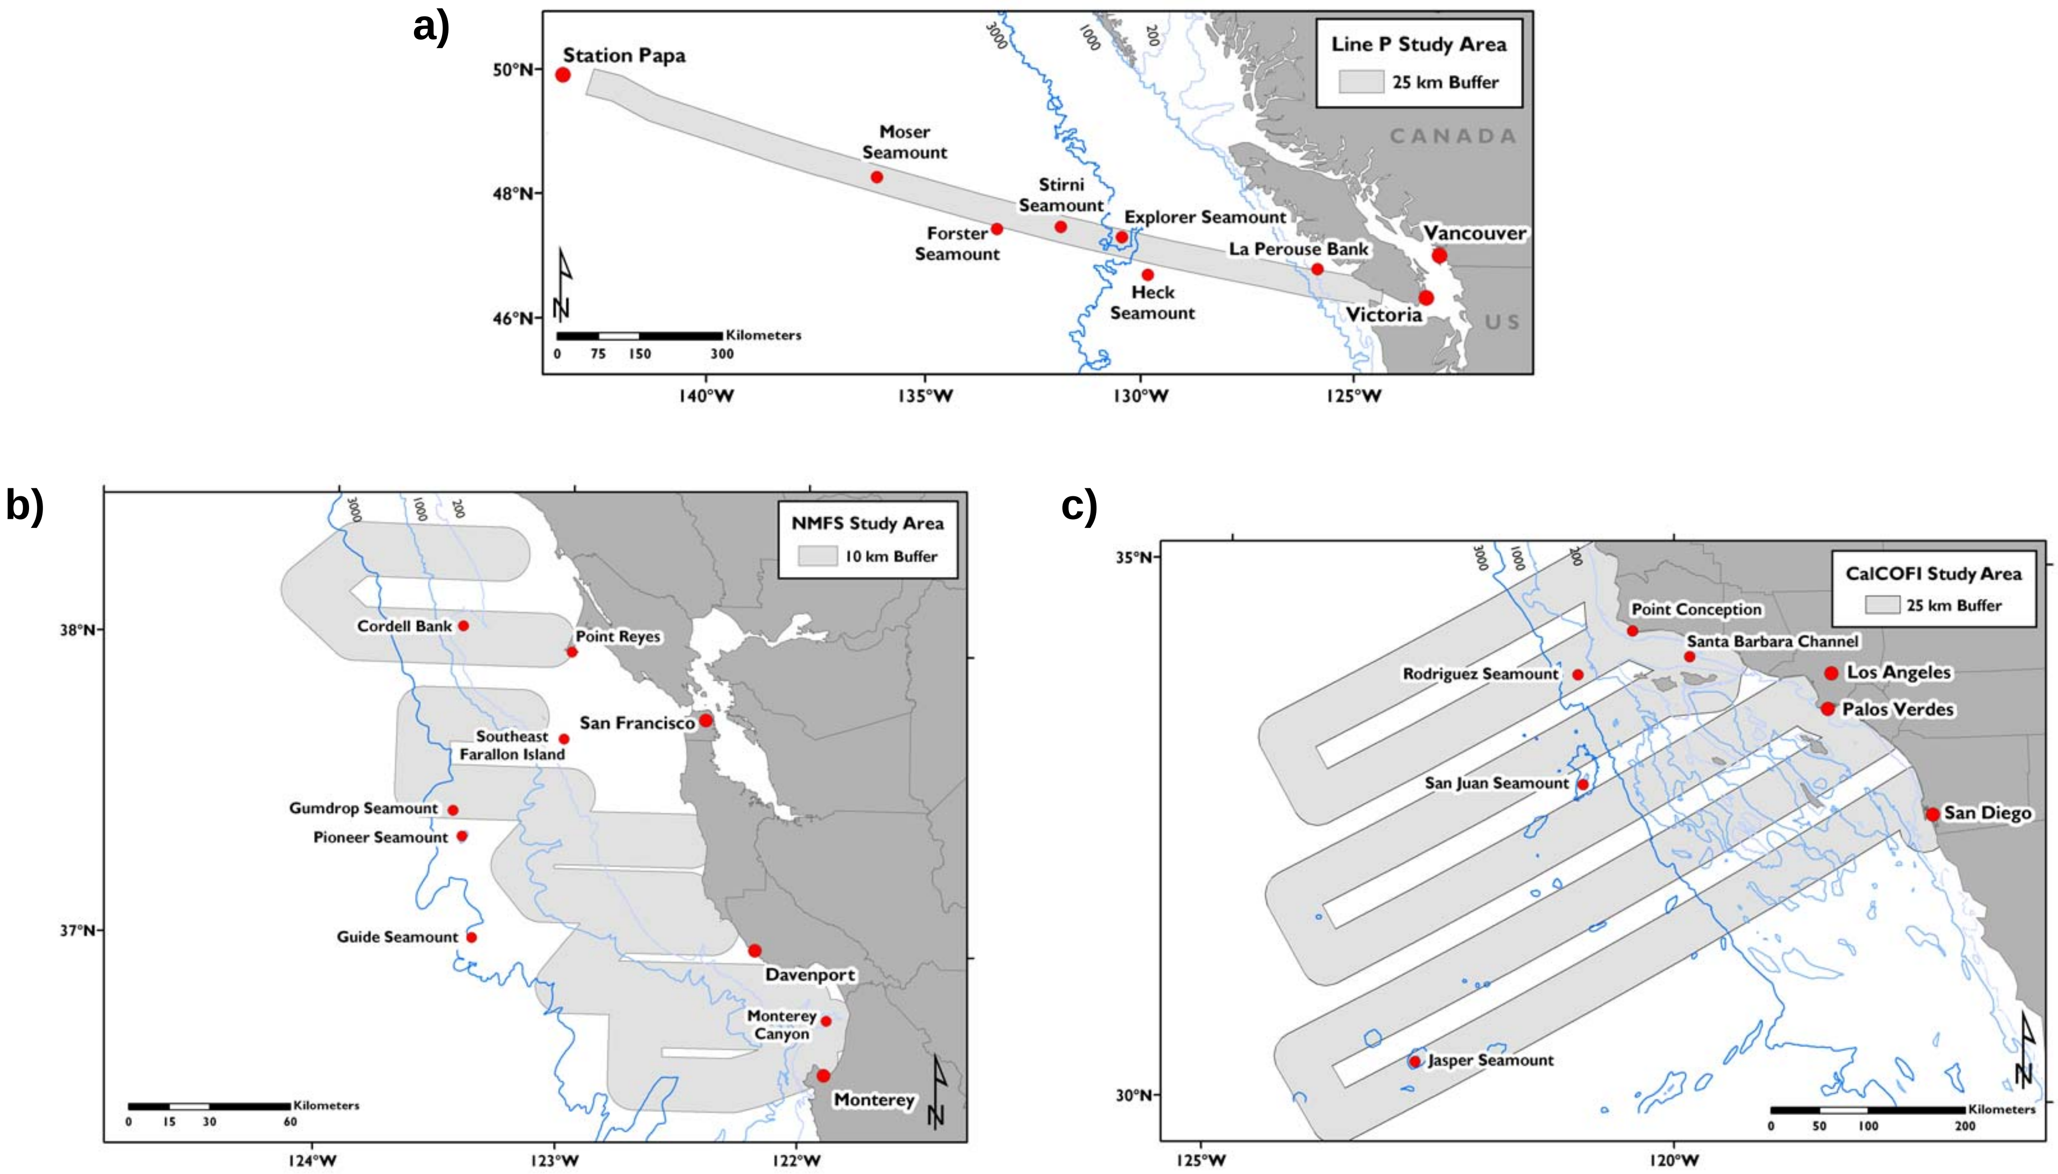

Figure 2. Examples of three (3) long-term oceanographic research programs within the CCLME. Each of these programs has been in operation for over continuous 20 years: (a) the Department of Fisheries and Oceans, Canada, "Line P" project; (b) the National Marine Fisheries Service "Rockfish Recruitment Survey"; and, (c) the "California Cooperative Oceanic Fisheries Investigation" run by a consortium of National Marine Fisheries Service, California Department of Fish and Game, and Scripps Institution of Oceanography. Some shallow-water topographies (offshore seamounts) are illustrated.

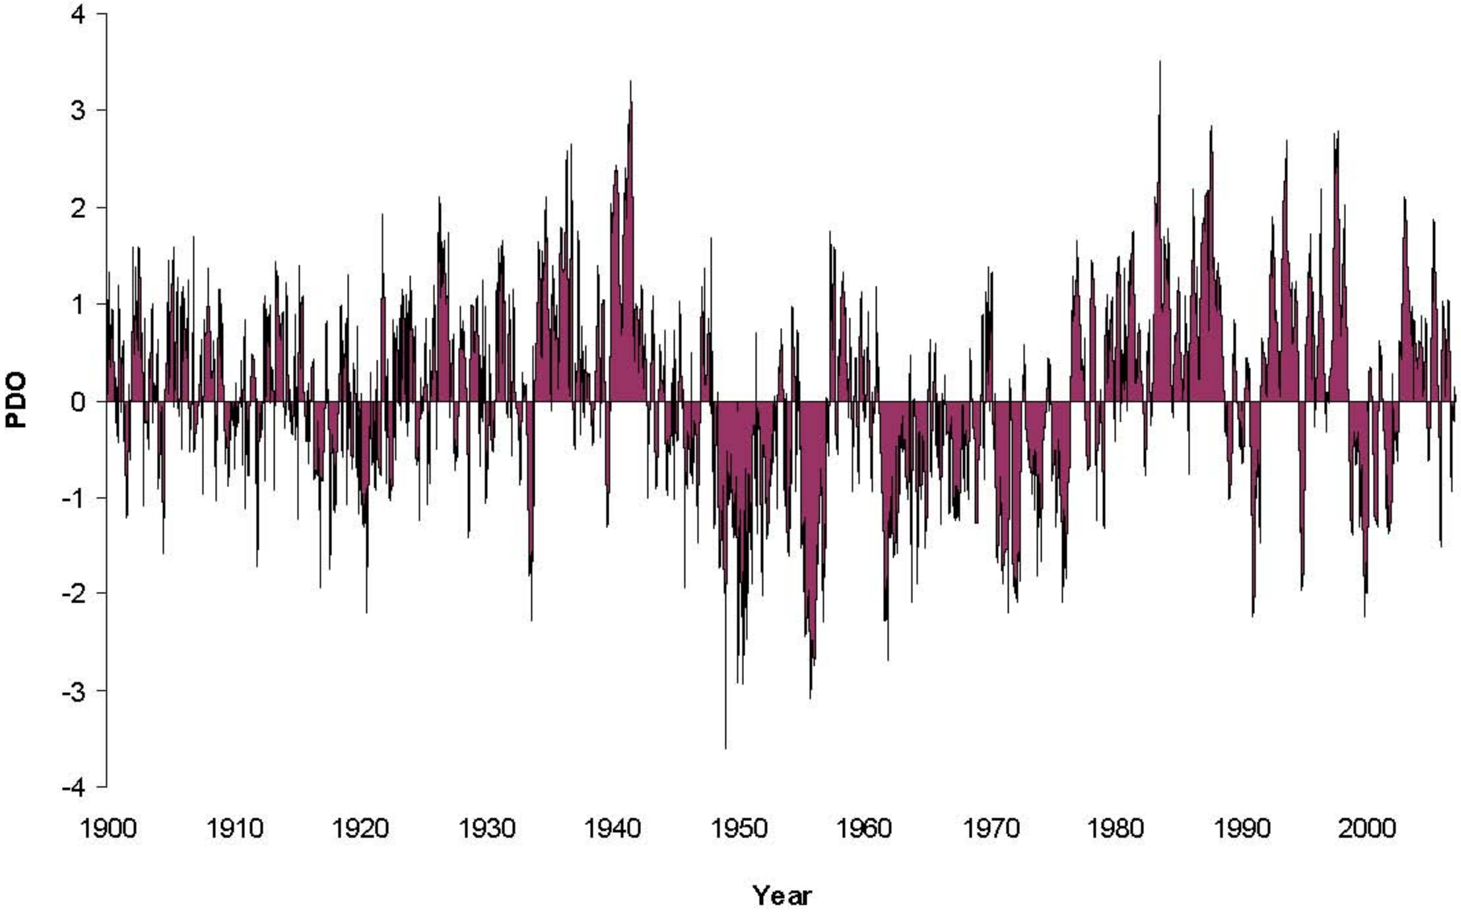

Figure 3. The Pacific Decadal Oscillation (PDO) index (1900-2006). Data courtesy Nate Mantua (Joint Institute for the Study of the Atmosphere and Ocean, UW). Positive values indicate warm eastern North Pacific SST, whereas negative values indicate cool temperatures. The long-term ocean warming signal has been removed to illustrate interannual and interdecadal SST variation. http://jisao.washington.edu/pdo/PDO.latest

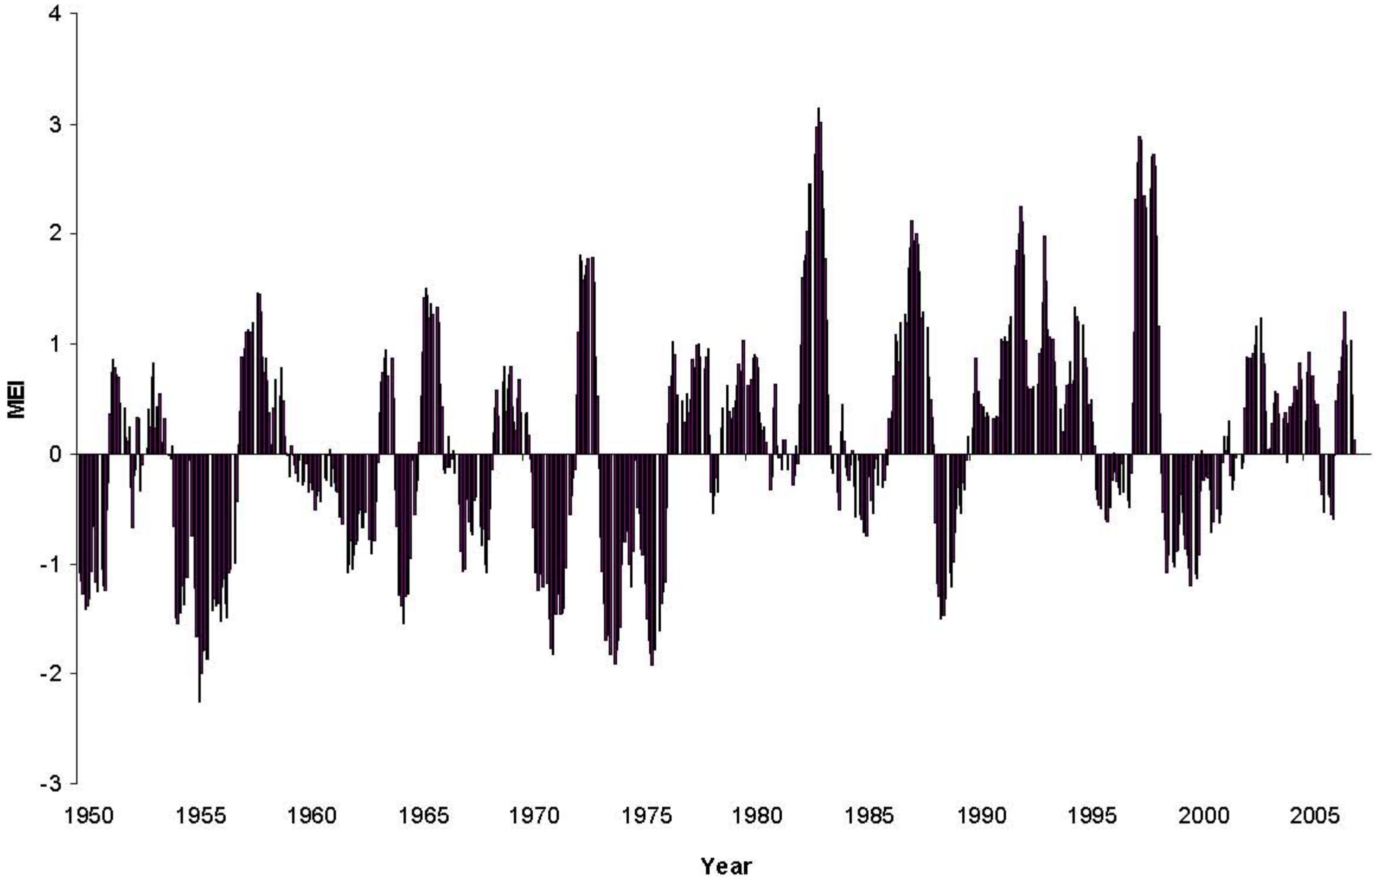

Figure 4. The Multivariate El Niño Index (MEI), 1950-2006. Data courtesy Klaus Wolter (NOAA-Earth System Research Laboratory). Positive values reflect El Niño events whereas negative values indicate La Niña. The MEI is a composite index constructed using 7 environmental variables. http://www.cdc.noaa.gov/people/klaus.wolter/MEI/table.html.

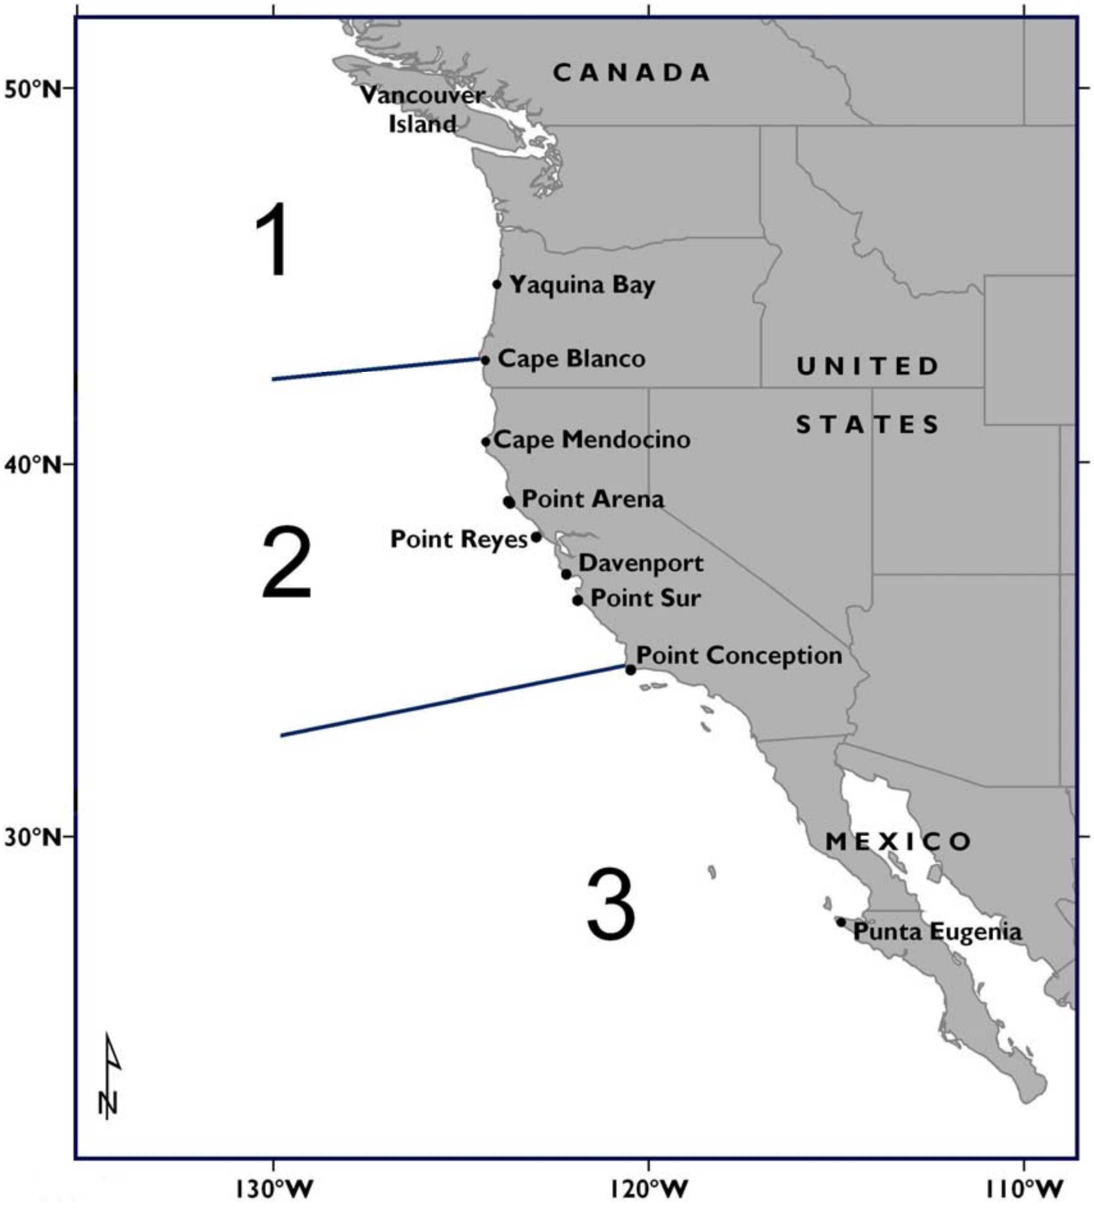

Figure 5. Eco-regions of the CCLME as defined by U.S. GLOBEC (1992). Physical oceanography and biological attributes of the ecosystem vary by region. The degree to which each "sub-ecosystem" co-varies with climate variability and change will be developed in future IEA reports.

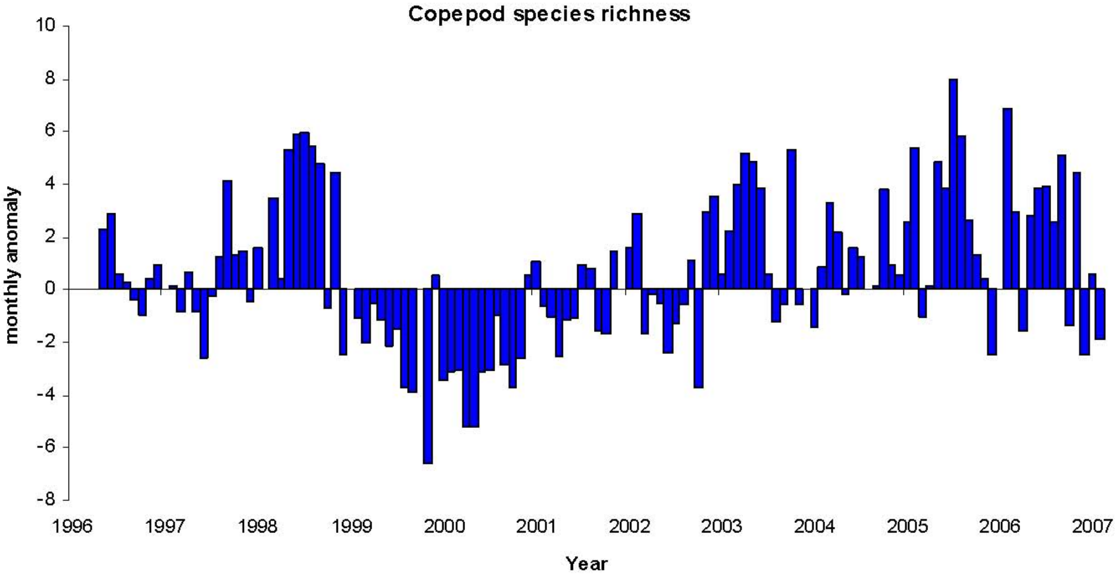

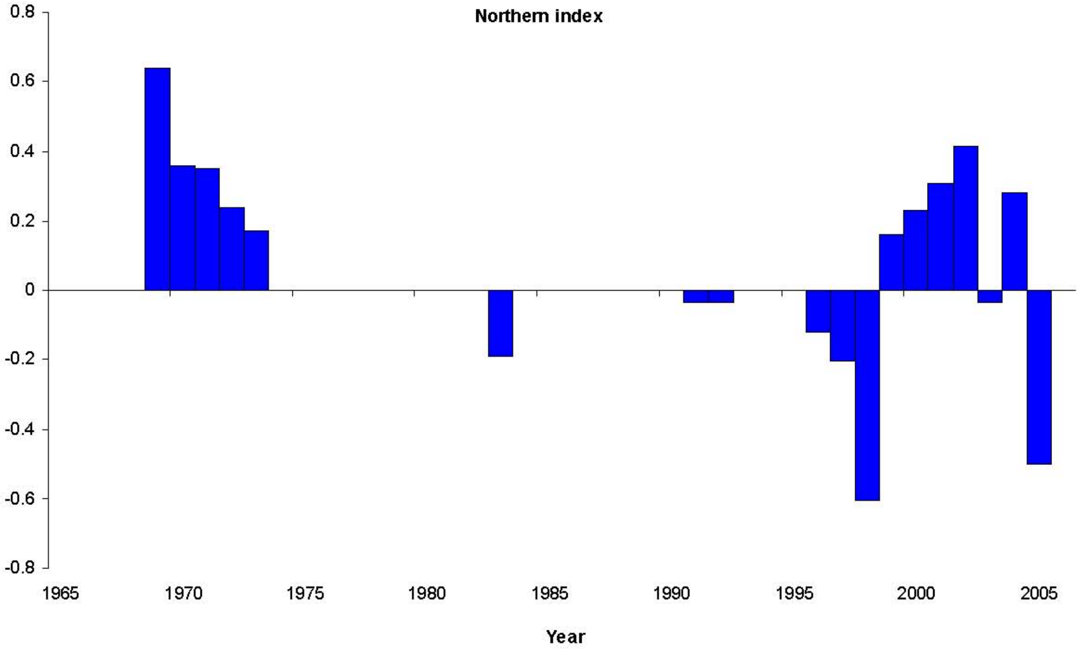

Figure 6. Copepod species richness index (1996-2006), and the "boreal" copepod index (1965-2005) from Newport, Oregon. Note that the time scales differ between the two plots. Data courtesy Bill Peterson (NOAA Fisheries, NWFSC).

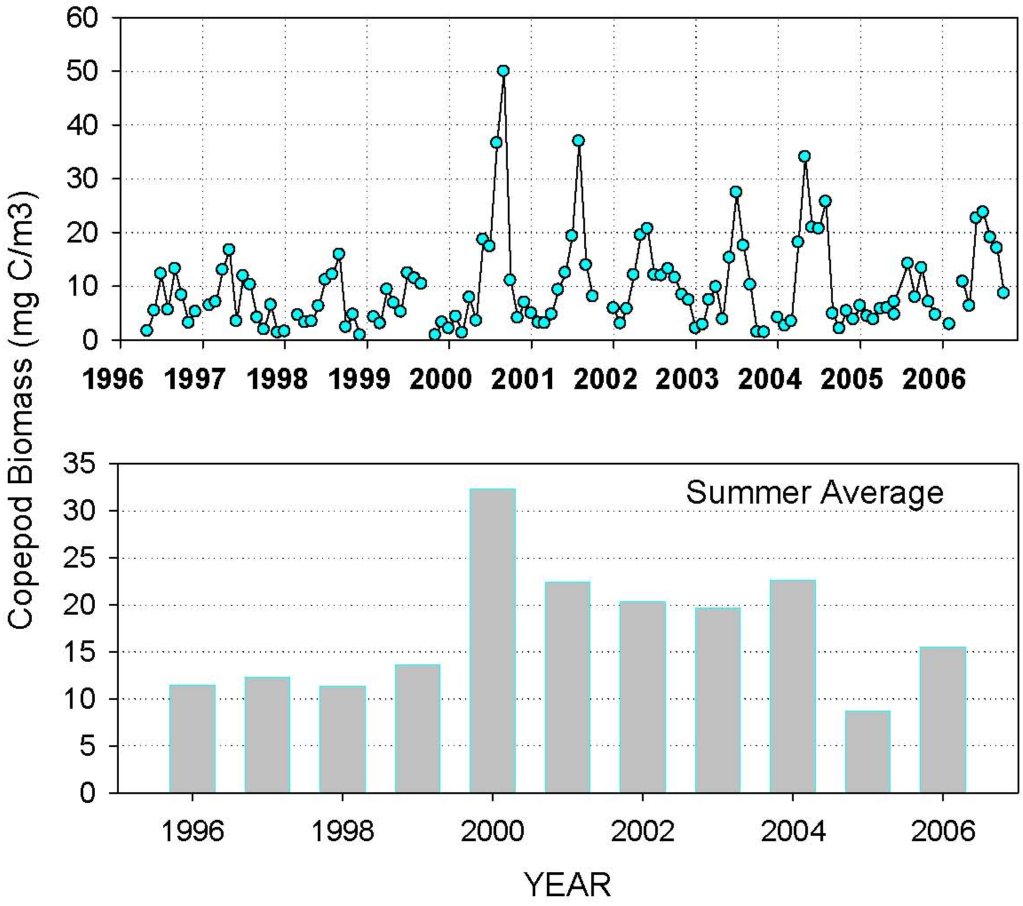

Figure 7. Copepod biomass index from Newport, Oregon (1996-2006). Monthly copepod biomass values (top panel) and average summer biomass values (bottom panel). Data courtesy Bill Peterson (NOAA Fisheries, NWFSC).

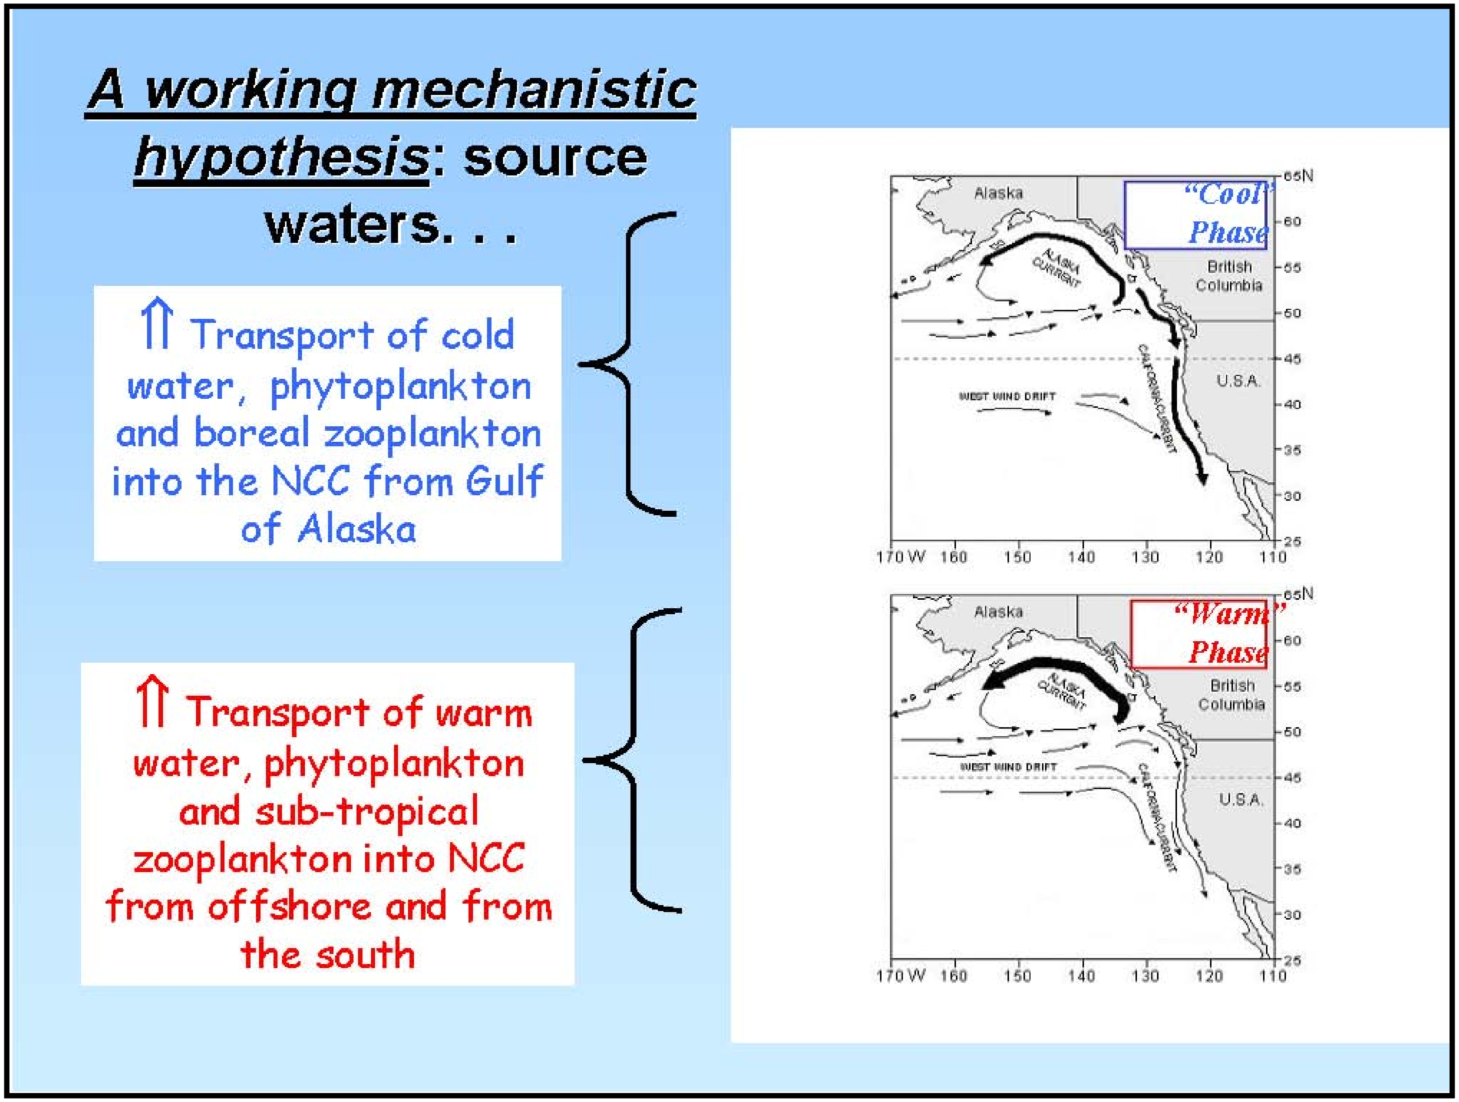

A working mechanistic hypothesis: source waters. . .

⇑ Transport of cold water, phytoplankton and boreal zooplankton into the NCC from Gulf of Alaska

⇑ Transport of warm water, phytoplankton and sub-tropical zooplankton into NCC from offshore and from the south

Figure 8. Hypothesized mechanism for variation in copepod indices off Newport, Oregon. Figure courtesy Bill Peterson (NOAA Fisheries, NWFSC). Transport of organisms from the north and south is proposed to explain these indices.

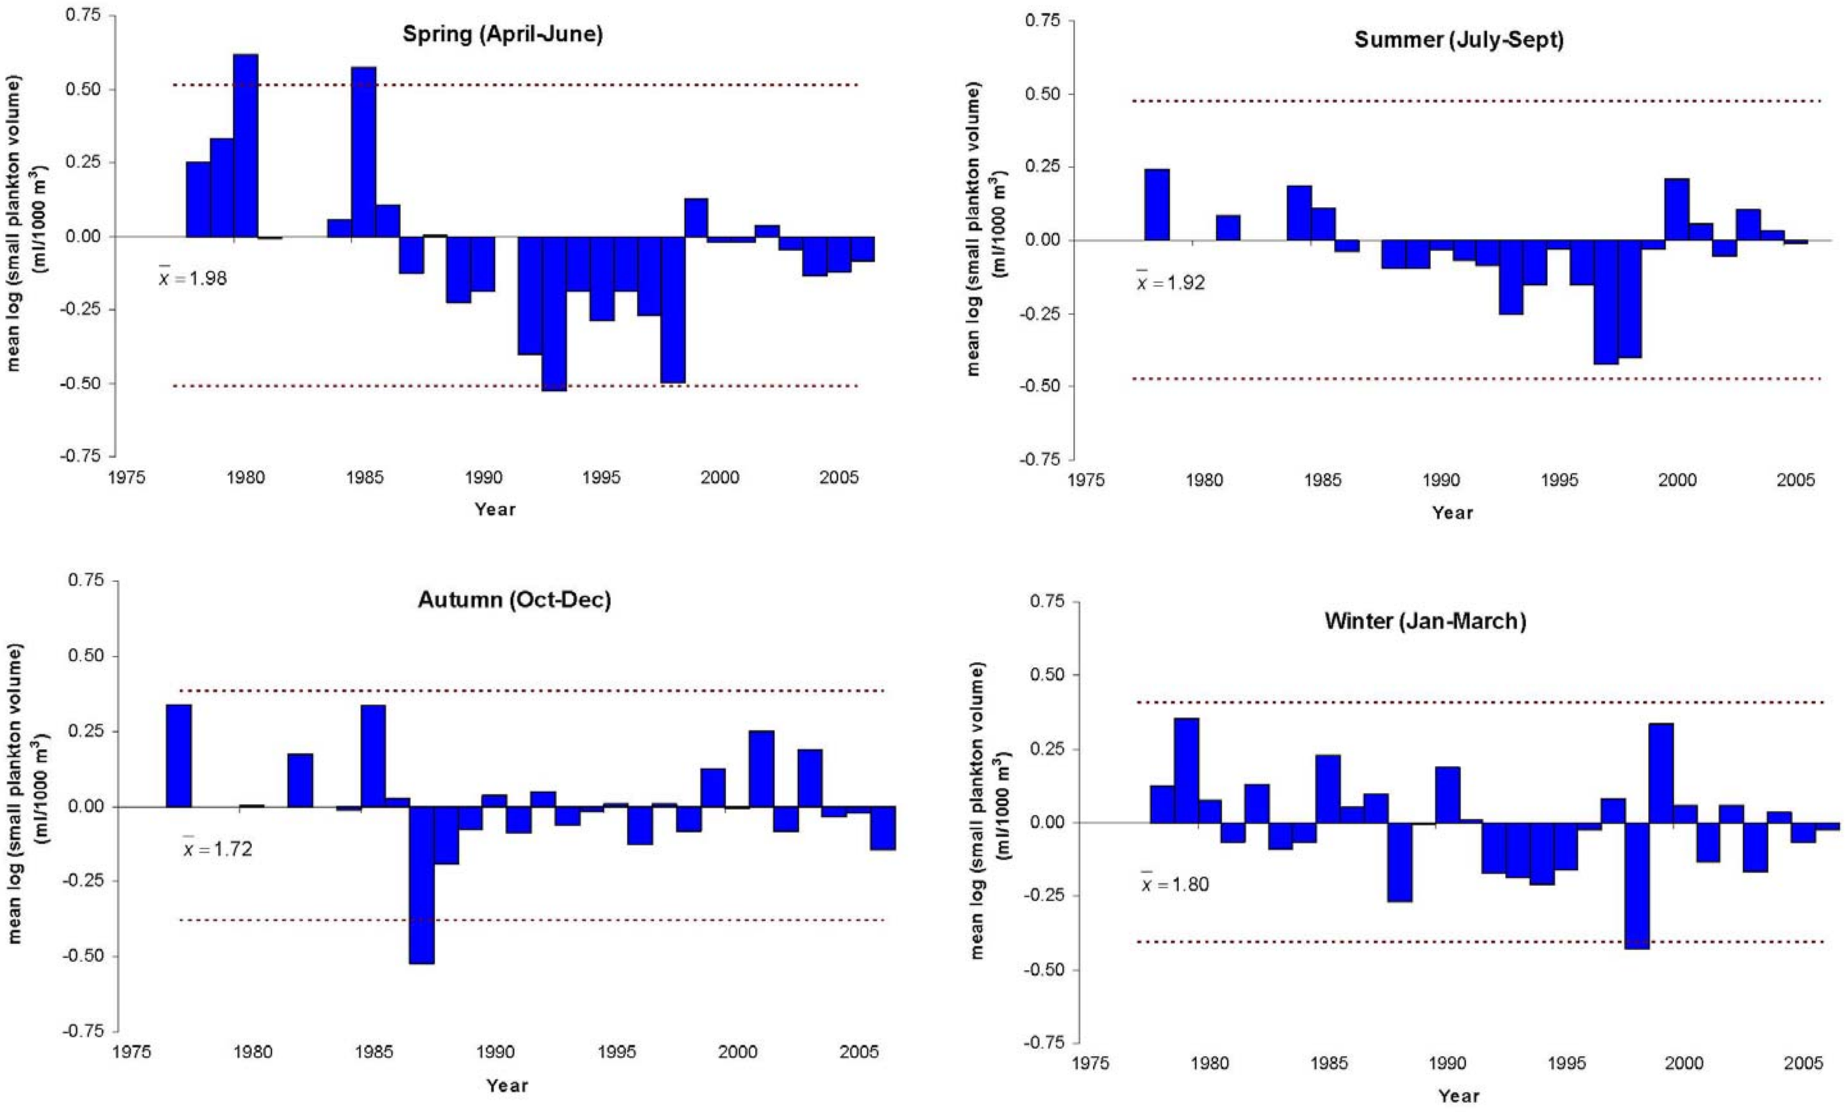

Figure 9. The southern California small plankton volume (SPV) index from CalCOFI (1977 - 2006). SPV includes all plankton with a displacement volume of < 5mL, representing copepods and euphausiids. Anomalies show the deviation of each annual seasonal value from the long-term seasonal mean. Dotted lines represent 1 standard deviation above/below the long-term seasonal mean. Data courtesy Rich Charter (NOAA-Fisheries Resources, SWFSC).

Graphs represent abundance anomalies: (a) the first and second principal components scores; (b) species showing an overall decline in abundance; (c) species showing a recent increase in abundance. Data courtesy Steve Ralston (NOAA-NMFS, SWFSC).

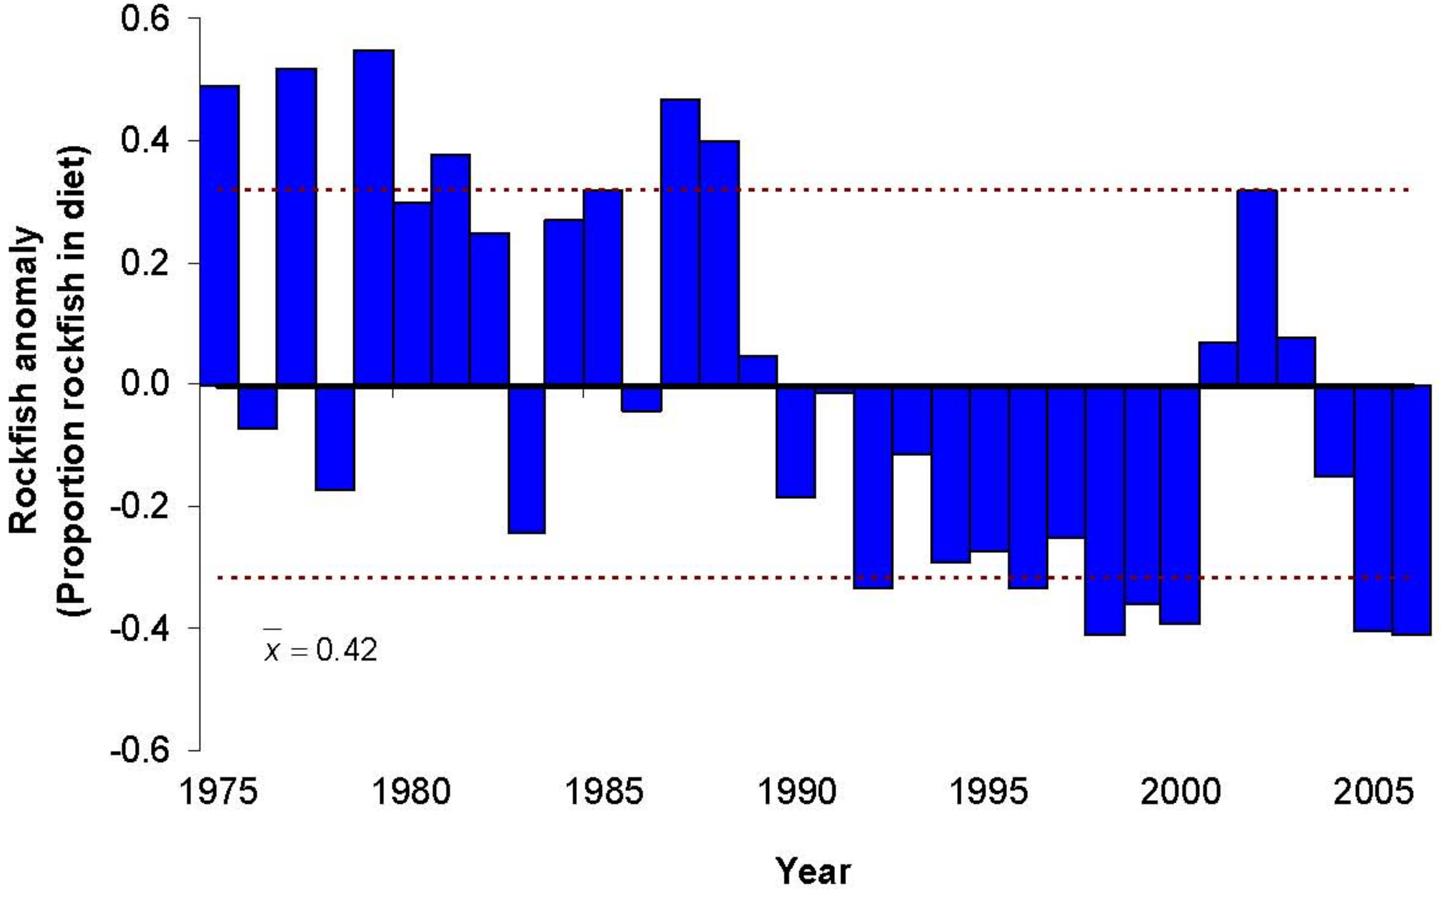

Figure 15. Juvenile (age O) rockfish (*Sebastes* spp.) index based on the diet of a seabird (Common Murre, *Uria aalge*), in central-northern California (1975 – 2006). Data courtesy Pete Warzybok (PRBO Conservation Science).

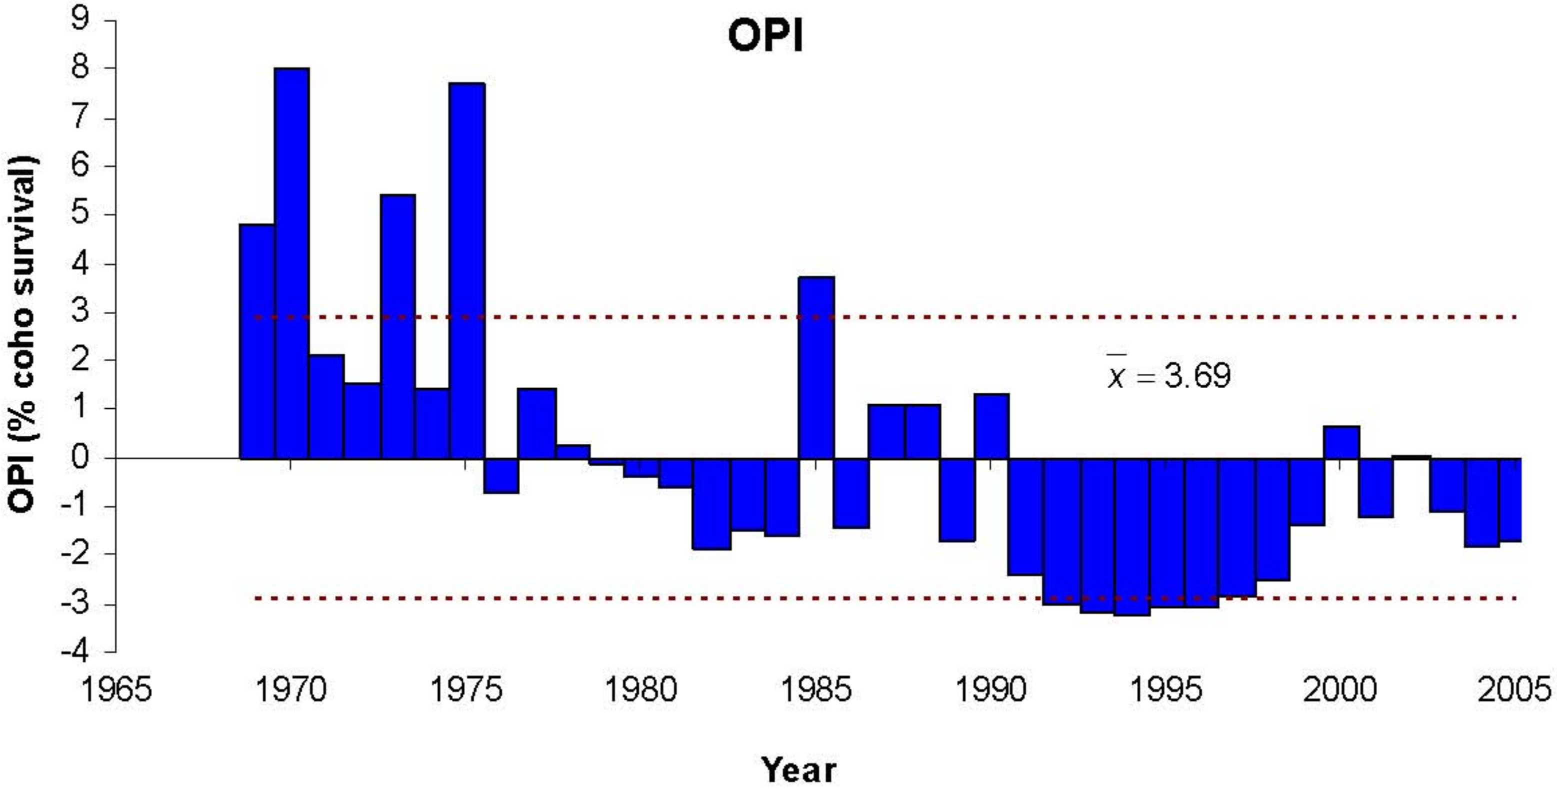

Figure 16. Coho salmon survival at sea as represented by the OPI (Ocean Production Index) anomalies, 1969-2006. Year shown is survival of coho salmon plotted against the year that the fish went to sea (1.5 y before spawning in their natal hatcheries). The 0-line on the y-axis represents the long-term mean (value also shown in graph), and anomalies represent the deviation of each annual value from the long-term mean. Hatched lines represent 1 ± standard deviation from the long-term mean. Data courtesy Bill Peterson (NOAA Fisheries, NWFSC).

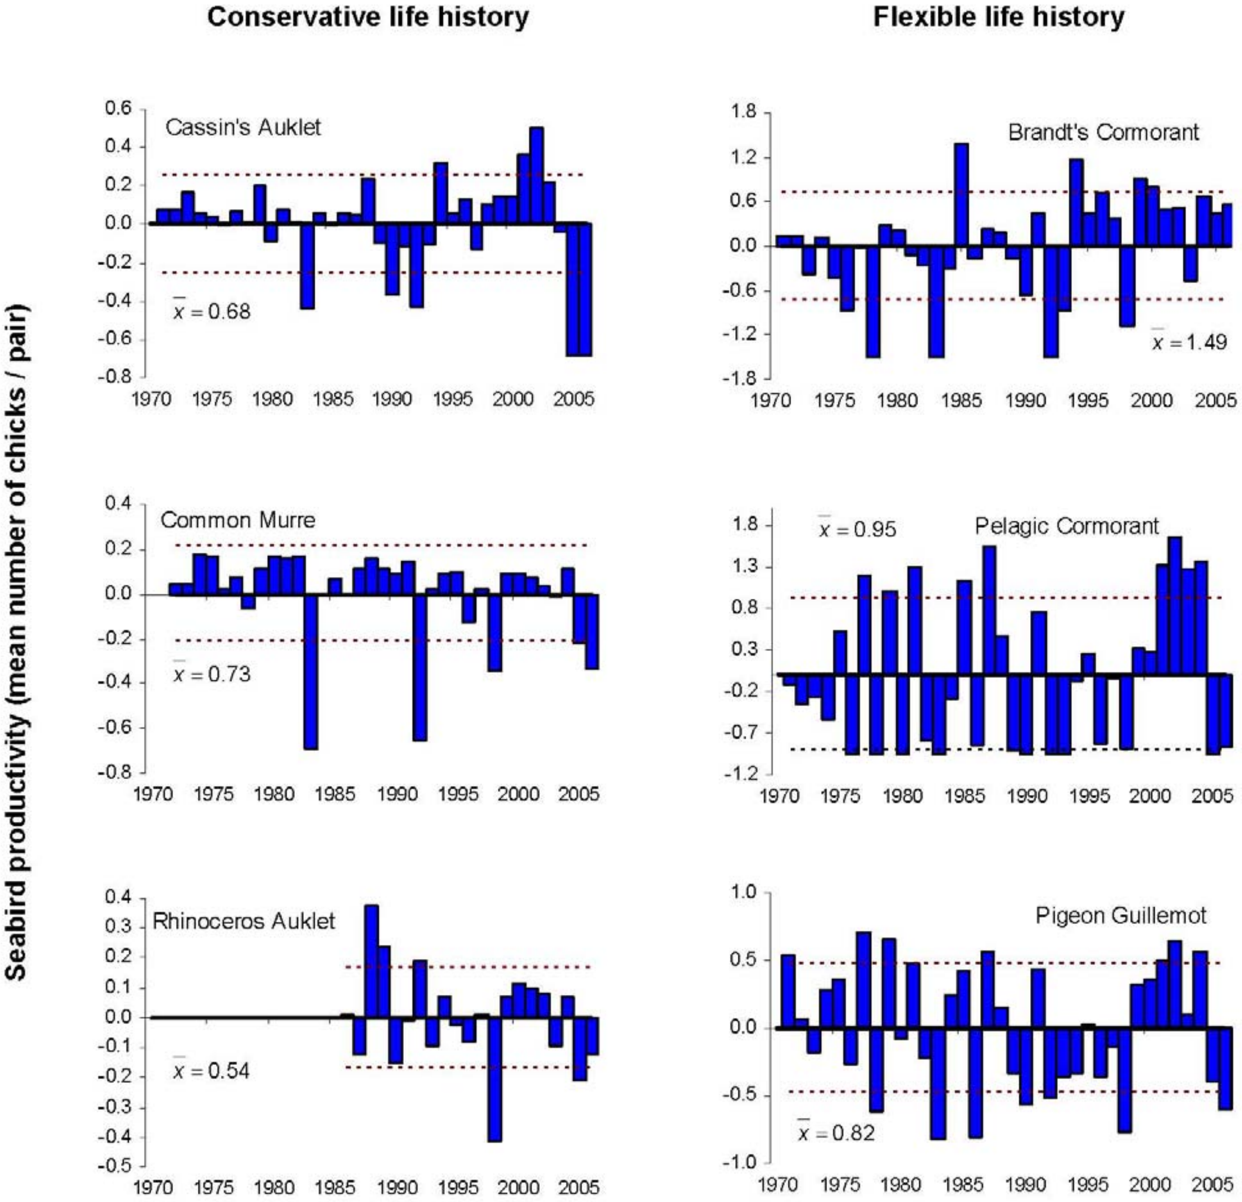

Figure 17. The Farallon seabird productivity index, 1971 - 2006. Data courtesy U.S. Fish and Wildlife Service and PRBO Conservation Science. The annual reproductive success anomalies for 6 species showing varying life history strategies are shown. Auklets and murres lay a single egg per breeding attempt and have great longevity, whereas the cormorants and guillemot lays multi-egg clutches and less longevity. Only the Brandt's Cormorant shows an increase in productivity through time. Data courtesy Russ Bradley, Pete Warzybok, and Bill Sydeman (PRBO).

NOAA Technical Memorandum NMFS-NWFSC Series

The Northwest Fisheries Science Center of NOAA's National Marine Fisheries Service uses the NOAA Technical Memorandum NMFS-NWFSC series to issue scientific and technical publications. Manuscripts have been peer-reviewed and edited. Publications in this series can be cited in the scientific and technical literature. Technical editing services at NWFSC are provided by Al Brown.

The Northwest Fisheries Science Center's NOAA Technical Memorandum NMFS-NWFSC series continues the NMFS-F/NWC series established in 1970 by the Northwest and Alaska Fisheries Science Center, which subsequently was divided into the Northwest Fisheries Science Center and the Alaska Fisheries Science Center. The latter uses the NOAA Technical Memorandum NMFS-AFSC series.

NOAA Technical Memorandums NMFS-NWFSC are available at the Northwest Fisheries Science Center website, https://www.nwfsc.noaa.gov/index.cfm.

Executive Summary

This document is a companion to the ecosystem status report (ESR) provided by the California Current Integrated Ecosystem Assessment team (CCIEA) to the Pacific Fishery Management Council (PFMC) in March of 2017. The CCIEA team provides such reports annually, as one component of the overall CCIEA goal of providing quantitative, integrative science tools, products, and synthesis in support of ecosystem-based management of marine resources in the California Current.

The indicators summarized in this report represent our best understanding of environmental, ecological, and socioeconomic conditions in the California Current Ecosystem approximately through 2016, though some time series are slightly more up-to-date and others slightly less so depending on the time required for data processing. The indicators have been codeveloped by the CCIEA team and the PFMC through an iterative process since the inception of the CCIEA project in 2009.

Oceanographic and climate-related indicators revealed a shift relative to the previous several years. Following the unprecedented warm anomaly of 2013–16 and the major El Niño event of 2015–16, most large-scale climate indices for the Northeast Pacific (the Oceanic Niño Index, the Pacific Decadal Oscillation, and the North Pacific Gyre Oscillation) returned to relatively neutral values. Coastal upwelling was relatively weak in the northern California Current throughout 2016; upwelling along the central coast was initially weak, but strengthened by summer, while upwelling on the southern coast was average to above-average. Snowpack rebounded from the extremely low levels of 2015, although much of the 2016 snow melted rapidly, leading to low streamflows; precipitation was well above average in early 2017.

Ecological indicators are expected to lag, to varying degrees, behind the shift in oceanographic and climate patterns. Copepod biomass off Newport, OR, was dominated by relatively energy-poor species as of fall 2016, similar to observations from the last several years. The spring/summer pelagic forage community was once again highly diverse in 2016. Surveys experienced poor catches of sardine (*Sardinops sagax*), market squid (*Doryteuthis opalescens*), and euphausiids. However, surveys had high but patchy catches of juvenile rockfish (*Sebastes* spp.), juvenile Pacific hake (*Merluccius productus*), and anchovy (*Engraulis mordax*). Chinook salmon (*Oncorhynchus tshawytscha*) escapements through 2014–15 varied by region and life-history type. Environmental conditions appear to have been poor for Chinook and coho salmon (*O. kisutch*) that went to sea over the past several years. California sea lions (*Zalophus californianus*) at the San Miguel Island colony experienced very poor foraging conditions to support pups in the 2015 cohort, though preliminary evidence suggests better conditions for the 2016 pups.

Socioeconomic indicators are primarily focused on fishing activity and on human wellbeing in fishery-dependent coastal communities. Commercial fishing landings and revenues declined markedly in 2015, driven mainly by drops in the harvest of Pacific hake, coastal pelagic species, and crabs. The diversification of commercial fishery landings continued the long-term declining trend at all scales (i.e., by state, vessel size, and ex-vessel revenue levels). An index of social vulnerability suggested that several commercial fishing-dependent coastal communities have disproportionately high social vulnerability, and therefore may be heavily impacted by shocks to commercial fishing revenues.

Introduction

Ecosystem-based management of fisheries and other marine resources has emerged as a priority in the U.S. (Ecosystem Principles Advisory Panel 1999, Fluharty et al. 2006, McFadden and Barnes 2009, NMFS 2016) and for many marine resource management agencies worldwide (Browman et al. 2004, Sainsbury et al. 2014, Walther and Möllmann 2014, Long et al. 2015). According to its official policy statement, the NOAA National Marine Fisheries Service (NOAA Fisheries) defines ecosystem-based fisheries management (EBFM) as "*a systematic approach to fisheries management in a geographically specified area that contributes to the resilience and sustainability of the ecosystem; recognizes the physical, biological, economic, and social interactions among the affected fishery-related components of the ecosystem, including humans; and seeks to optimize benefits among a diverse set of societal goals*" (NMFS 2016). This definition includes considerations of interactions within and among fisheries, protected species, aquaculture, habitats, and human communities that depend upon fisheries and related marine ecosystem services. It also includes consideration of the direct and indirect impacts of fisheries on other ecosystem components. An EBFM approach is intended to improve upon traditional fishery management practices that primarily are focused on the level of individual fished stocks.

Successful implementation of EBFM requires a considerable amount of effort and coordination, due to the formidable amount of information required and uncertainty involved. Research on marine systems and adjacent, associated systems amasses tremendous amounts of data from numerous disciplines. These data represent a wide range of processes and are expressed in currencies ranging from physical or chemical units to species biomass estimates to revenue streams or sociological measures. Assimilating this volume of diverse information into synthesis products is inherently difficult. Furthermore, even the best modern monitoring programs are still confronted with uncertainties because of the technical, logistical, and financial challenges of measuring statuses and changes in large, complex, and highly variable systems like the ocean and the human societies that depend upon and interact with it.

In response to this complexity and uncertainty, scientists throughout the world have developed many frameworks for organizing science and information in order to clarify and synthesize this overwhelming volume of data into science-based guidance for policymakers. NOAA Fisheries has adopted a framework called Integrated Ecosystem Assessment (IEA; Levin et al. 2008, Levin et al. 2009), which can be summarized in five progressive steps (Figure 1):

1. Identifying and scoping ecosystem goals, objectives, targets and threats.
2. Assessing the status and trends of the ecosystem through the use of valid ecosystem indicators.
3. Assessing the risk of key threats and stressors to the ecosystem.
4. Analyzing management strategy alternatives and identifying potential tradeoffs.
5. Implementing selected actions, and monitoring and evaluating management success.

As implied by Figure 1, this approach is iterative. Following the implementation of management actions, all other steps in the IEA loop must be revisited in order to ensure that a) evolving goals and objectives are clearly identified, b) monitoring plans and indicators are appropriate for the management objectives in mind, c) existing and emerging risks are properly prioritized, and d) management actions are objectively and regularly evaluated for success.

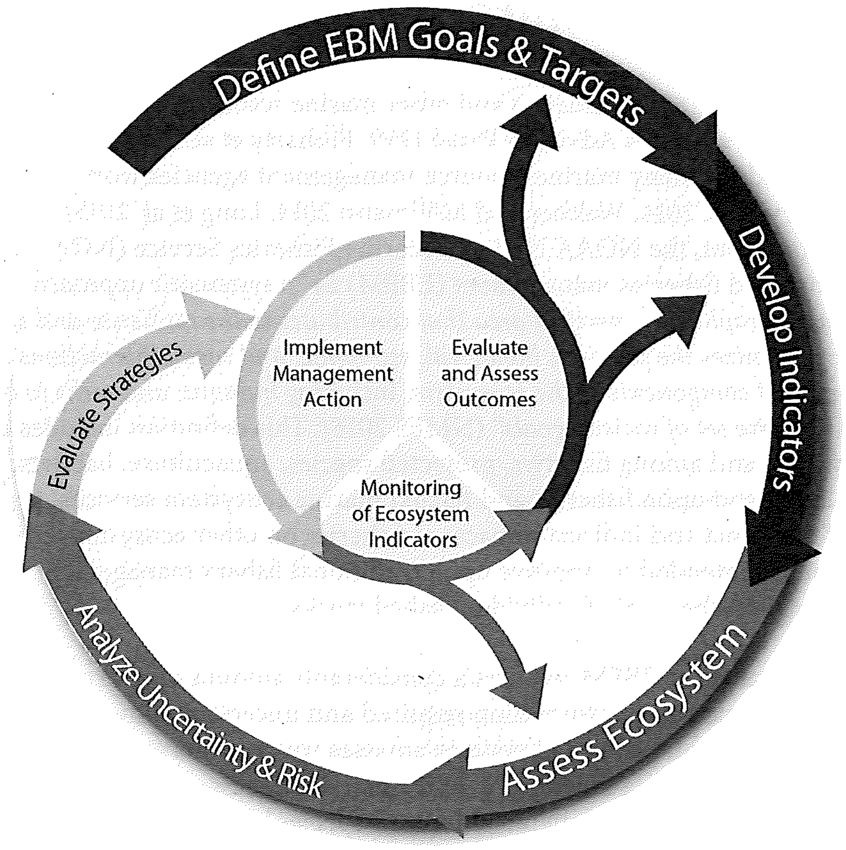

Figure 1. Loop diagram of the five progressive steps in iterations of the integrated ecosystem assessment (IEA) process. From Samhouri et al. (2014).

As the IEA framework was adopted at the national level, regional teams began implementing the IEA approach in different large marine ecosystems in U.S. waters. In 2009, NOAA line offices along the U.S. West Coast initiated the California Current Integrated Ecosystem Assessment (CCIEA). The CCIEA team focused on the California Current, a major current system oriented north–south at the eastern boundary of the northeast Pacific Ocean. The California Current flows along the West Coast of North America from central Vancouver Island, Canada, in the north, to Punta Eugenia, Mexico, in the south. Since its inception, and in keeping with the principles of ecosystem-based management, the CCIEA team has recognized that the California Current Ecosystem (CCE) is a dynamic, interactive, social–ecological system with multiple levels of organization and diverse goals and endpoints from the natural and social sciences (Figure 2). The challenging task of assembling and interpreting information from this broad range of disciplines, locations, and time frames engages over 50 scientists from NOAA's Northwest and Southwest Fisheries Science Centers, other NOAA offices, and colleagues from other agencies, academia, and nongovernmental entities. Information on CCIEA research efforts, tools, products, publications, partnerships, and points of contact is available on the CCIEA website.[1]

---

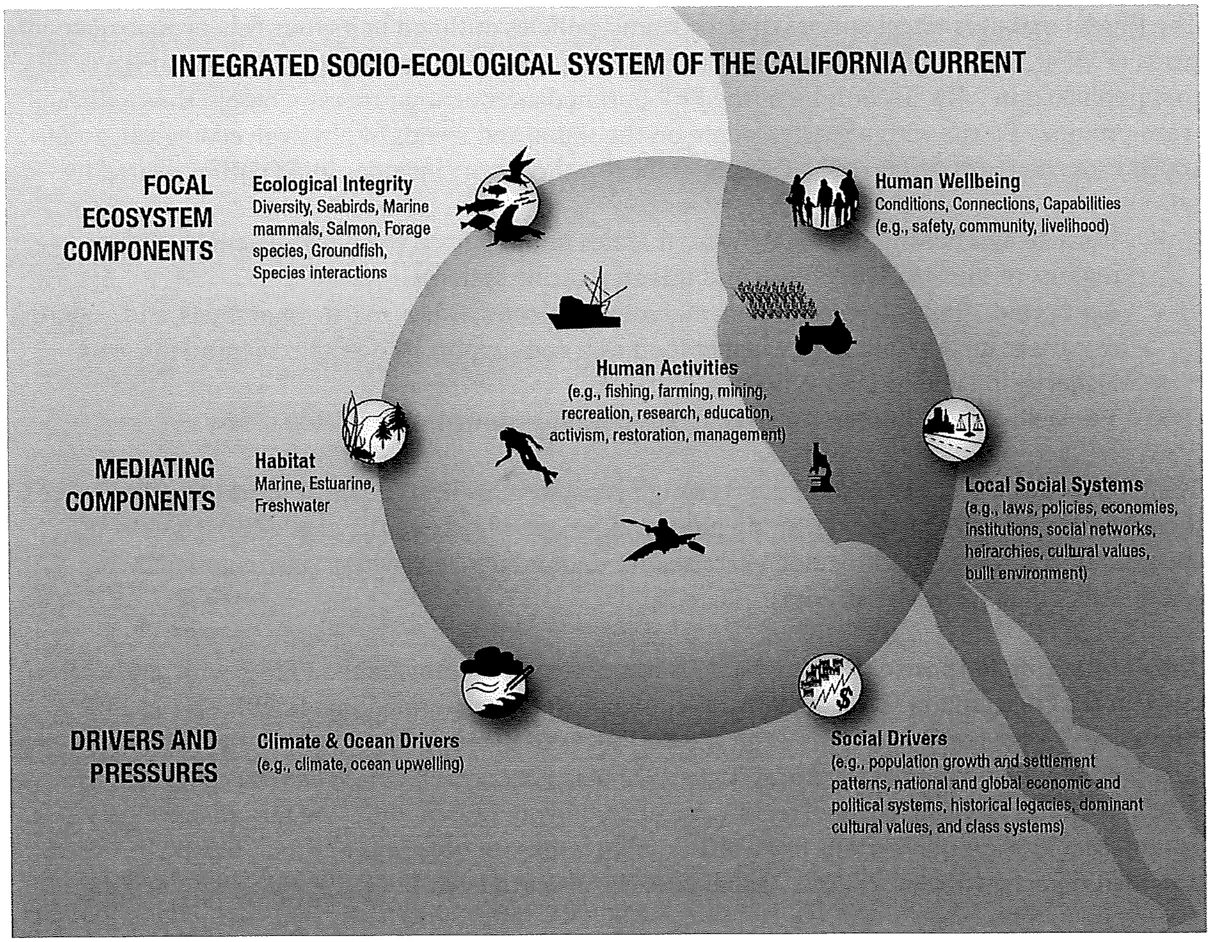

Figure 2. Conceptual model of the California Current social–ecological system. The model represents the complex and inextricable connections between natural components (left) and human components (center and right). These components are arranged in three tiers: 1) focal ecosystem components, which are often associated with broad objectives such as ecological integrity and human wellbeing; 2) mediating components, such as habitat and local social systems; and 3) drivers and pressures, which are generally external forces on the ecosystem. Human activities are placed at the center to emphasize their broad extent and because they are where management actions are directly implemented in order to achieve objectives elsewhere in the system. From Levin et al. (2016).

The primary management partner of the CCIEA team to date has been the Pacific Fishery Management Council (PFMC),[2] made up of representatives from California, Oregon, Washington, and Idaho; a representative of the West Coast indigenous tribes; four at-large members; one NOAA Fisheries member; and five nonvoting members representing key state and federal partners. The PFMC is the regional fishery management council that oversees federally managed fisheries and implementation of the Magnuson–Stevens Fishery Conservation and Management Act in the Exclusive Economic Zone off the U.S. West Coast.

---

[2] http://www.pcouncil.org

The PFMC manages target species directly under policies outlined in its four fishery management plans (FMPs), and may incorporate nonbinding guidance from its Fishery Ecosystem Plan (FEP),[3] first published in 2013. Section 1.4 of the FEP outlined a reporting process wherein the CCIEA team provides PFMC with a yearly update on the status and trends of physical, ecological, and social ecosystem attributes of the CCE. Specifically, the report includes information related to:

- Climate and oceanographic drivers, at scales ranging from the North Pacific basin to regions of the U.S. West Coast and inland riverine systems.
- Key species groups (e.g., plankton, macroinvertebrates, fishes, marine mammals, and seabirds) that make up the California Current food web and support its overall ecological integrity.
- Fisheries-related human activities.
- The wellbeing of humans in coastal communities along the U.S. West Coast.

The report tracks ecosystem attributes through ecosystem indicators, most of which were derived through a rigorous indicator screening process developed by Kershner et al. (2011); details of specific CCIEA indicator screening exercises are documented elsewhere (Levin and Schwing 2011, Levin et al. 2013, Harvey et al. 2014).

The overarching purpose of the ecosystem status reports is to provide the PFMC with a general sense of the condition of the ecosystem, as context for its decisionmaking. In 2015–16, an FEP "initiative" was enacted to further align the indicators in the reports to the needs of the PFMC (see Supplemental Ecosystem Workgroup Report 2).[4] Since 2012, the CCIEA team has provided the PFMC with five ecosystem status reports, most recently in March 2017. The reports have previously been available as online sections of PFMC briefing books for meetings at which the CCIEA team provided reports (November 2012, March 2014–17; also available at CCIEA Publications: Reports[5]).

This Technical Memorandum is a companion document to the ecosystem status report delivered by the CCIEA team to the PFMC in March 2017, representing the status and trends of ecosystem indicators in the CCE through 2016 and, in some cases, early 2017 (Harvey and Garfield 2017a,b). It is intended to be the first in an ongoing annual series of Technical Memorandums that will provide a more thorough ecosystem status report of the CCE than the one we present to the PFMC. We will continue to provide the annual report to the PFMC, and this Technical Memorandum series will largely be based on that report. However, as this series evolves, the Technical Memorandums will incorporate more indicators and analyses, covering a broader range of ecosystem attributes. This is because the CCIEA team looks to support other management partners in addition to the PFMC, and our goal over the next several years is for our annual ecosystem status report to feature information in support of ecosystem-based management (EBM) in other sectors and services in addition to fisheries (Slater et al. 2017). The Technical Memorandum format should therefore enable increased information content, contributions from a broader range of authors, and value to a wider range of audiences than the reports produced to date. It is our hope that these improvements will lead to greater dialogue with potential partners and stakeholders; such dialogue and engagement is at the heart of the initial step of the IEA process (Figure 1), and is essential to each other step in all iterations as well.

Notes on Interpreting Time Series Figures

Throughout this report, many data figures will follow one of two common formats, time series plots or quad plots, both illustrated with sample data in Figure 3; see figure caption for details. Time series plots generally contain a single dataset, whereas quad plots are used to summarize the recent averages and trends for multiple time series in a single panel, as when we have time series of multiple populations that we want to compare in a reasonably simple manner. Where possible, we also include estimates of error or uncertainty in the data. Generally, error estimates are standard deviations or standard errors in the observations. In coming years, we will include model fits to time series data where appropriate; model fits will most likely be derived from Multivariate Auto-Regressive State Space (MARSS) models, as has been recommended to the CCIEA team by the PFMC Scientific and Statistical Committee's Ecosystem Subcommittee (SSCES).

Sampling Locations

Figure 4 shows the CCE and major headlands that demarcate potential biogeographic boundaries, in particular Cape Mendocino and Point Conception. We generally consider the region north of Cape Mendocino to be the "Northern CCE," the region between Cape Mendocino and Point Conception the "Central CCE," and the region south of Point Conception the "Southern CCE."

Figure 4a also shows sampling locations for much of the regional climate and oceanographic data (see Regional Climate Indicators) presented in this report. In particular, many of the physical and chemical oceanographic data summarized in this document are collected on the Newport Line off Oregon and the California Cooperative Oceanic Fisheries Investigations (CalCOFI) grid off California. Physical oceanography sampling is further complemented by basin-scale observations and models.

Freshwater habitats worldwide can be spatially grouped into "ecoregions" according to the designations of Abell et al. (2008); see also Freshwater Ecoregions of the World, FEOW[6]). The freshwater ecoregions in the CCE are shown in Figure 4b (derived from FEOW), and are the basis by which we summarize freshwater habitat indicators relating to streamflow and snowpack (see Hydrologic Indicators).

The map in Figure 4c represents sampling for most biological indicators, including copepods (Northern Copepod Biomass Anomaly), forage species (Regional Forage Availability), California sea lions (Marine Mammals), and Seabirds. Not shown is groundfish bottom trawl sampling (see Groundfish), which covers most trawlable habitat on the shelf and upper slope (depths of 55–1,280 m) in U.S. waters; the blue and green polygons in Figure 4c roughly approximate the areal extent of the NOAA Fisheries West Coast groundfish bottom trawl survey (Keller et al. 2017).

---

[6] http://www.feow.org

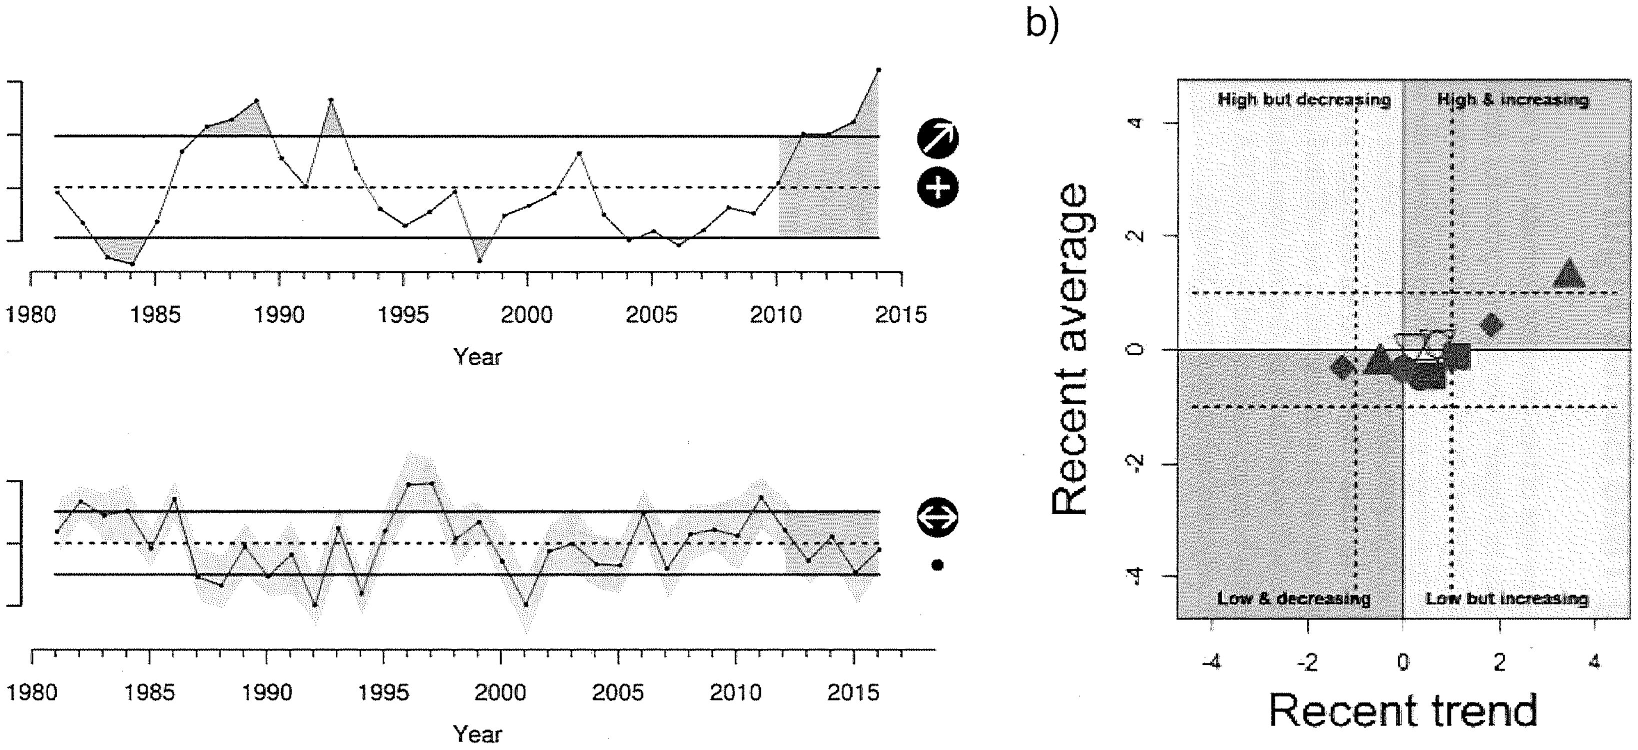

Figure 3. a) Sample time series plots, with indicator data relative to mean (dashed line) and ±1 SD, standard deviation (solid lines), of the full time series. Arrow at right indicates if the trend over the most recent 5 years (shaded green) is positive (↗), negative (↘) or neutral (↔). Symbol at lower right indicates if the recent mean was greater than (+), less than (–), or within 1 SD (·) of the long-term mean. When possible, time series include 95% confidence intervals (gray shading, lower panel). b) Sample quad plot. Each point represents one normalized time series. The position of a point indicates if the recent years of the time series are above or below the long-term average, and if they are increasing or decreasing; quadrants are "stoplight" colored to highlight the status of the indicator condition (where green = improving conditions, yellow = neutral, and red = declining conditions). Dashed lines represent ±1 SD of the full time series.

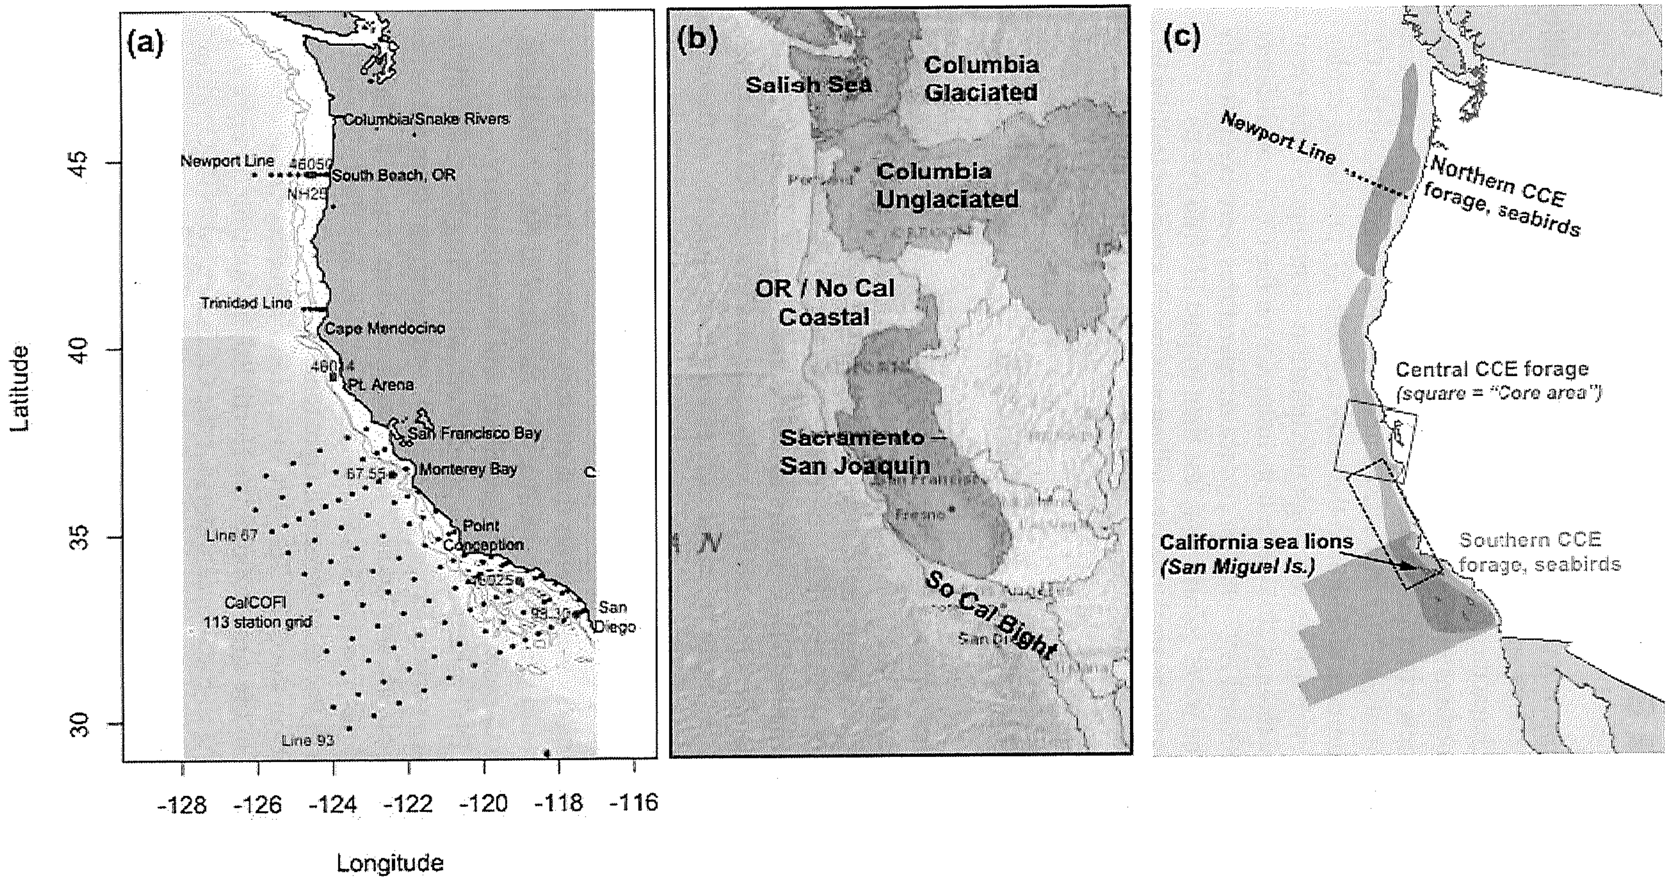

Figure 4. Maps of the California Current Ecosystem (CCE) and sampling areas. a) Key geographic features and oceanographic sampling locations. b) Freshwater ecoregions, where snowpack and streamflow indicators are measured. c) Biological sampling areas for copepods (Newport Line), pelagic forage species, seabirds, and California sea lions. Solid box = the "core" sampling area for forage in the Central CCE. Dotted box approximates the foraging area for adult female California sea lions from the San Miguel colony.

Climate and Ocean Drivers

Climate and ocean processes determine important ecosystem characteristics in the CCE, including water and air temperature, winds, currents and mixing of ocean waters, water chemistry, and precipitation. These environmental characteristics are important drivers of ecological processes and human activities. Overall, the northeastern Pacific Ocean has experienced exceptional climate variability in recent years, reaching new extremes for many indicators related to climate and ocean drivers. After a series of events beginning in 2013 that caused unprecedented warming in the CCE, conditions have changed since the summer of 2016 into the winter of 2016–17, producing cooler coastal waters and a succession of winter storms with high precipitation. A strong El Niño event peaked in the tropical Pacific in the winter of 2015–16, but its influence on the CCE was different than strong El Niño events of 1982–83 and 1997–98. Sea surface temperatures were exceptionally high, but the extent of heating into the water column was less than in past El Niño events (Figure 5). Late winter upwelling was not as weak, and upwelling was much stronger leading into the spring. The following sections provide in-depth descriptions of basin-scale, regional-scale, and hydrologic indicators of climate and ocean variability in the CCE.

Basin-Scale Indicators

The CCE is driven by atmosphere–ocean energy exchange that occurs on many temporal and spatial scales. To capture large-scale variability, the CCIEA team tracks three indices: the status of the equatorial El Niño–Southern Oscillation (ENSO), described by the Oceanic Niño Index (ONI); the Pacific Decadal Oscillation (PDO); and the North Pacific Gyre Oscillation (NPGO). Positive ONI and PDO values and negative NPGO values usually denote conditions that lead to low CCE productivity, whereas negative ONI and PDO values and positive NPGO values are associated with periods of high CCE productivity. These indices vary independently, so there is a wide range of observed variability in the CCE.

ENSO events impact the CCE by modifying the jet stream and storm tracks, deepening the nearshore thermocline, and generating coastal currents that enhance poleward transport of equatorial and subequatorial waters (and species). A positive ONI indicates El Niño conditions, which usually means more storms to the south, weaker upwelling, and lower primary productivity in the CCE. A negative ONI means La Niña conditions, which usually lead to higher productivity. The PDO is related to sea surface temperature (SST), and is derived from sea surface temperature anomalies (SSTa) in the Northeast Pacific, which often persist in "regimes" that last for many years. In positive PDO regimes, coastal SSTa in the Gulf of Alaska and the CCE tend to be warmer, while those in the North Pacific Subtropical Gyre tend to be cooler. Positive PDOs are associated with lower productivity in the CCE. The NPGO is a low-frequency variation of sea surface height, indicating variations in the circulation of the North Pacific Subtropical Gyre and the Alaskan Gyre, which in turn relate to the source waters for the CCE. Positive NPGO values are associated with increased equatorward flow, along with increased surface salinities, nutrients, and chlorophyll-*a*. Negative NPGO values are associated with decreases in such values, implying fewer subarctic source waters and generally lower productivity.

This past year saw the ONI shift from El Niño to neutral and even La Niña conditions, the PDO switch from strongly positive to neutral, and the NPGO move from strongly negative to neutral (Figure 6). Each of these indices would suggest a return to conditions of higher productivity. However, the Northeast Pacific and the CCE continued to show the aftereffects of the very anomalous conditions experienced during 2013–16. The large marine heat wave, a.k.a. "the Blob" (Bond et al. 2015), dissipated in fall 2016 in the Northeast Pacific, but anomalously warm surface waters were present in the Gulf of Alaska and immediately along the North American west coast during the winter (Figure 7). Summer SSTa showed no lasting influence of the El Niño event, with anomalies average to slightly below-average along the coast from Vancouver to San Diego. However, temperatures in subsurface waters of the Northeast Pacific remained warm, with anomalies >1°C down to 160 m and >0.5°C down to below 200 m (Harvey and Garfield 2017b). This deep warming is interpreted as a remnant effect of the marine heat wave.

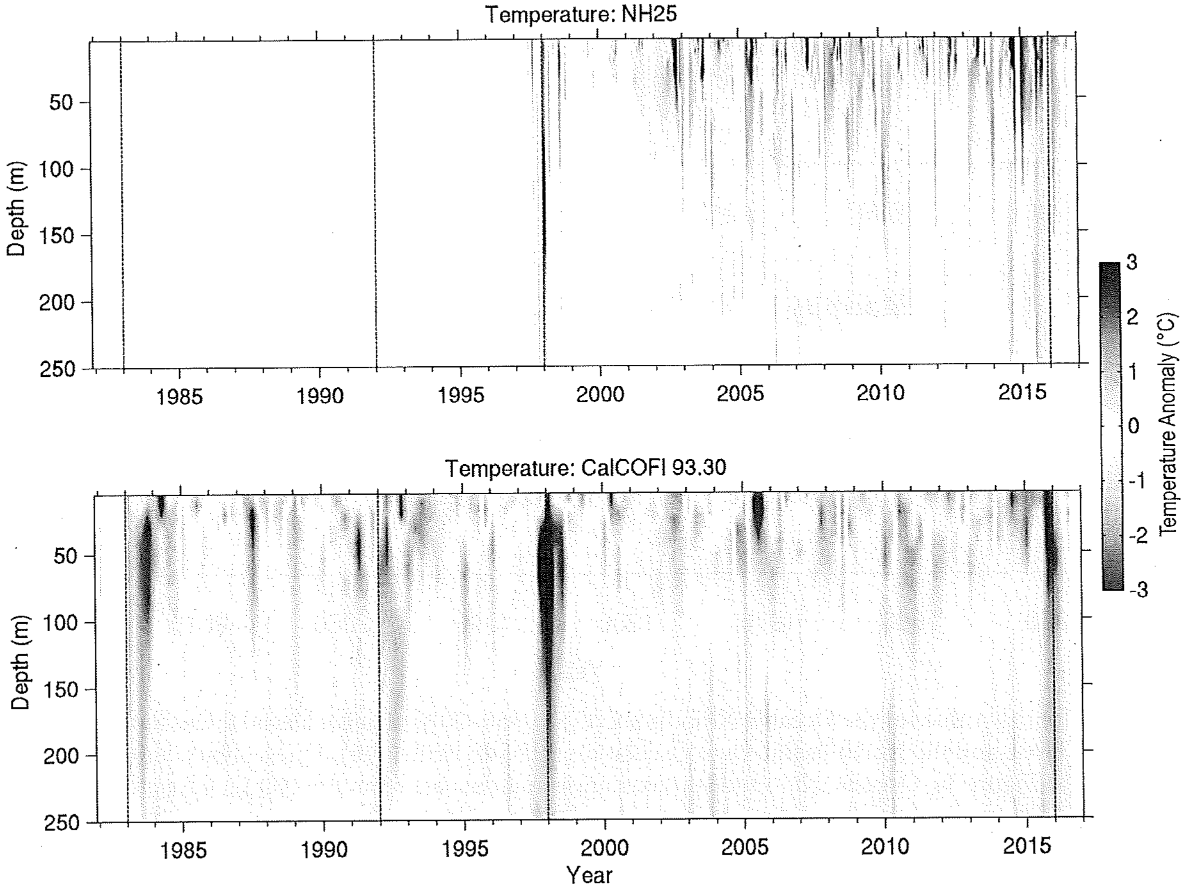

Figure 5. Time–depth temperature contours from nearshore stations NH25 and CalCOFI 93.30 (see Figure 3a). Vertical lines mark El Niño events. Newport Hydrographic (NH) line temperature data are from Dr. Bill Peterson (NOAA). CalCOFI hydrographic line data are from the CalCOFI website.* CalCOFI data before 2016 are CSV format files from the Access database, while 2016 data are preliminary CSV files from the CTD (conductivity, temperature, depth) database.

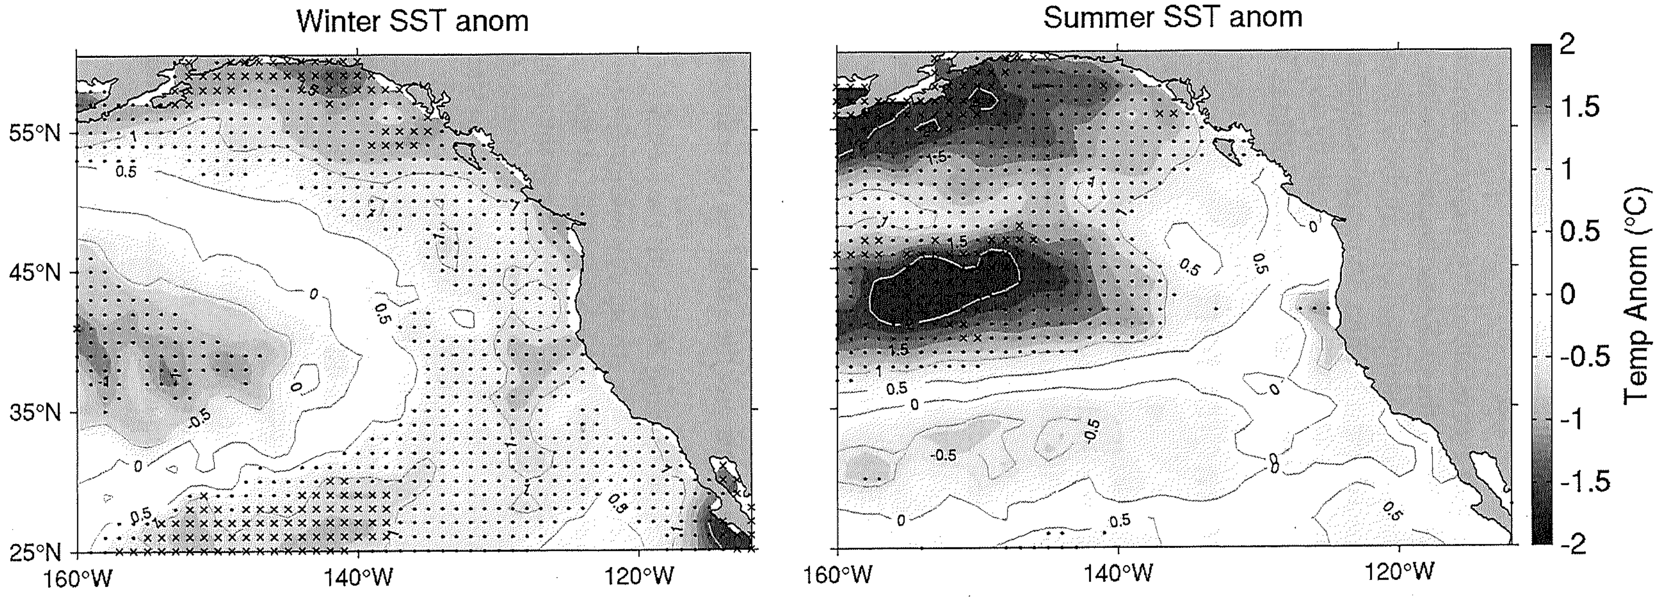

Figure 7. Sea surface temperature anomalies (SSTa) in winter (Jan–Mar, left) and summer (Jul–Sep, right), 2016. The time series at each grid point began in 1982. Positive anomalies of the marine heat wave and El Niño are seen in the Gulf of Alaska in winter and summer, and off Baja California in winter. Black circles mark cells where the anomaly was >1 SD above the long-term mean. Black Xs mark cells where the anomaly was the highest of the time series. Sea surface temperature maps are optimally interpolated remotely-sensed temperatures (Reynolds et al. 2007). The daily optimal interpolated Advanced Very High Resolution Radiometer (AVHRR) SST can be downloaded from the NOAA SWFSC Environmental Research Division Data Access Program (ERDDAP).*

---

* http://upwell.pfeg.noaa.gov/erddap/griddap/ncdcOisst2Agg.html

Another marine heat wave formed off Baja California in 2014 and strengthened in 2015, keeping nearshore SSTs >0.5°C above normal. This event was likely caused by weaker atmospheric forcing in the Southern California Bight and along the Mexican coast (Leising et al. 2015, McClatchie et al. 2016). By summer 2016, SSTs in this region dropped to near-average values (Figure 7).

In summary, while the 2015–16 El Niño was one of the largest ever recorded in terms of equatorial warming and the ONI, the large-scale environmental response of the CCE was dominated in the north by the lingering impacts of the marine heat wave, with only moderate influence from the El Niño, whereas in the south, the CCE was more strongly influenced by the El Niño. Thorough summaries of these dynamics are in Leising et al. (2015) and McClatchie et al. (2016). These large-scale forces help explain the dynamics of some biological indicators in Focal Components of Ecological Integrity, below.

Regional Climate Indicators

Seasonal high pressure over the Gulf of Alaska and low pressure over the U.S. Southwest drive the upwelling-favorable winds that fuel the high spring–summer productivity that is typical of the CCE. Upwelling is a physical process of moving cold, nutrient-rich water from deep in the ocean up to the surface, and is forced by strong, northerly alongshore winds. Upwelling is critically important to productivity and ecosystem health in the CCE, as it is local coastal upwelling that allows the primary production at the base of the food web. The most common metric of upwelling is the Bakun Upwelling Index (UI), which is a measure of the magnitude of upwelling anywhere along the coast. The timing, strength, and duration of upwelling in the CCE are highly variable by region and by year. The cumulative upwelling index (CUI) is one way to display this variability. The CUI provides an estimate of the net influence of upwelling on ecosystem structure and productivity over the course of the year. The CUI integrates the onset date of upwelling-favorable winds (the "spring transition"), a general indication of the strength of upwelling, relaxation events, and the end of the upwelling season.

Upwelling strength displayed significant regional variability during 2016, with the least favorable conditions in the Northern CCE. At lat 45°N (near Newport, OR), strong downwelling from January through March was followed by average upwelling from April to July; CUI at this latitude was much lower than the strong upwelling of 2015 (Figure 8), and similar to the reduced upwelling of the 1998 El Niño event (McClatchie et al. 2016). At lat 39°N (near Point Arena, CA), the spring transition to upwelling began weakly in mid-March and strengthened in May, leading to above-average upwelling by July and comparable CUI to 2015 by August. In the Southern California Bight (lat ~33°N), the CUI was close to the long-term mean during the beginning of the season, and above average after June. This is in stark contrast to the reduced upwelling seen throughout the year in 1998 following that year's comparably large El Niño. Additional upwelling information for 2012–16 is summarized in Harvey and Garfield (2017b).

Although CUI was stronger in the south than the north in 2016, productivity did not increase concomitantly as one might expect. This is likely because of increased stratification and a deeper thermocline in this region, due to the lingering effects of the marine heat wave, plus the influence of the 2015–16 El Niño event (McClatchie et al. 2016).

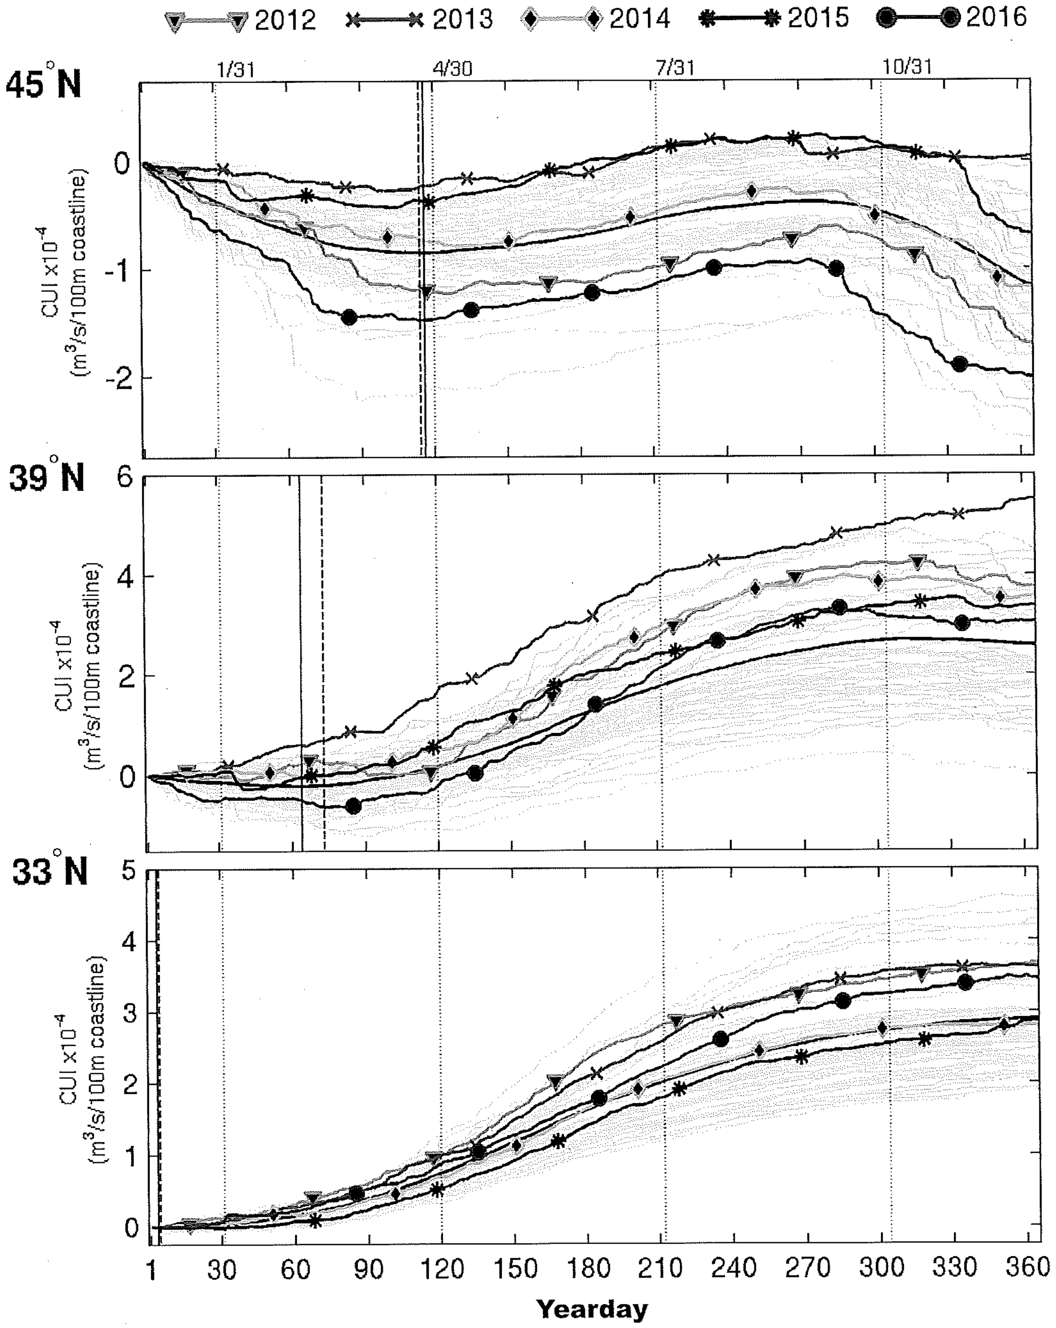

Figure 8. Cumulative Upwelling Index (CUI) at three latitudes, 1967–2016. Black trend = long-term mean; gray trends = 1967–2011; colored trends = 2012–16. Black vertical lines mark the 2016 spring transition date (dashed) and long-term mean spring transition date (solid). Dotted red vertical lines mark the ends of January, April, July, and October. Cumulative Upwelling Index curves are calculated from the six-hourly upwelling index product.*

Hypoxia and Ocean Acidification

Nearshore dissolved oxygen (DO) levels and ocean acidification (OA) are related to the strength of coastal upwelling. DO is required for organismal respiration, and DO levels are dependent on a number of physical and biological processes, including circulation, air–sea exchange, and community-level production and respiration. Waters with DO levels below 1.4 ml/L (2 mg/L) are considered to be hypoxic. Low DO can compress habitat and cause stress or even die-offs for sensitive species. OA is caused by increased levels of anthropogenic CO_2 in seawater, which impacts the chemical environment of marine organisms by reducing both pH and carbonate ion concentrations. A key indicator of OA effects is aragonite saturation state, a measure of how corrosive seawater is to organisms with shells made of aragonite (a form of calcium carbonate). Values <1.0 indicate corrosive conditions that have been shown to be stressful for many CCE species, including oysters, crabs, and pteropods. Upwelling, which drives primary production in the CCE, also transports hypoxic, acidified waters onto continental shelves, where increased community-level respiration can further reduce water-column DO and exacerbate OA (Chan et al. 2008, Feely et al. 2008).

At the three stations shown here, DO was seasonally variable, with peaks in the winter, but all measurements were consistently above the hypoxia threshold of 1.4 ml/L in 2016 (Figure 9). The five-year annual trend at each site has been stable, but there is evidence of seasonal increases in DO. Briefly, station NH25 off Newport, OR, has experienced increasing winter DO over the past five years. At the nearshore station 93.90 off southern California, DO has declined since 1984, driven mainly by winter values, and was ~1 SD below the mean in winter 2016. However, the recent trend is stable and possibly increasing based on seasonal averages. At the offshore station 90.90, summer DO has increased in recent years. Nearshore DO values are almost always lower than those offshore (93.30 vs. 90.90 in Figure 9). Additional data are summarized in Harvey and Garfield (2017b).

In nearshore waters off Newport, OR (station NH5), aragonite levels at 40 m depth are typically saturated (>1.0) during the winter and spring, and then fall below 1.0 in the summer and fall; this was the case again in 2016 (Figure 10). Further offshore (station NH25) at 150 m depth, aragonite saturation state follows the same seasonal cycle but across a narrower range, and aragonite levels at this area and depth are almost always <1.0. However, aragonite levels were elevated slightly in the anomalous conditions of the past two years. In fact, according to seasonal data, winter aragonite levels have increased over the past five years at both stations (Harvey and Garfield 2017b).

Hydrologic Indicators

Freshwater conditions are critical for salmon populations and for estuarine habitats that support many marine species. The freshwater indicators presented here focus on snowpack and streamflow, and are summarized by freshwater ecoregion (Figure 4b). Snow-water equivalent (SWE) is the total water content in snowpack, which provides a steady source of freshwater into the summer months. Maximum streamflows in winter and spring are important for habitat formation, but can cause scouring of salmon nests. Minimum streamflows in summer and fall can restrict habitat for in-stream juveniles and migrating adults. All three indicators are influenced by climate and weather patterns, and will be affected as the effects of climate change intensify.

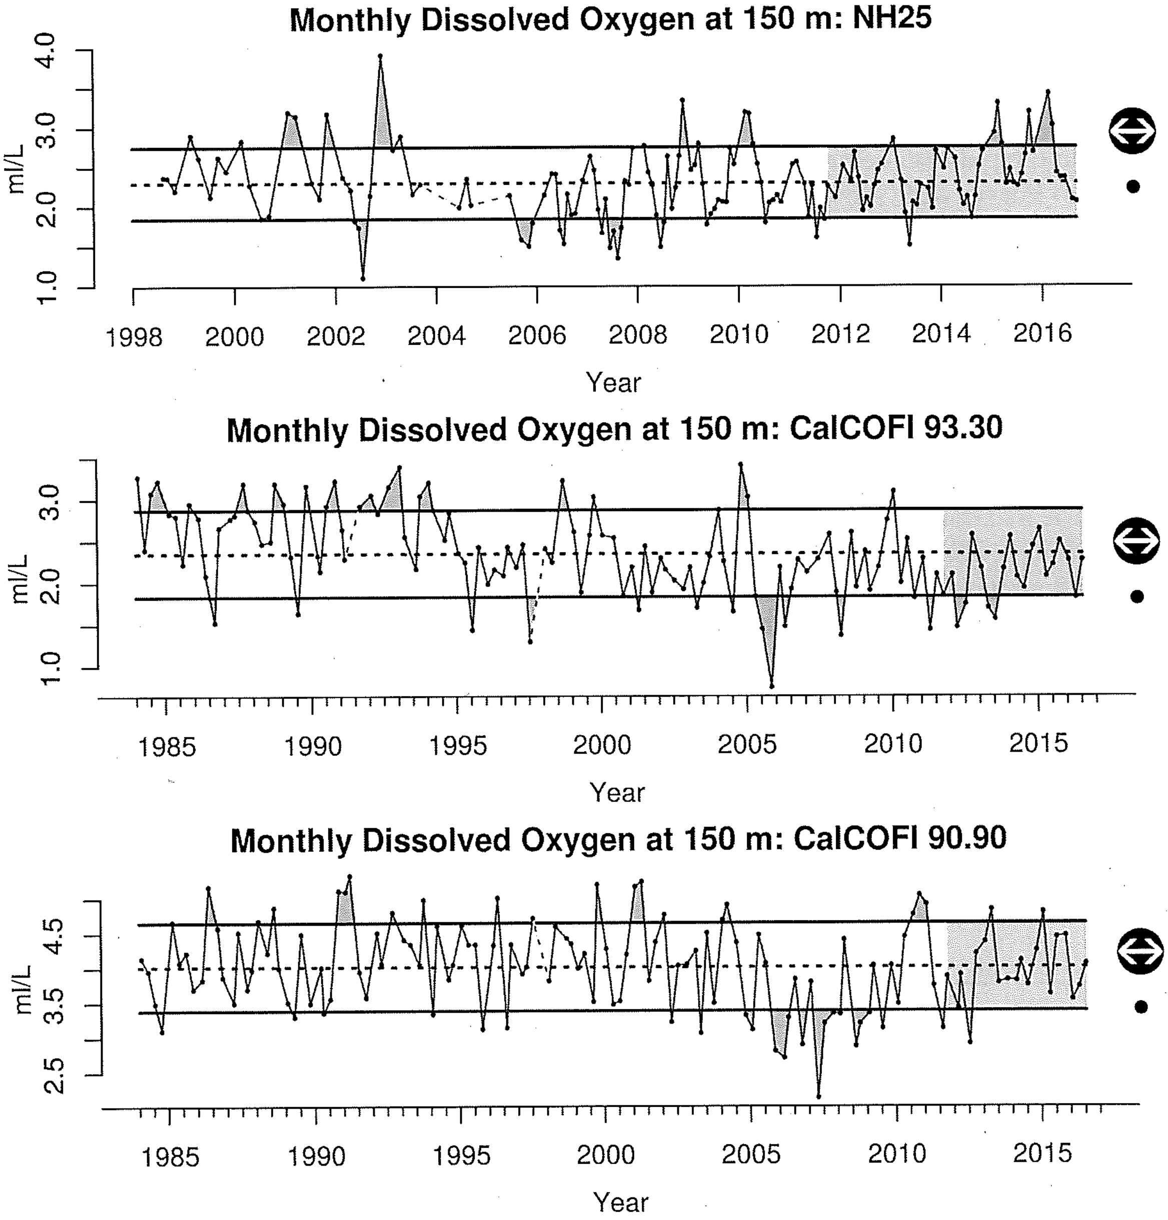

Figure 9. Dissolved oxygen (DO) at 150 m depth off Oregon and southern California through 2016. Stations NH25 (Newport, OR) and 93.30 (Southern CA) are <50 km from shore; station 90.90 (Southern CA) is >300 km from shore. Lines, colors, and symbols are as in Figure 3a; dashed red lines indicate data gaps >6 months. Newport Hydrographic (NH) line DO data are from Dr. Bill Peterson (NOAA). CalCOFI hydrographic line data are from the CalCOFI website. Note: CalCOFI data before 2016 are from the bottle data CSV database, while 2016 data are preliminary data from the CTD CSV database.

After years of steady declines and a historic low in 2015, SWE returned to average levels in all ecoregions in 2016 (Figure 11). However, despite the rebound of SWE in early 2016, high spring and summer air temperatures resulted in rapid snowmelt. These factors led to an increase in maximum flows in 2016, although not to levels considered dangerous to most salmon stocks. The early and rapid melt helped contribute to worsening trends in minimum flow in most of the ecoregions (Harvey and Garfield 2017b). SWE in 2017 was on pace to exceed 2016 following a series of winter storms earlier this year (Harvey and Garfield 2017b).

We summarized streamflow using quad plots that compile recent status and trends in flow anomalies at the finer spatial scale of individual Chinook salmon (*Oncorhynchus tshawytscha*) evolutionarily signifcant units (ESUs, sensu Waples 1995). Here, high and increasing maximum flows are regarded as undesirable (i.e., the red quadrant of the max flow plot in Figure 12) due to the potential for scouring redds; low and decreasing minimum flows are also undesirable (the red quadrant of the min flow plot) because of the potential for stress related to temperature, oxygen, or space. The maximum flow events are within ±1 SD of long-term averages and generally lack signficant trends, although four ESUs indicate a recent increase (Figure 12, left). On the other hand, miminum flow anomalies have worsening trends for many ESUs, particularly those sensitive to low-flow conditions, such as the Sacramento winter run and the Klamath/Trinity ESUs (Figure 12, right).

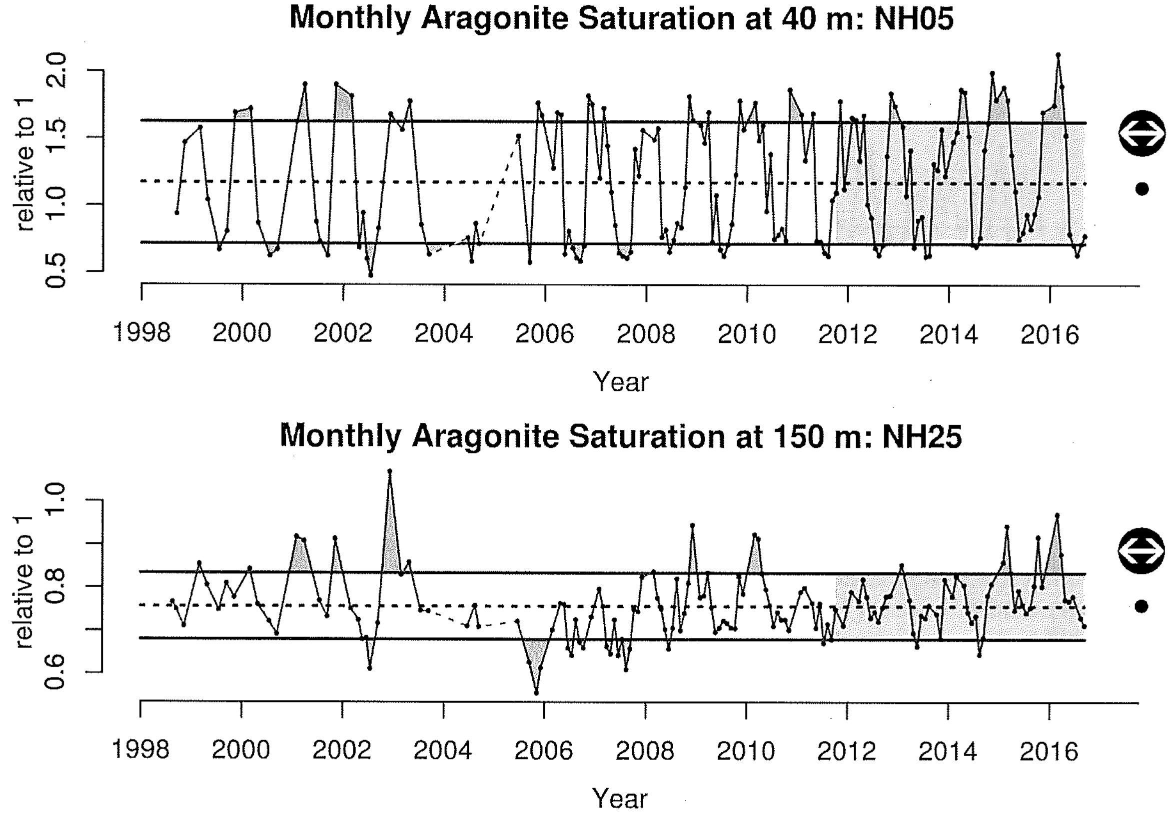

Figure 10. Monthly aragonite saturation values off of Newport, Oregon, 1998–2016. Lines, colors, and symbols are as in Figure 3a; dashed red lines indicate data gaps >6 months. Aragonite saturation state data were provided by Dr. Bill Peterson (NOAA).

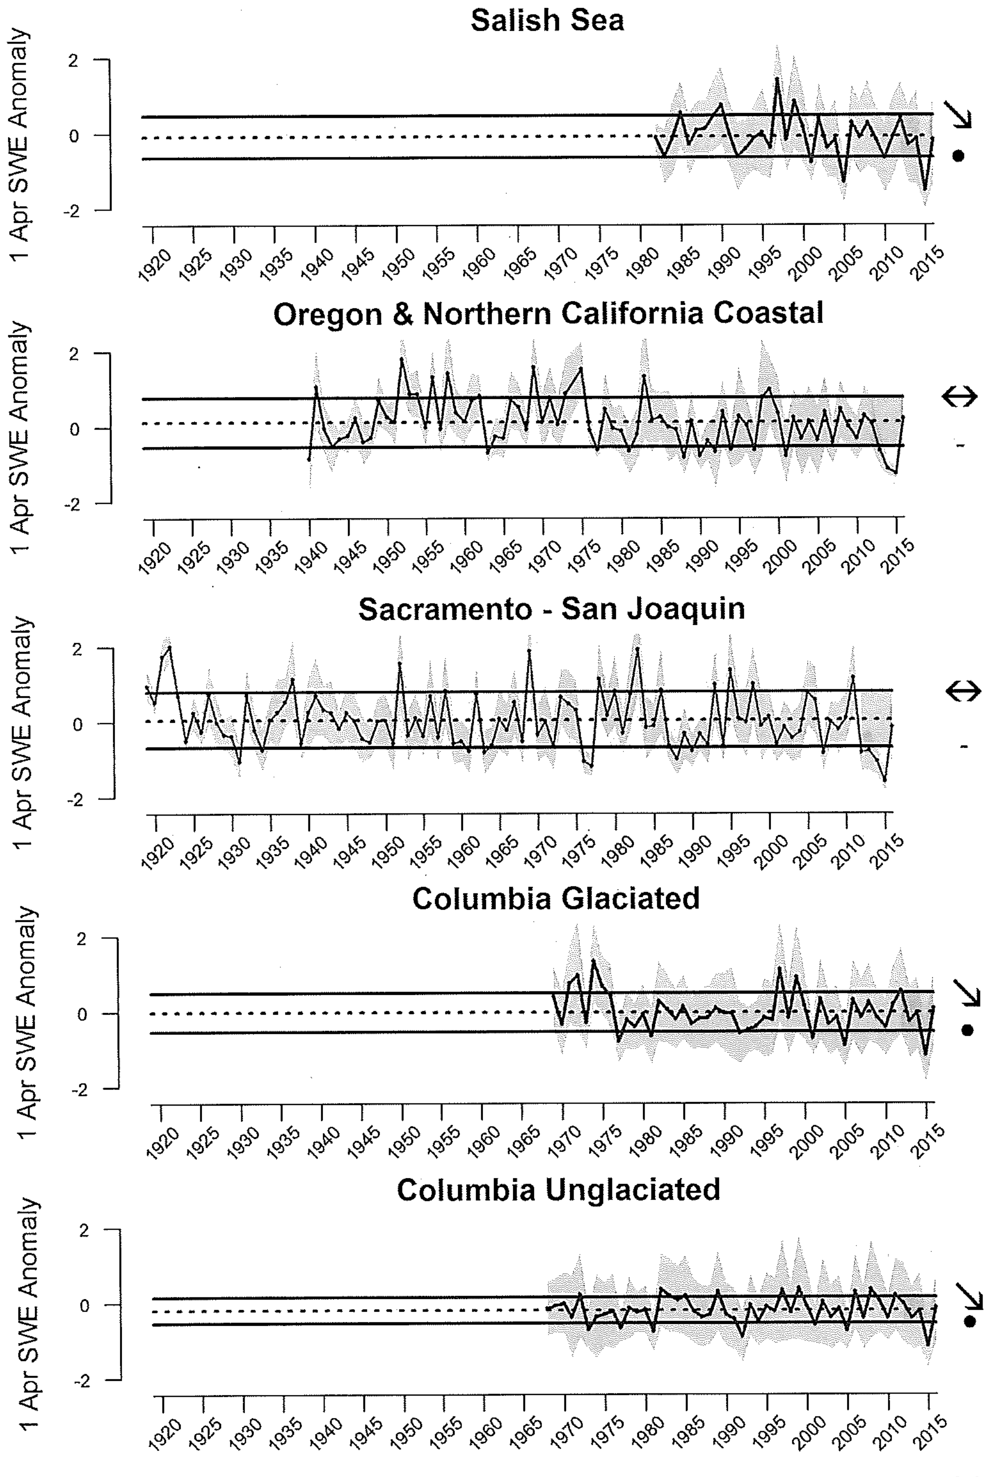

Figure 11. Anomalies of April 1st snow-water equivalent (SWE) in five freshwater ecoregions of the CCE through 2016. Lines, symbols, and colors are as in Figure 3a. Ecoregions are mapped in Figure 4a. SWE data are from the California Data Exchange Center's Resources snow survey* and the Natural Resources Conservation Service's SNOTEL sites† in WA, OR, CA, and ID.

Focal Components of Ecological Integrity

The CCIEA team examines many indicators related to the abundance and condition of key species, the dynamics of community structure, and ecological interactions. Many CCE species and processes respond very quickly to changes in ocean and climate drivers, while other responses may lag by many years. These dynamics are challenging to predict. Over the last several years, many ecological integrity metrics have indicated conditions of poor productivity at low trophic levels and poor foraging conditions for many predators. In 2016, we also continued to observe unexpected community structure in pelagic waters throughout the CCE. It remains to be seen how different populations have been affected, or whether 2017 will represent a shift away from the unproductive conditions observed since 2014.

Northern Copepod Biomass Anomaly

Copepod biomass anomalies represent interannual variation in biomass of two groups of copepod taxa: northern copepods (e.g., *Pseudocalanus mimus*, *Acartia longiremis*, and *Calanus marshallae*), which are "cold-water" species rich in wax esters and fatty acids that appear to be essential for pelagic fishes, and southern copepods (e.g., *Acartia tonsa*, *Calanus pacificus*, *Calocalanus* spp.,

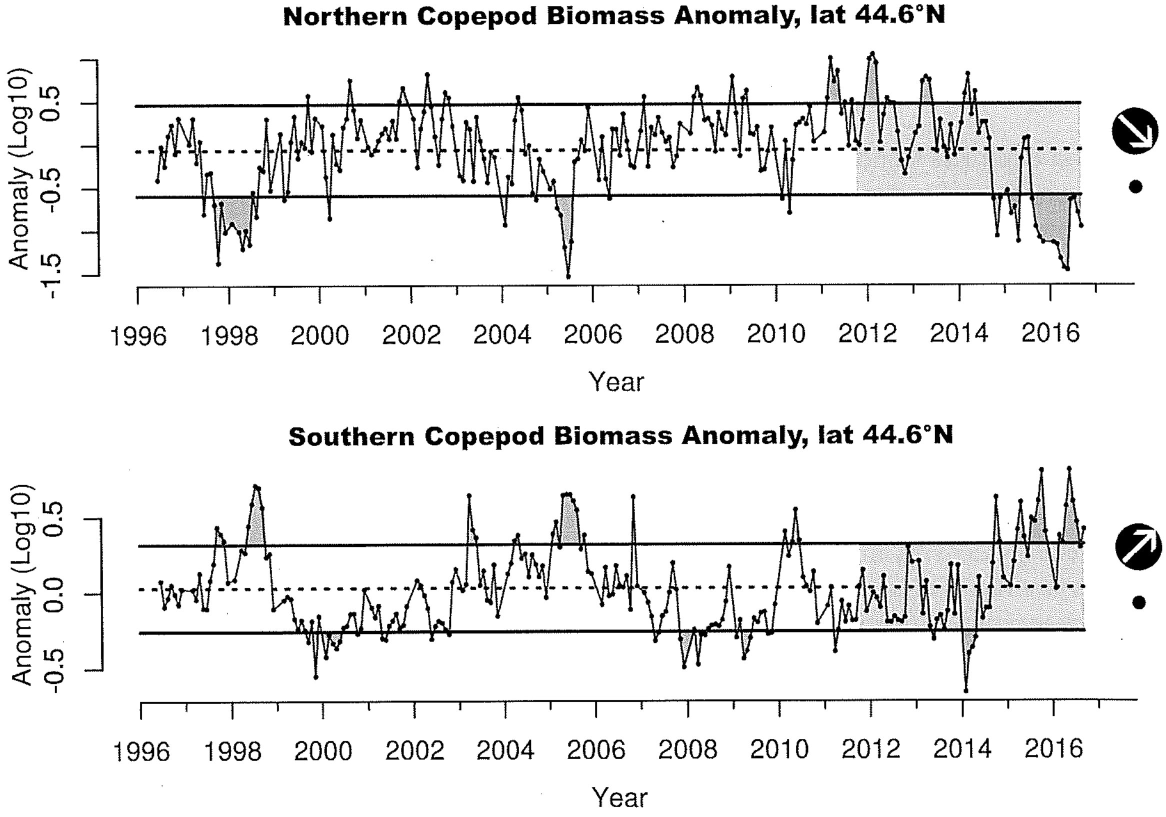

Figure 13. Monthly northern (top) and southern (bottom) copepod biomass anomalies from 1996–2016 in waters off Newport, OR. Lines, colors, and symbols are as in Figure 3a. Copepod biomass anomaly data were provided by Dr. Bill Peterson (NOAA).

Clausocalanus spp., *Corycaeus anglicus, Ctenocalanus vanus, Mesocalanus tenuicornis,* and *Paracalanus parvus*), which are "warm-water" species that are generally smaller and have lower lipid content and nutritional quality. In summer, northern copepods usually dominate the coastal zooplankton community as represented by collections along the Newport Line (see Figures 4a and 4c), while southern copepods dominate the community during winter. This pattern is often altered during El Niño events and/or when the PDO is positive, leading to higher biomass of southern copepods (Keister et al. 2011, Fisher et al. 2015). Threshold values for the anomalies have not been set, but positive values of northern copepods in summer are correlated with stronger returns of Chinook salmon to Bonneville Dam, and values >0.2 are associated with better survival of coho salmon (*Oncorhynchus kisutch*; Peterson et al. 2014).

With the exception of a brief period during summer 2015, the northern copepod anomaly has remained >1 SD below the long-term mean since the autumn of 2014 (Figure 13, top). During this same period, the southern copepod biomass anomaly increased significantly and was strongly positive in much of 2016 (Figure 13, bottom). These anomaly patterns are consistent with warm surface waters and poor feeding conditions for pelagic fishes, and reflect a sustained departure from the generally productive ocean conditions for much of 2011–14. Moreover, 17 species of copepods have been collected since autumn 2014 that had not been observed in these waters previously. It appears that many of these exotic copepod species were offshore, central Pacific species, not the typical southern species that are often transported northward to the Newport Line during major El Niño events.

Regional Forage Availability

This section describes trends in forage availability, based on spring/summer research cruises that have been conducted independently in three different regions (Figure 4c) for decades. The species shown below represent a substantial portion of the available forage in the regions sampled by the cruises. *We consider these regional indices of relative forage availability and variability, not indices of absolute abundance of coastal pelagic species* (CPS). Absolute abundance estimates should come from stock assessments and comprehensive monitoring programs, which these surveys are not. Moreover, the regional surveys that produce these data use different methods (e.g., gear selectivity, timing, frequency, and survey objectives); thus, the amplitudes of each time series are not necessarily comparable among regions.

The CCE forage community is a diverse portfolio of species and life history stages, varying in behavior, energy density, and availability to predators. Years with abundant pelagic fish, market squid (*Doryteuthis opalescens*), and krill (e.g., *Euphausia pacifica* and *Thysanoessa spinifera*) are generally associated with cooler waters, strong upwelling, and higher productivity (Santora et al. 2014, McClatchie et al. 2016). Here, we present the forage indicators in quad plots analogous to Figure 3b; time series data are summarized elsewhere (Harvey and Garfield 2017b).

Northern CCE

The Northern CCE survey targets juvenile salmon in June in surface waters, but also catches juvenile and adult pelagic fishes, market squid, and gelatinous zooplankton. Except for jack mackerel (*Trachurus symmetricus*), recent average catch-per-unit-effort (CPUE) of most forage species were within 1 SD of the long-term mean and showed no discernable short-term trends (Figure 14). Sardine (*Sardinops sagax*) and anchovy (*Engraulis mordax*) CPUEs remained near the lowest levels observed in this survey's time series (Harvey and Garfield 2017b). The two main species of gelatinous zooplankton were within the long-term mean range, although the small water jelly *Aequorea* sp. declined from 2015 and the large sea nettle *Chrysaora* was relatively uncommon. Anecdotally, a related survey in this region, which uses different methods and only began in 2011, caught many adult anchovy near the Columbia Plume, and saw evidence of anchovy spawning off Oregon in 2015 and 2016. The related survey also showed a steep drop in krill in 2015 and 2016, concurrent with an increase in gelatinous salps. The survey also found young-of-the-year (YOY) rockfish (*Sebastes* spp.) and Pacific hake (*Merluccius productus*) more abundant in 2016 than previous years.

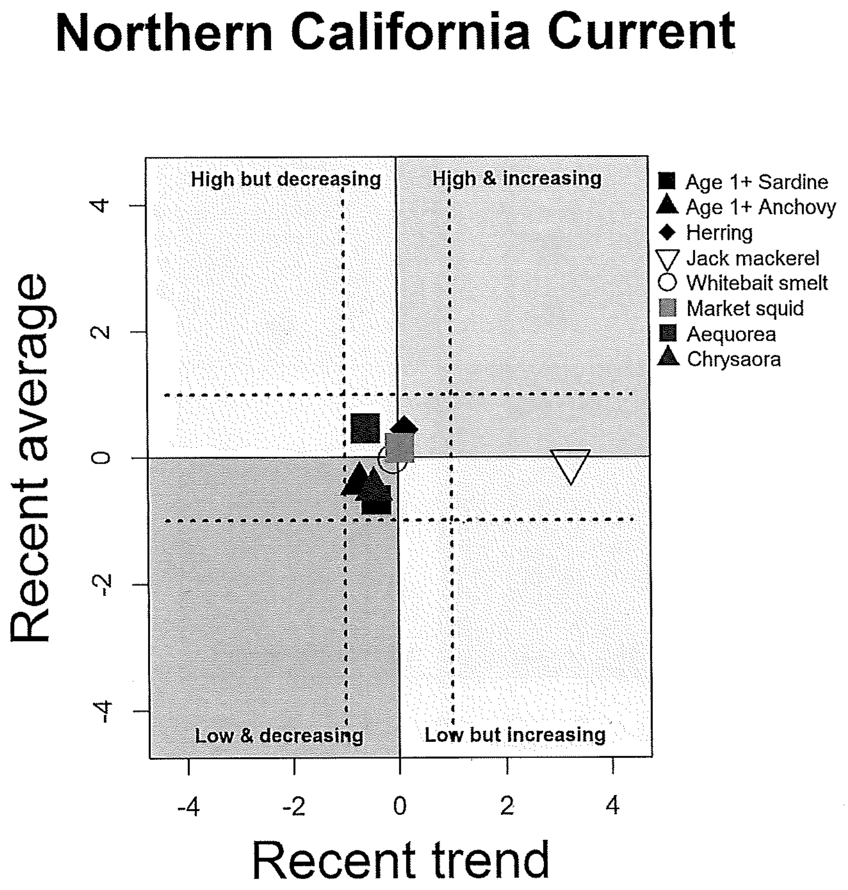

Figure 14. Means and trends of CPUE for key forage in the Northern CCE. Means and trends are from 2012–16 and normalized relative to the full time series (1999–2016). Lines, colors, and symbols are as in Figure 3b. Pelagic forage data from the Northern CCE were provided by Dr. Ric Brodeur (NOAA) and were derived from surface trawls conducted as part of the Bonneville Power Authority Plume Survey.

Central CCE

Data presented here are from the "core area" of a survey (see Figure 4c) that targets YOY rockfishes, but also samples other forage fishes, market squid, and zooplankton. The Central CCE forage community in 2016 exhibited many of the anomalous catch levels and trends observed in recent years. Adult sardine and anchovy CPUEs remained relatively low, whereas YOY rockfish CPUE was above average for the fourth year in a row (Figure 15; see also Harvey and Garfield 2017b). YOY Pacific hake CPUE also maintained its recent increase, and YOY sanddabs (*Citharichthys* spp.) remained above the long-term mean. Krill and market squid CPUE have declined in recent years, particularly squid since 2014. *Chrysaora* jellyfish also declined, though that may be due to avoidance of sites where *Chrysaora* has fouled sampling gear in the past. However, salps were relatively abundant, as were warm-water species such as pelagic crabs (*Pleuroncodes planipes*; data not shown).

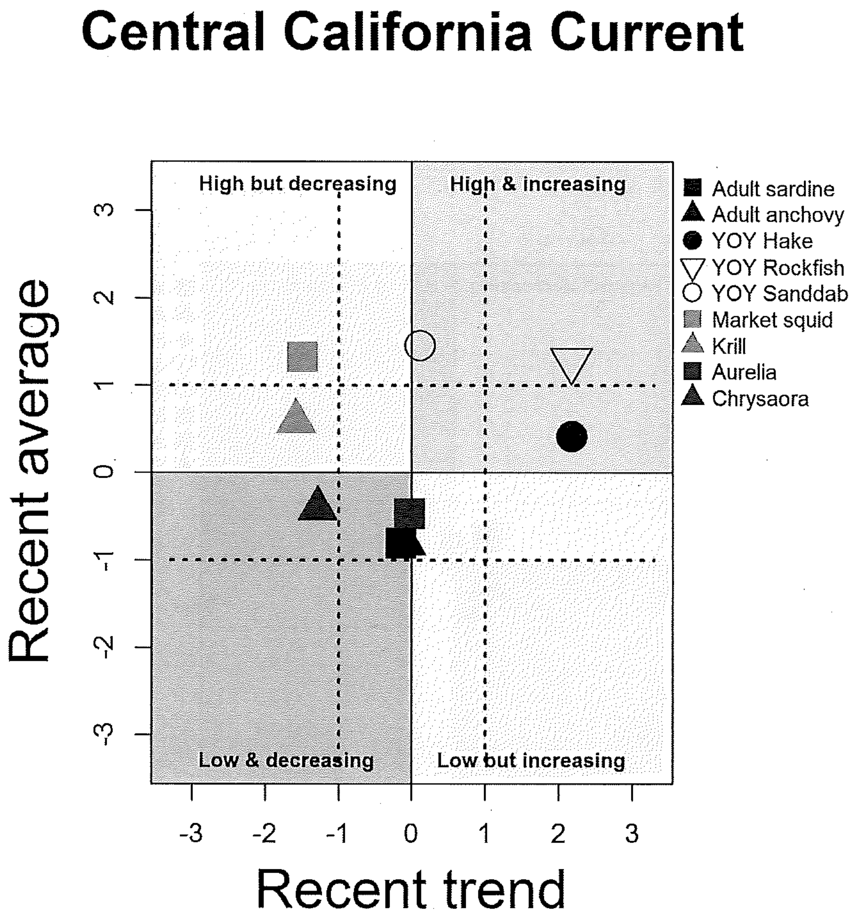

Figure 15. Means and trends of CPUE for key forage in the Central CCE (core area). Means and trends are from 2012–16 and normalized relative to the full time series (1990–2016). Lines, colors, and symbols are as in Figure 3b. Pelagic forage data from the Central CCE were provided by Dr. John Field (NOAA) from the SWFSC Rockfish Recruitment and Ecosystem Assessment Survey.*

Southern CCE

The forage abundance indicators for the Southern CCE come from larval fish surveys conducted by CalCOFI. The larval biomass is assumed to correlate with the spawning stock biomass (SSB) of forage species such as sardine, anchovy, market squid, shortbelly rockfish (*Sebastes jordani*), and some mesopelagic species. Recent CPUE for the four species that have been analyzed through 2016 were within ±1 SD of their long-term means, but anchovy showed a significant increasing trend while market squid show a recent decline (Figure 16). The increase in larval anchovy CPUE in recent years is consistent with anecdotal nearshore observations of large schools of adult anchovy in the Southern California Bight.

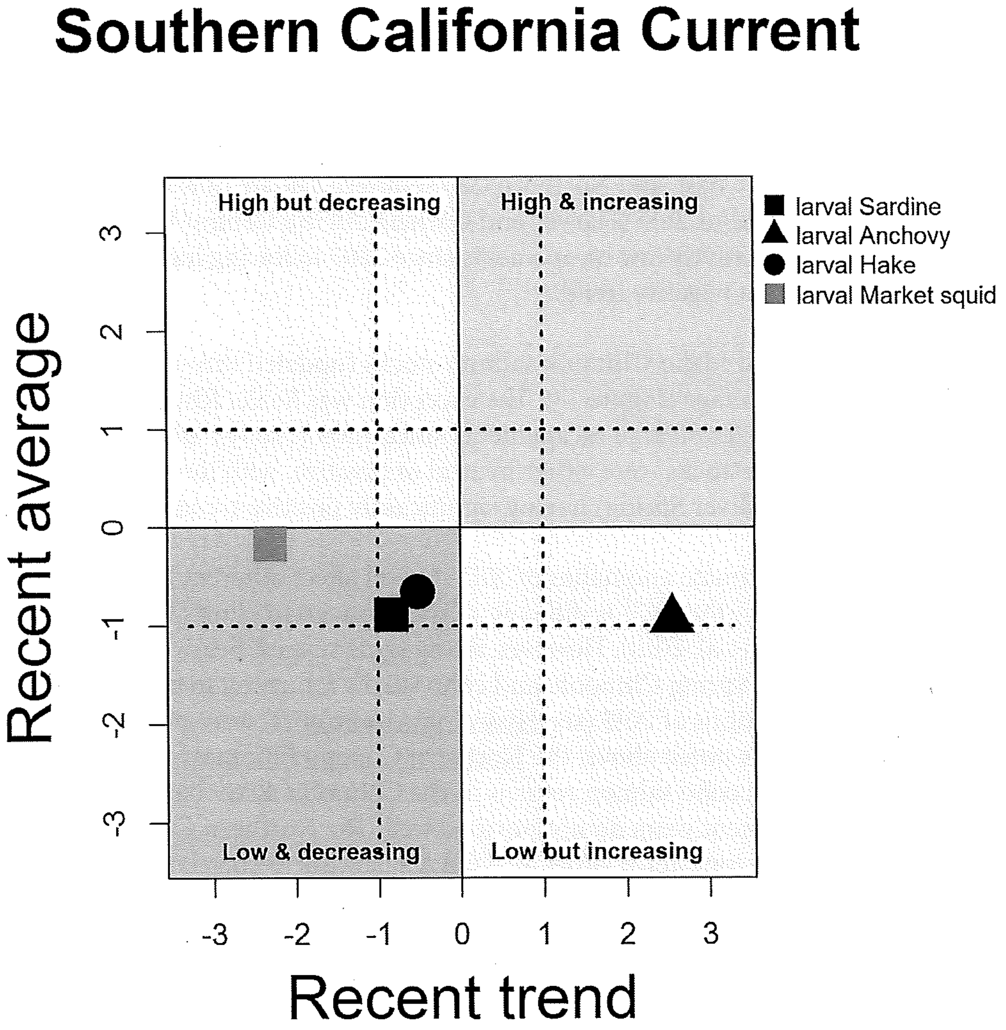

Figure 16. Means and trends of CPUE for key forage in the Southern CCE. Means and trends are from 2012–16 and normalized relative to the full time series (1990–2016). Lines, colors, and symbols are as in Figure 3b. Pelagic forage data from the Southern CCE were provided by Dr. Andrew Thompson (NOAA) and were derived from spring CalCOFI surveys.

Salmon

For indicators of the abundance of Chinook salmon populations, we compare the trends in natural spawning escapement along the CCE to evaluate the coherence in production dynamics, and also to get a more complete perspective of their status across the greater portion of their range. When available, we use escapement time series back to the 1970s; however, some populations have shorter time series (for example, Central Valley Spring starts in 1995, Central Valley Winter starts in 2001, and Coastal California starts in 1991). Here, we present the Chinook salmon escapements in quad plots; time series data for specific populations are summarized elsewhere (Harvey and Garfield 2017b).

Due to data limitations, California Chinook salmon escapements are updated only through 2015. Generally, California Chinook salmon escapements were within 1 SD of their long-term averages (Figure 17), although 2015 escapements were generally near the low end of the normal range (Harvey and Garfield 2017b). Most California stocks have neutral trends over the last decade, which is a noteworthy change from our last report: trends that had been positive for Central Valley Fall, Klamath Fall, California Coast, and Northern CA/Southern OR are now neutral after poor escapements in 2013, 2014, and/or 2015 (Harvey and Garfield 2017b). Central Valley Winter Run Chinook salmon have had relatively low escapements since 2007 following high escapements in 2005–06, leading to the recent negative trend.

For Oregon, Washington, and Idaho Chinook salmon stocks (updated through 2014), most recent escapements were close to average (Figure 17). The exception was Snake River Fall Chinook, which have experienced a series of large escapements since 2009 (Harvey and Garfield 2017b). Ten-year trends for northern stocks were either neutral or positive, with three (Lower Columbia, Snake River Fall, and Snake River Spring) having significantly positive trends from 2005–14.

Predicting exactly how the climate anomalies of 2013–16 will affect different brood years of salmon from different parts of the CCE is difficult, despite concerted efforts by many researchers (e.g., Burke et al. 2013, Wells et al. 2016). However, many signs suggest below-average returns may occur for Fall Chinook, Spring Chinook, and coho stocks returning to the Columbia Basin. The poor hydrological conditions of 2015 (see Hydrologic Indicators) were problematic for both juvenile and adult salmon. As noted above, the Northern Copepod Biomass Anomaly is positively associated with Chinook and coho salmon returns in the Columbia River basin (Peterson et al. 2014), and its low levels in recent years do not portend well. The Northern Copepod Biomass Anomaly is just one part of a long-term effort by NOAA scientists to correlate oceanographic conditions and pelagic food web structure with salmon productivity (e.g., Burke et al. 2013). Their assessment is that physical and biological conditions for smolts that went to sea between 2013 and 2016 are generally consistent with poor returns of Chinook and coho salmon to much of the Columbia Basin in 2017, as depicted in the "stoplight chart" in Table 1.

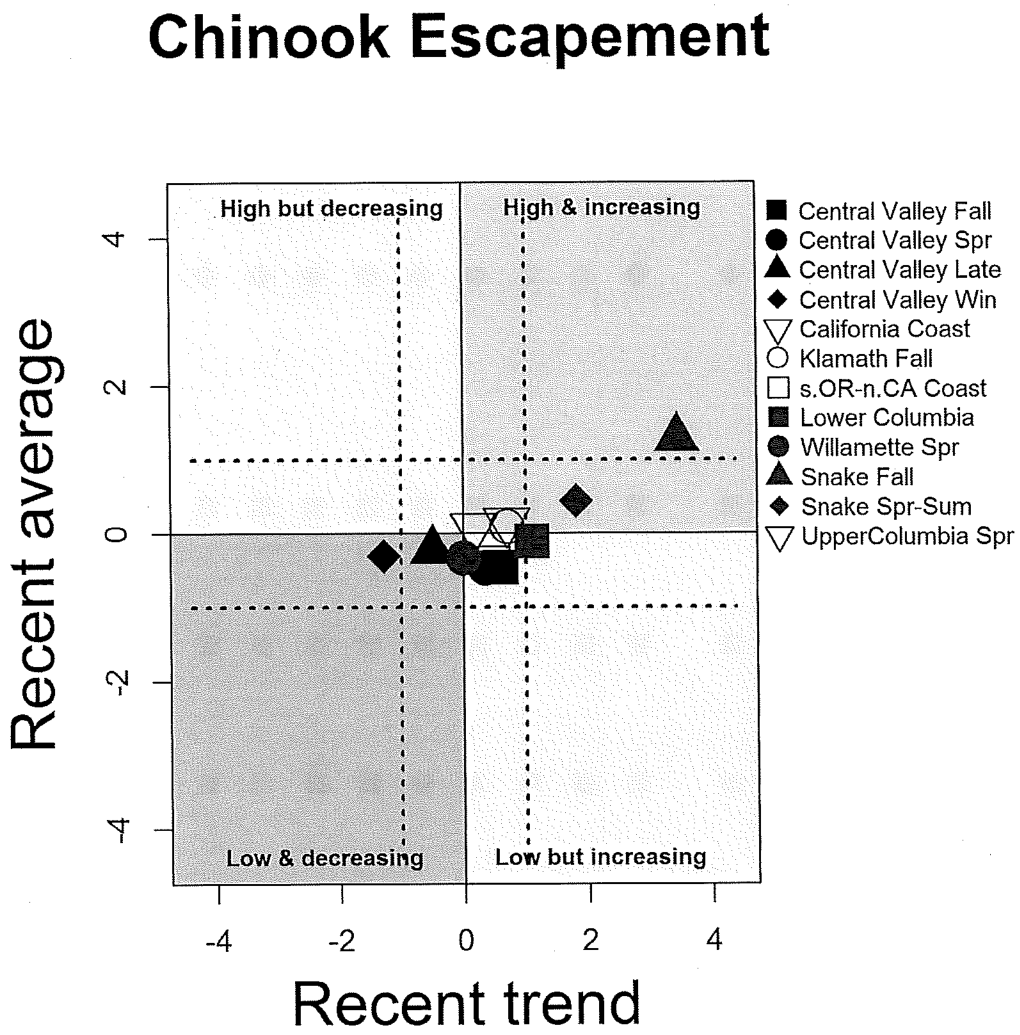

Figure 17. Chinook salmon escapement anomalies through 2015. "Recent average" is mean natural escapement (includes hatchery strays) from 2006–15 relative to the mean of the full time series. "Recent trend" indicates the escapement trend from 2006–15. Base colors and lines are as in Figure 3b. Chinook salmon escapement data were derived from the California Department of Fish and Wildlife,* from Pacific Fishery Management Council preseason reports,† and from NWFSC's "Salmon Population Summary" database.‡

Groundfish: Stock Abundance and Community Structure

The CCIEA team regularly presents the status of groundfish biomass and fishing pressure based on the most recent stock assessments. About one-third of the species in the groundfish Fishery Management Plan (FMP) have been formally assessed since 2007. Two key indicators derived from these stock assessments are summarized here. The first indicator describes how close groundfish population abundances are to biomass targets or limits, including being in "overfished" status. It is expressed on the x-axis of Figure 18 in terms of the spawning output (SO) of the mature population biomass. Specifically, it is the ratio of SO in the terminal year of the assessment ($SO_{terminal}$) to the target SO that supports maximum sustainable yield (SO_{MSY}) for that stock. For flatfishes, SO_{MSY} is assumed to be 25% of the theoretical SO of an unfished population; for other groundfishes, SO_{MSY} is assumed to be 40% of unfished SO. The target reference point (TRP) for $SO_{terminal}/SO_{MSY}$ is 1.0. If $SO_{terminal}/SO_{MSY}$ falls below the established limit reference point (LRP; 0.5 for flatfishes, 0.6 for all other groundfishes), then the stock is designated to be overfished, and a rebuilding plan with various management measures will be implemented.

The second key groundfish indicator describes the fishing rate and whether or not "overfishing" (i.e., fishing greater than the target fishing rate) is currently occurring on assessed stocks. Overfishing technically occurs when catches exceed overfishing limits (OFLs), but not all assessed stocks are managed by individual OFLs. Our best alternative was to compare fishing rates to proxy fishing rates at maximum sustainable yield (F_{MSY}), which are used to set OFL values. The y-axis of Figure 18 is therefore not a direct measure of overfishing, but rather a measure of whether fishing rates are above proxy-MSY fishing rates ($F_{30\%}$ for flatfishes, $F_{50\%}$ for other groundfish). This occurs when the ratio of $F_{terminal}/F_{MSY}$ is >1.0, i.e., above the horizontal dashed line in Figure 18.

Most of the recently assessed groundfish species are near or above the biomass LRPs, and are thus not in an overfished status (Figure 18). Only two stocks (Pacific ocean perch [*Sebastes alutus*] and yelloweye rockfish [*S. ruberrimus*], both last assessed in 2011) remained below the rockfish LRP as of their most recent assessment. Only two stocks (black rockfish [*S. melanops*] stocks in California and Washington, both assessed in 2015) were being fished above F_{MSY} in their most recent assessments.

Because 2017 was a year in which many stock assessments were conducted, the information in Figure 18 will be updated substantially in the 2018 ecosystem status report, as well as in the 2018 iteration of this Technical Memorandum series.

As noted in Regional Forage Availability, YOY rockfish were highly abundant in the Central CCE in 2015 and 2016, and results from both shipboard and scuba surveys also revealed large numbers of pelagic and post-settled juvenile rockfish along the Washington coast in 2016. Given the anomalously warm and unproductive oceanographic conditions of 2013–16, these findings run counter to what we might have expected from conceptual models linking climate and productivity conditions to groundfish populations (Harvey and Garfield 2017b). It will be several years before these fish are large enough to be caught in bottom trawls; thus, we will have to wait to determine how groundfish populations changed following the recent climate anomalies.

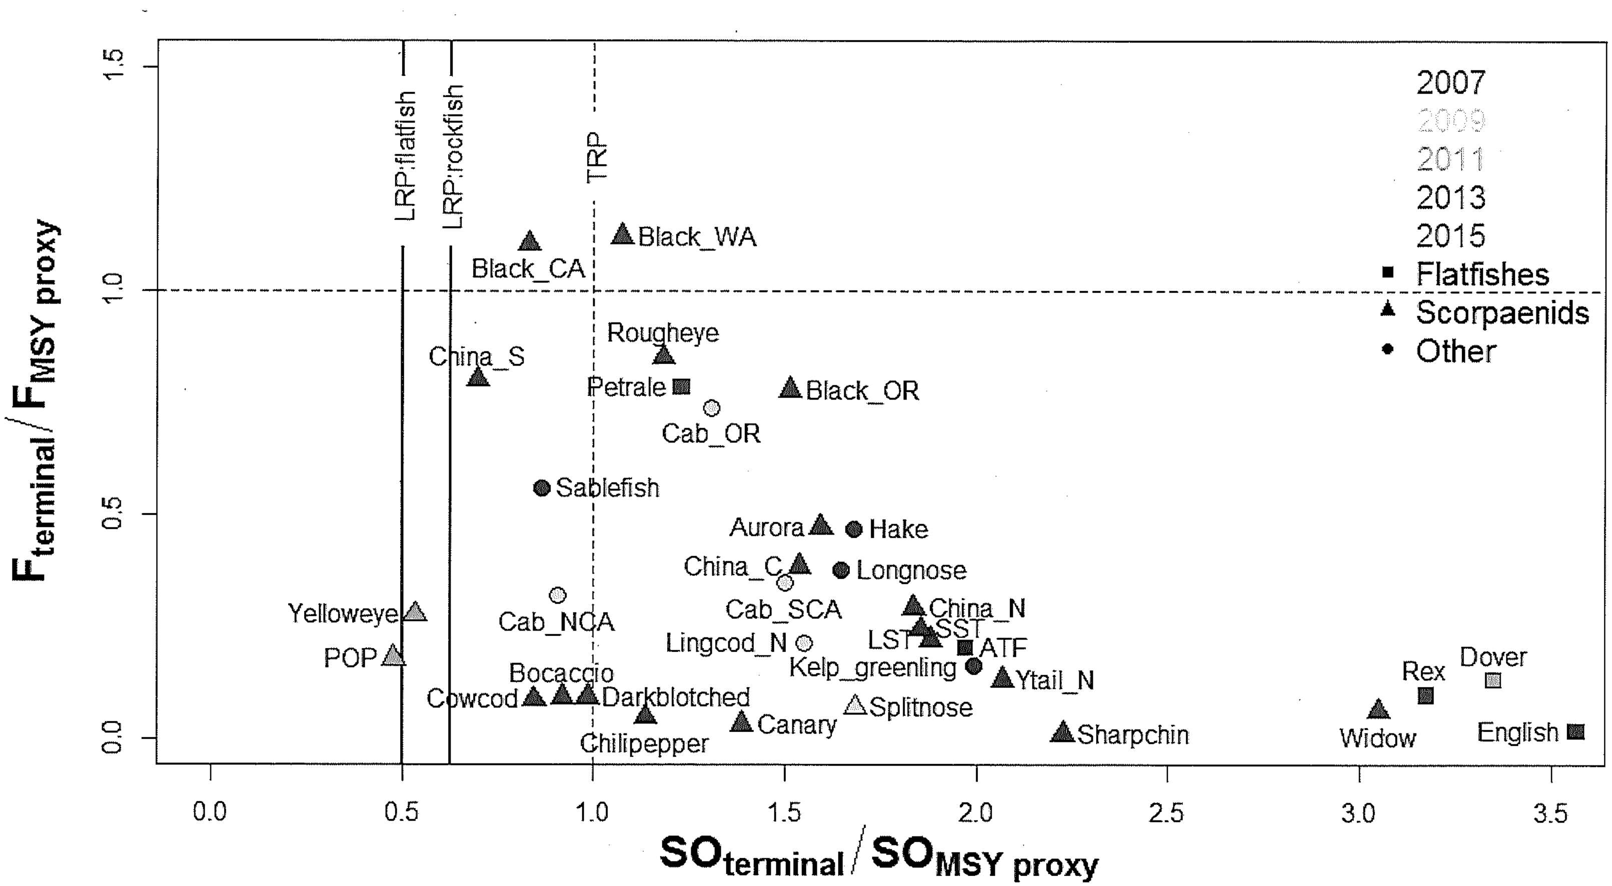

Figure 18. Stock status of CCE groundfish, based on spawning output (SO) and fishing rate (F) from the most recent stock assessment of each stock. The x-axis is an indicator of the biomass of the stock, expressed as SO in the terminal assessment year relative to SO at the theoretical stock biomass associated with maximum sustainable yield (MSY). The y-axis is an indicator of fishing pressure, expressed as F in the terminal assessment year relative to F consistent with MSY. Horizontal dashed line = overfishing rate limit reference. Vertical lines = biomass target reference point (TRP, dashed line) and limit reference points (LRP, solid lines; falling to the left of these lines indicates overfished status for flatfish or rockfish/other groundfish). Symbols indicate groupings of taxa; colors indicate year of most recent assessment. Groundfish stock status data were provided by Dr. Jason Cope (NOAA) and were derived from NMFS stock assessments.

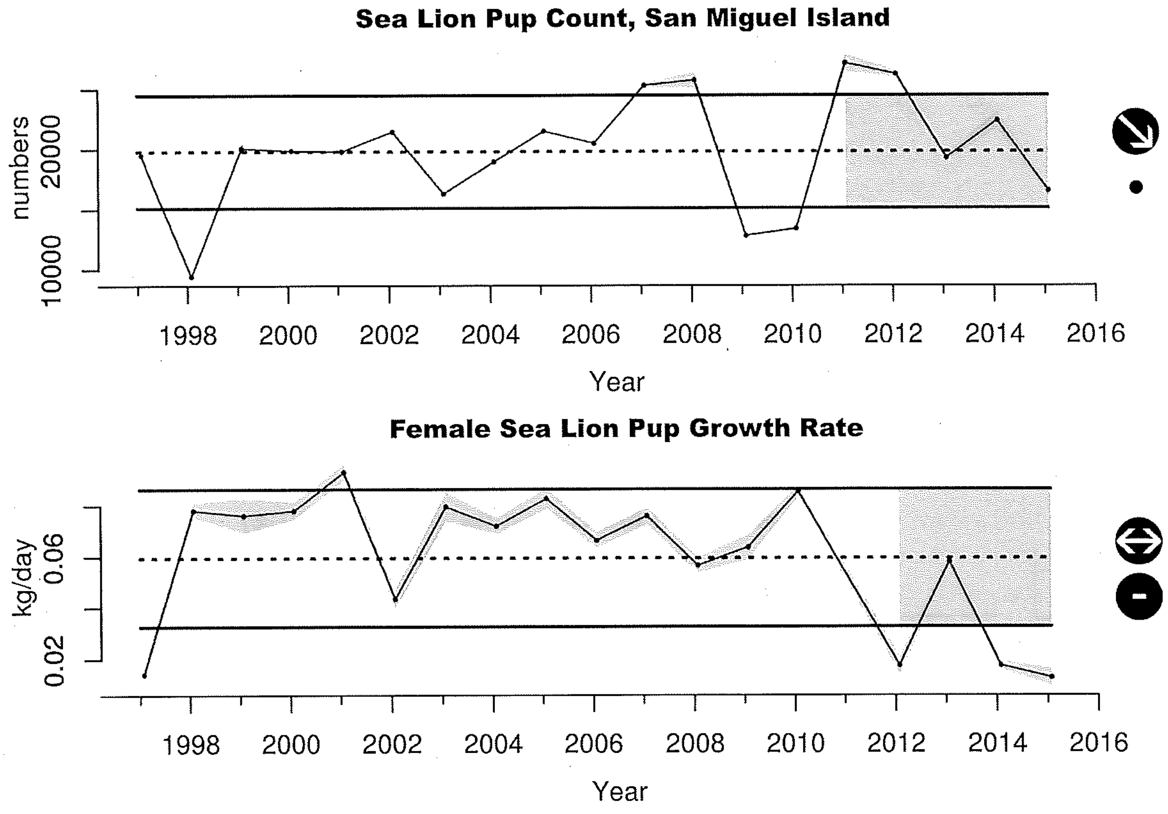
Marine Mammals

California sea lions (*Zalophus californianus*) are permanent residents of the CCE, breeding on the Channel Islands and feeding throughout the CCE, and so are good indicators for the population status of pinnipeds in the system. California sea lions may also be sensitive indicators of prey availability in the Central and Southern CCE: the sea lion pup count in the San Miguel Island breeding colony relates to prey availability for adult females during gestation (October–June), while pup growth is related to prey availability to adult females during the 11-month lactation period (Melin et al. 2012).

Over recent years, California sea lion adult females experienced extremely poor feeding conditions (Figure 19). Pup counts declined from 2011–15, and pup growth was near historic lows in at least three of the last five cohorts. These results, coupled with high rates of springtime pup stranding and mortality in 2013–16, reflect the extent of poor foraging conditions for pinnipeds in the Central and Southern CCE and may foretell a decrease in the California sea lion adult population. Other pinniped species that breed in this region but forage further offshore (Guadalupe fur seals [*Arctocephalus townsendi*] and northern fur seals [*Callorhinus ursinus*]) also experienced poor pup growth in the same time period.



Sea Lion Pup Count, San Miguel Island

Female Sea Lion Pup Growth Rate

Figure 19. California sea lion pup counts at San Miguel Island (top) and estimated mean daily growth rate of female pups from 4–7 months (bottom) for the 1997–2015 cohorts. Lines, colors, and symbols are as in Figure 3a. California sea lion data were provided by Dr. Sharon Melin (NOAA).

Preliminary results suggest that the 2016 cohort of California sea lion pups at San Miguel was more abundant and experienced better early growth than the preceding four cohorts, implying that foraging conditions may have improved.

Seabirds

Seabird species richness data were unavailable for this report, so we instead present regional time series for three key species. Data are derived from visual shipboard surveys during sampling cruises in regions shown in Figure 4c. Sooty shearwaters (*Ardena grisea*) migrate from the southern hemisphere to the CCE in spring and summer to prey on small fish and zooplankton near the shelf break. Cassin's auklets (*Ptychoramphus aleuticus*) and common murres (*Uria aalge*) are resident species that feed over the shelf; Cassin's auklets prey on zooplankton, while common murres target small fish.

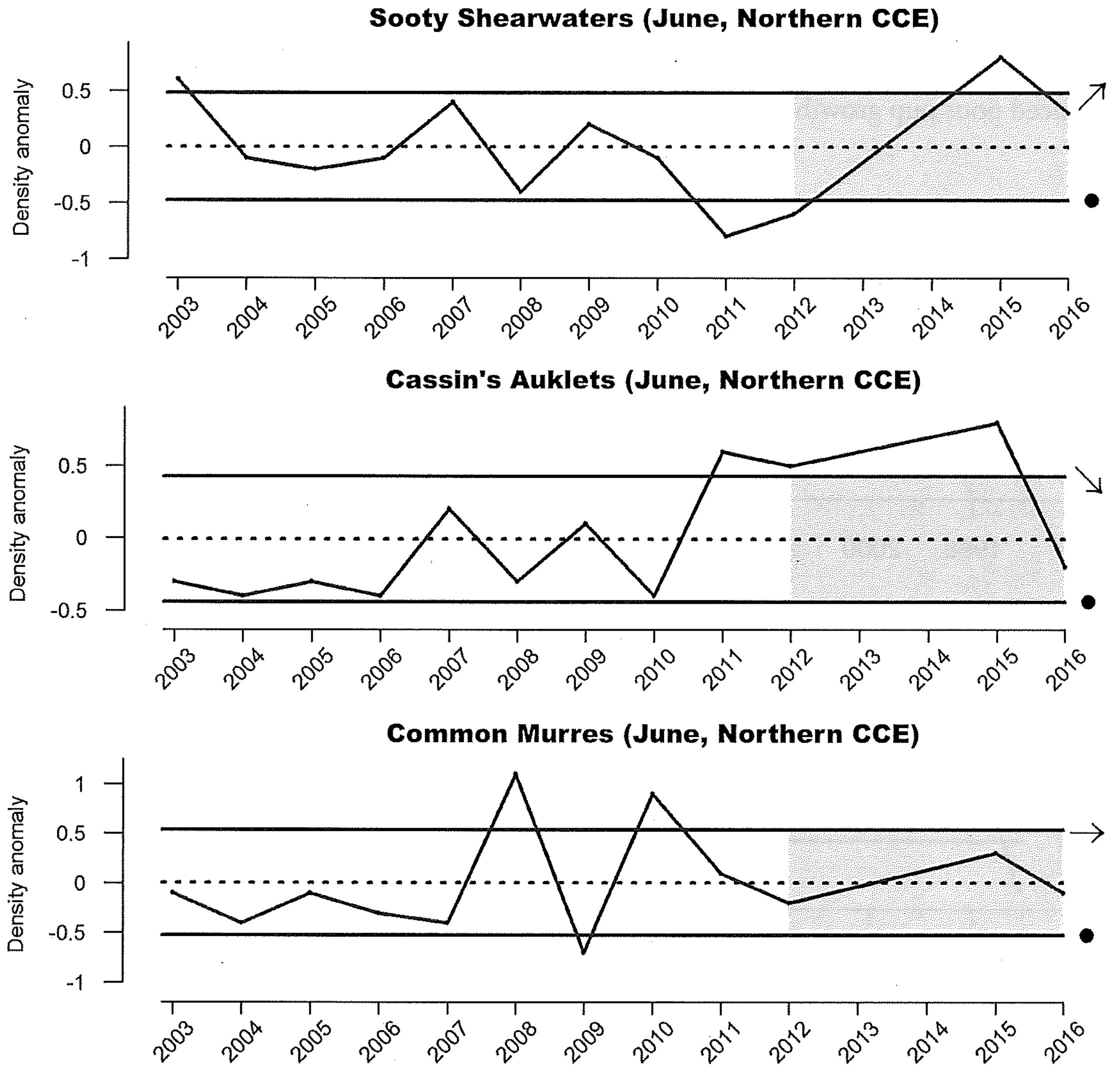


Figure 20. Anomalies in at-sea densities of sooty shearwaters, Cassin's auklets, and common murres in June in the Northern CCE through 2016. Lines, colors, and symbols are as in Figure 3a. Seabird abundance data from the Northern CCE were collected and provided by Dr. Jeannette Zamon (NOAA).

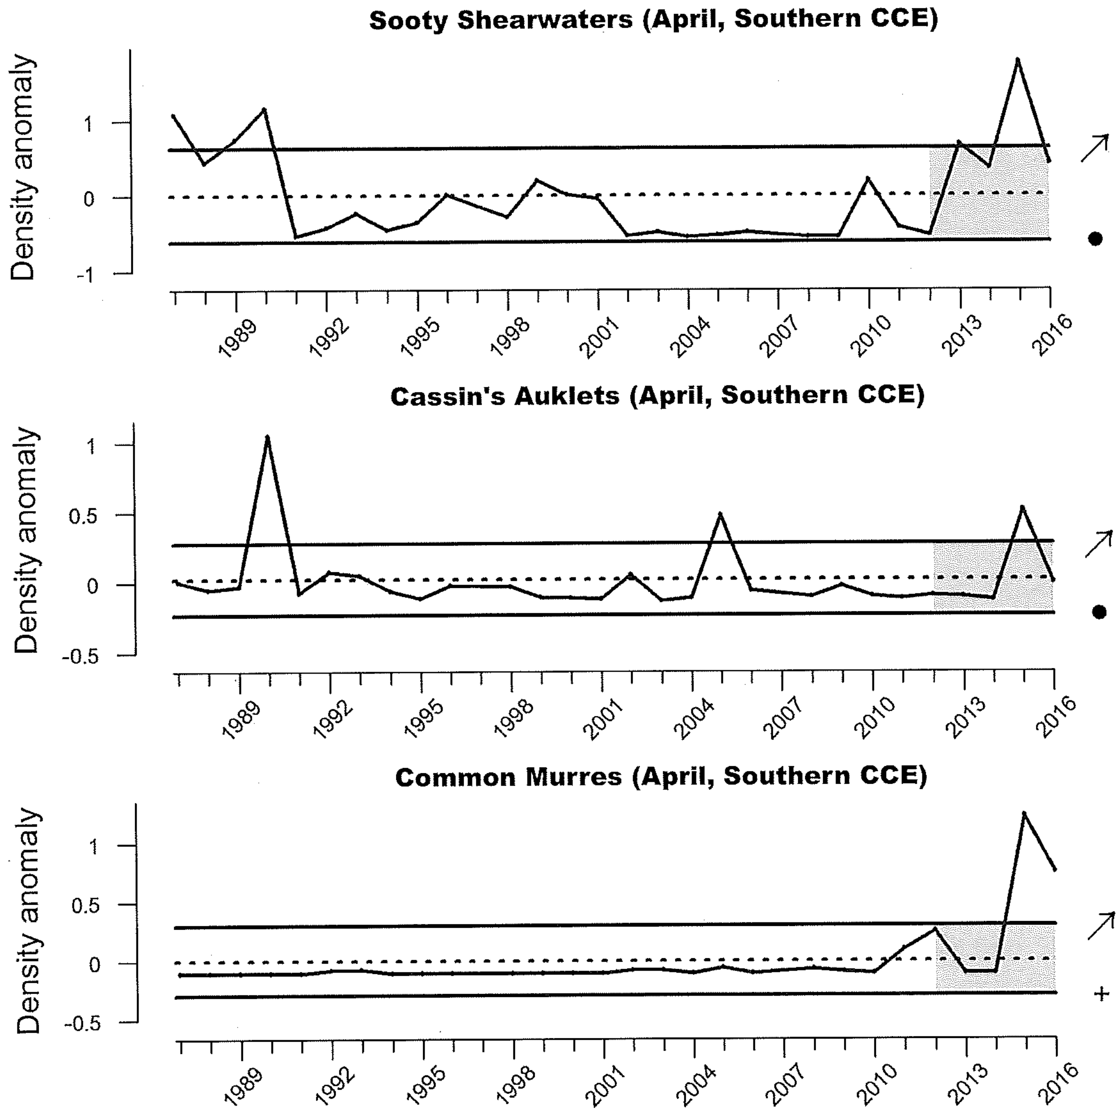
In the Northern CCE sampling area, all three species exhibited temporal variability, particularly since the mid-2000s (Figure 20). Sooty shearwaters have increased in recent years, while Cassin's auklets declined in 2016, possibly related to an exceptional mortality event in 2014–15. Common murre counts showed no trend. (Note: No data were collected in 2013 or 2014.)

In the longer Southern CCE time series, sooty shearwaters had increasing springtime density trends over the past five years (Figure 21), which represents a return to densities observed in the late 1980s. Common murre densities had been minimal since data collection began in 1987 until an uptick in 2011, followed by strongly positive anomalies in 2015 and 2016. By contrast, Cassin's auklets in the Southern CCE have been just below average density over the last 10 years.



Sooty Shearwaters (April, Southern CCE)

Cassin's Auklets (April, Southern CCE)

Common Murres (April, Southern CCE)

Figure 21. Anomalies in at-sea densities of sooty shearwaters, Cassin's auklets, and common murres in April in the Southern CCE through 2016. Lines, colors, and symbols are as in Figure 3a. Seabird abundance data from the Southern CCE are from CalCOFI surveys, courtesy of Dr. Bill Sydeman (Farallon Institute).

The positive density anomalies in recent years are surprising, given the recent and persistent warm conditions. (For example, sooty shearwaters increased despite their cold-water affinities.) These are abundance indicators of long-lived birds, however, and we may need condition indicators like diet, hatching rates, fledgling success, or others to fully understand recent seabird dynamics. To illustrate this, in each of the past several years, at least one seabird species has experienced a "wreck"—anomalously large numbers of dead birds washing up on beaches throughout much of the CCE (e.g., Cassin's auklets in 2014 and common murres in 2015). In the summer of 2016, rhinoceros auklets (*Cerorhinca monocerata*) experienced a wreck, although it was largely confined to the Northern CCE (Harvey and Garfield 2017b).

Human Activities

Coastwide Landings by Major Fisheries

Data for fishery landings are current through 2015. Overall, total landings decreased over the last five years, driven mainly by steep declines in landings of Pacific hake, CPS, and crab in 2015 (Figure 22). Landings of groundfish (excluding hake) were historically low from 2011–15, while hake landings were highly variable. Landings of coastal pelagic fishes and market squid decreased over the last five years. Shrimp landings increased to historic highs, particularly from 2013–15, whereas crab declined sharply from a peak in 2013. Salmon landings were highly variable, while highly migratory species (HMS) landings were relatively consistent; both were within ±1 SD of historic averages. Recreational landings were historically low from 2004–15, and showed no recent trend. Total commercial fishery revenues (in adjusted 2015 dollars) have declined sharply since 2013, driven by declines in landings of crab, market squid, and hake (Harvey and Garfield 2017b). State-by-state commercial and recreational landings and revenue trends are summarized in Harvey and Garfield (2017b).

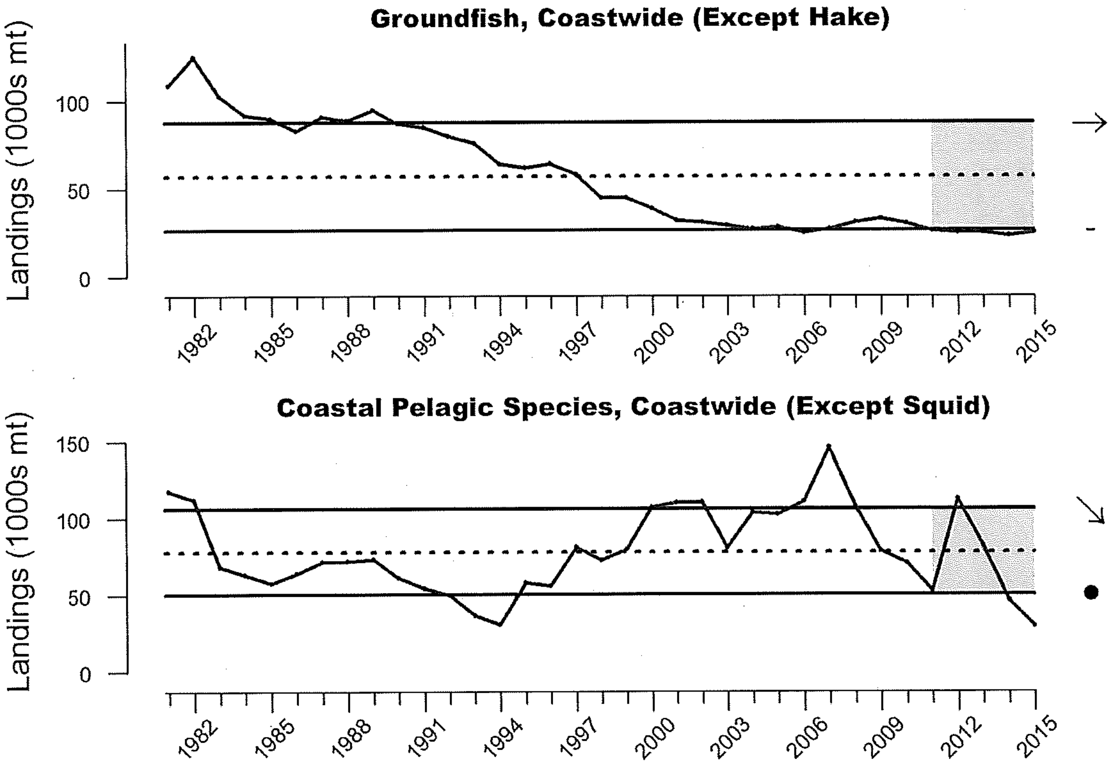


Figure 22. Annual landings of West Coast commercial and recreational fisheries, including total landings across all fisheries from 1981–2015. Lines and symbols are as in Figure 3a. Data for commercial landings are from PacFIN.* Data for recreational landings are from RecFIN.†

Gear Contact with Seafloor

Benthic marine species, communities, and habitats can be disturbed by natural processes as well as by human activities (e.g., bottom contact fishing, mining, or dredging). The impacts of fishing likely differ by gear and by habitat type, with hard, mixed, and biogenic habitats needing longer to recover than soft sediments.

We compiled estimates of coastwide distances affected by bottom-contact gear from 1999–2015. Estimates from 2002–15 include bottom trawl and fixed gear, while 1999–2002 includes only bottom trawl data. We calculated trawling distances based on set and haul-back points, and fixed gear distances based on set and retrieval locations of pot, trap, and longline gear. We weighted distances by gear and habitat type, according to sensitivity values described in Table A3a.2 of the 2013 PFMC Groundfish Essential Fish Habitat Synthesis Report[7] (available online only). Gear contact with the seafloor was at historically low levels over the most recent five-year period (Figure 23). The dominant source of seafloor-gear interaction was bottom trawl contact with soft sediments on the shelf and upper slope of the Northern CCE (Harvey and Garfield 2017b). There is uncertainty in the estimation of bottom contact among fixed gear types (e.g., longline vs. pot and trap gear), but this uncertainty is minor compared to the signal from bottom trawl gear.

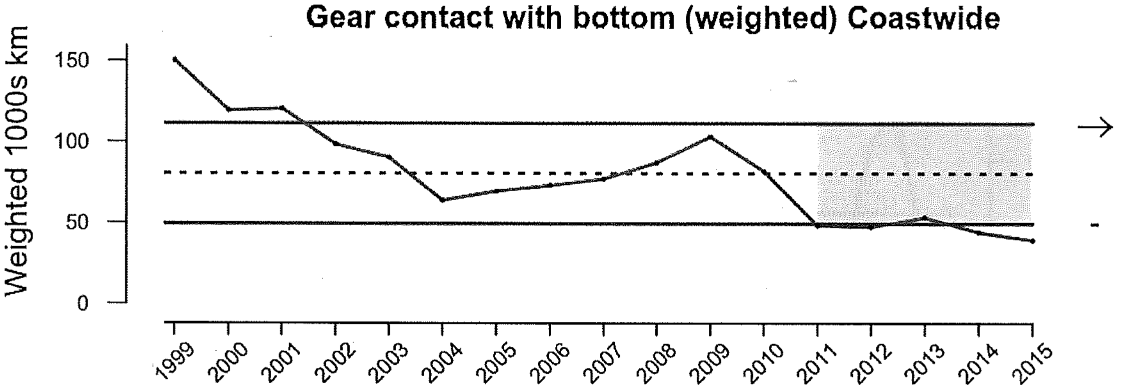

Figure 23. Cumulative weighted distance of fishing gear contact with bottom habitat across the entire CCE, 1999–2015. Lines, colors, and symbols are as in Figure 3a. Data for total benthic habitat distance disturbed by bottom-contact fishing gears were provided by Mr. Jon McVeigh (NOAA). Weightings for benthic habitat sensitivity values come from PFMC's Pacific Coast Groundfish 5-Year Review of Essential Fish Habitat.

Aquaculture and Seafood Production

Aquaculture activities satisfy some of the demands for seafood and may be related to benefits (e.g., water filtration by bivalves, nutrition, income, or employment) or impacts (e.g., habitat conversion, waste discharge, or species introductions). Shellfish aquaculture production in the CCE has been at historically high levels in recent years (updated through 2014 as of this report), and finfish aquaculture (exclusively Atlantic salmon [*Salmo salar*]) has been near the upper limits of historical averages (Figure 24). Demand for seafood products is increasingly being met by aquaculture, and may be influencing the increases in production.

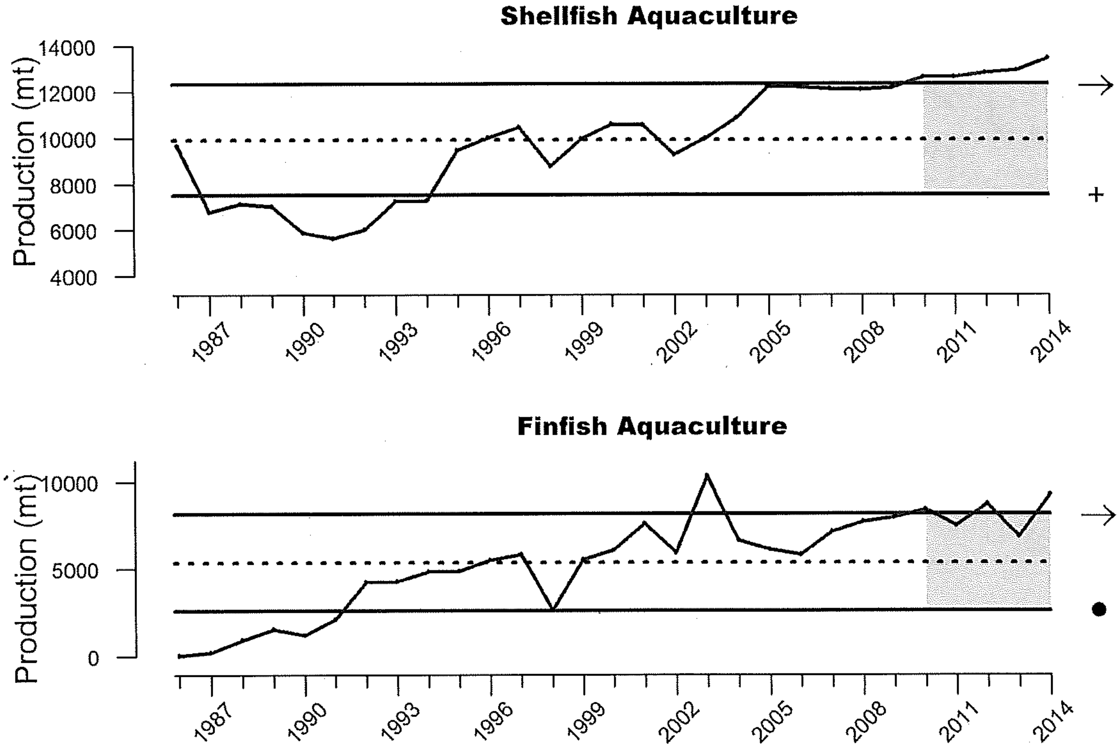

Figure 24. Aquaculture production of shellfish (clams, mussels, oysters) and finfish (Atlantic salmon) in CCE waters. Lines, colors, and symbols are as in Figure 3a. Shellfish aquaculture production data are from the Washington Department of Fish and Wildlife, the Oregon Department of Agriculture, and the California Department of Fish and Game. The only marine net-pen finfish aquaculture operations in the CCE occur in Washington State, and data came from the Washington Department of Fish and Wildlife.

Seafood demand in the U.S. was relatively constant from 2011–15, and had largely recovered from declines late in the previous decade (Figure 25). The recent average total consumption was above historical averages, while per-capita demand was within the historic range. With total demand already at historically high levels, increasing populations, and recommendations in U.S. Dietary Guidelines to increase seafood intake, total demand for seafood products seems likely to continue to increase for the next several years.

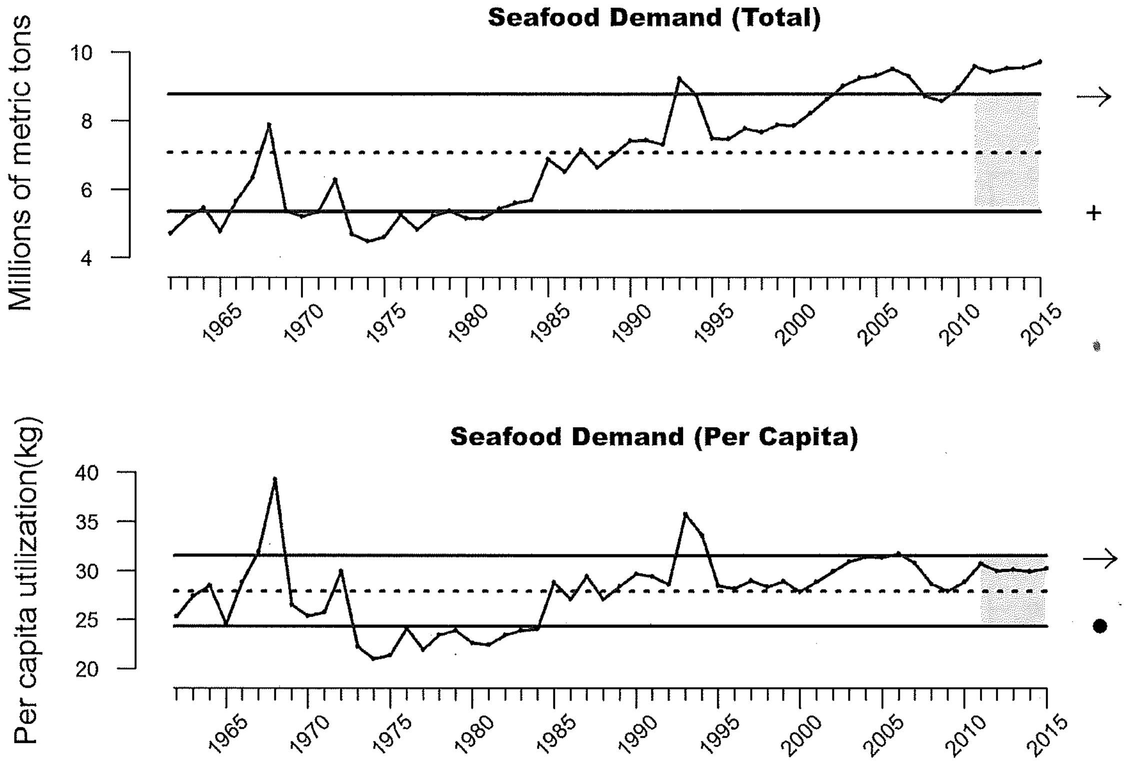

Figure 25. a) Total and b) per-capita use of fisheries products in the U.S., 1962–2015. Lines, colors, and symbols are as in Figure 3a. Data for total (imported and domestic) edible and inedible seafood consumption are from NOAA's Fisheries of the United States[*] annual reports describing the utilization of fisheries products.

Human Wellbeing

Social Vulnerability

Coastal community vulnerability indices are generalized socioeconomic vulnerability metrics for communities involved in commercial fishing. To assess social vulnerability in fishery-dependent communities, we use community-level social data, port-level fish ticket data, and a factor analysis approach to generate composite social vulnerability and commercial fishing indices for 1,139 coastal communities. The Community Social Vulnerability Index (CSVI; Jepson and Colburn 2013) is derived from social vulnerability data (demographics, personal disruption, poverty, housing characteristics, housing disruption, labor force structure, natural resource labor force, etc.). The fishing dependence composite index is based on commercial fishing engagement in a community (including fishery landings, revenues, permits, and processing) and commercial fishing reliance (per-capita enagagement). Figure 26 shows both indices for 25 highly fishing-dependent communities in five regions of the West Coast. Scores are relative to the entire CCE; for example, in 2014, the commercial fishing dependence of Moss Landing was ~33 SD greater than the average community. State-level summaries of CSVI scores are summarized elsewhere (Harvey and Garfield 2017b).

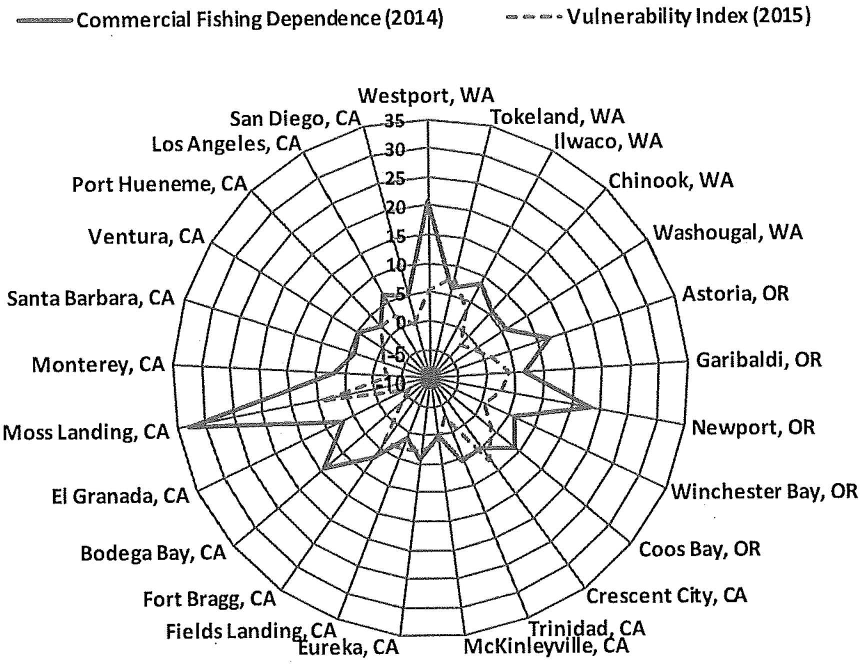

Figure 26. Commercial fishing dependence in 2014 (solid) and social vulnerability index in 2015 (dashed) for the five most fishing-dependent communities in Washington, Oregon, and northern, central, and southern California, expressed as standard deviations relative to all CCE communities. Shaded region is ≤1 SD. Fishery dependence and community social vulnerability index (CSVI) data were provided by Dr. Karma Norman (NOAA) and were derived from the U.S. Census Bureau,* the American Community Survey (ACS),† and PacFIN.

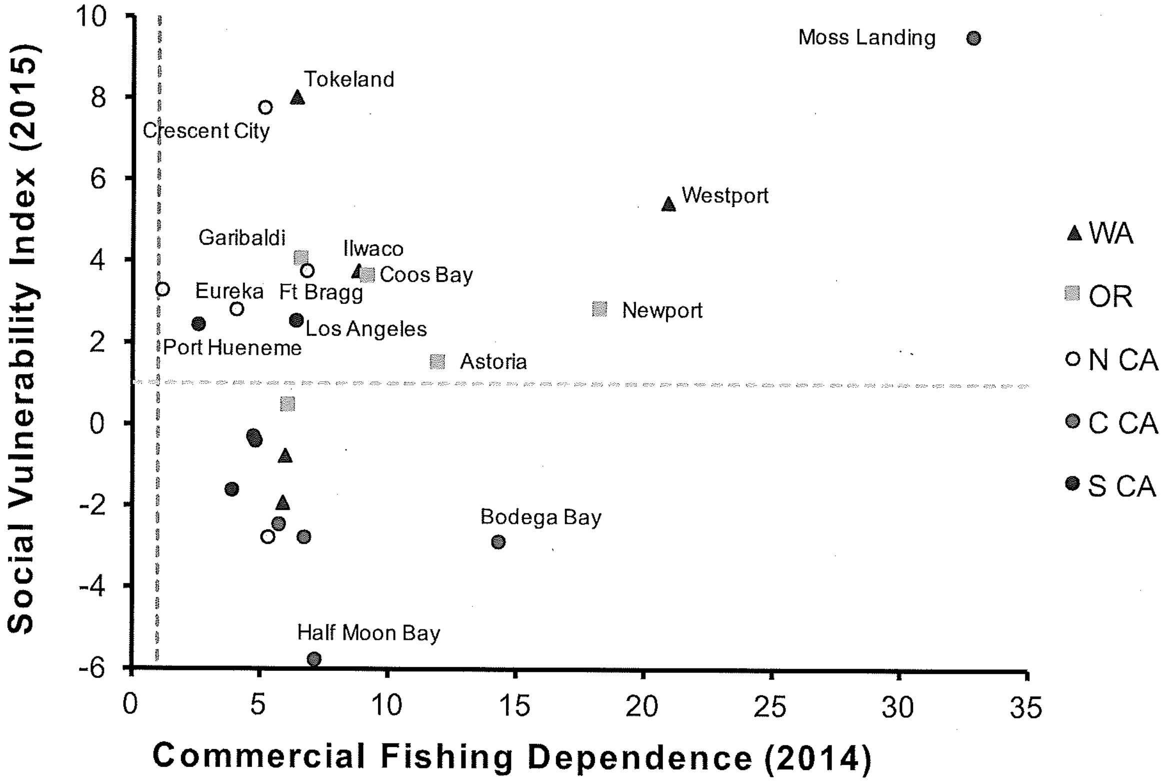
---

* http://www.census.gov/

† https://www.census.gov/programs-surveys/acs/

Figure 27 shows the two indices in x–y space, allowing us to readily identify fishing-dependent communities with high social vulnerability. Of note are communities like Moss Landing and Westport, which have relatively high commercial fishing dependence (~33 and 21 SD above average) and also a high CSVI (~10 and 5 SD above average). Communities that are strong outliers in both indices may be particularly socioeconomically vulnerable to a downturn in commercial fishing. Exogenous shocks of a management- or ecosystem-related nature may produce especially high individual and community-level social stress in these communities.



time periods as in Figure 26, but as x–y data color-coded by region. Dashed lines indicate 1 SD above the coastwide means, i.e., communities above and right of the two dashed lines have significantly greater social vulnerability and commercial fishing dependence than average communities in the CCE. Fishery dependence and community social vulnerability index (CSVI) data were provided by Dr. Karma Norman (NOAA) and were derived from the U.S. Census Bureau, the American Community Survey (ACS), and PacFIN.

Fleet Diversity Indices

Catches and prices from many fisheries exhibit high interannual variability, leading to high variability in fishers' income. Variability in annual revenue can be reduced by diversifying fishing activities across multiple fisheries or regions (Kasperski and Holland 2013). There may be good reasons for individuals to specialize, however, including reduced costs or greater efficiency. Thus, while diversification may reduce income variation, it does not necessarily promote higher average profitability. We measure diversification with the Effective Shannon Index (ESI). ESI = 1 when revenues are all from a single species group and region. It increases both as revenues are spread across *more* fisheries and as revenues are spread more *evenly* across fisheries. The index has an intuitive meaning: ESI = 2 if fishery revenues are spread evenly across 2 fisheries; ESI = 3 if revenues are spread evenly across 3 fisheries; and so on. If revenue is not evenly distributed across multiple fisheries, the ESI value is lower than the number of fisheries.

As of 2015, the fleet of vessels fishing on the U.S. West Coast and in Alaska was less diverse on average than at any point in the preceding 35 years (Figure 28). Between 2014 and 2015, some categories of vessels showed a small increase in ESI, while others decreased, but absolute changes were minor. The only vessel class to change by >2 SD was vessels 81–125 ft in length, for which ESI increased by about 5%; this change apparently was due to nonparticipation of some less-diversified vessels from West Coast fisheries in 2015. The long-term decrease in ESI from 1981–2015 was due both to entry and exit of vessels and changes for individual vessels. Over time, less-diversified vessels have been more likely to exit, which increases average diversification. However, vessels that remain in the fishery have also become less diversified since at least the mid-1990s, and newer entrants have generally been less diversified than earlier entrants. The overall result is a moderate decline in ESI since the mid-1990s or earlier for most vessel groupings. Notwithstanding these average trends, there are wide ranges of diversification levels and strategies within, as well as across, vessel classes, and some vessels remain highly diversified. It should be noted that increases in diversification from one year to the next may not always indicate an improvement in conditions for the fishing fleet. For example, if a class of vessels was heavily dependent on a single target species with highly variable revenues, such as Dungeness crab (*Metacarcinus magister*), an overall decline in the Dungeness crab fishery might cause ESI to increase. Also, an increase in ESI may be due to the exit of less-diversified vessels. Additional break-downs of diversification are provided in Harvey and Garfield (2017b).

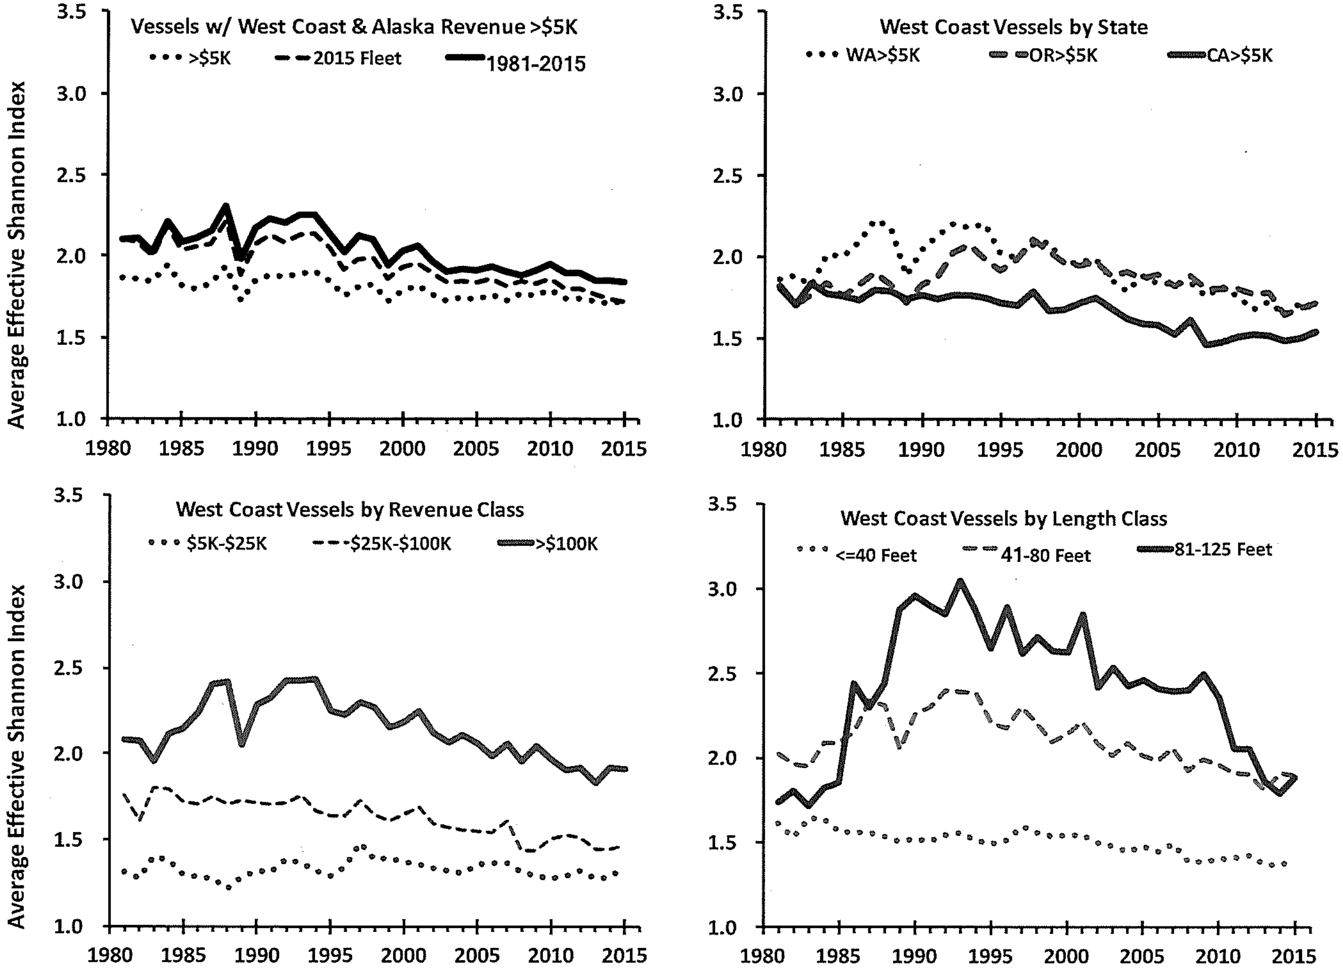


Figure 28. Average fishing vessel diversification for U.S. West Coast and Alaskan fishing vessels with over $5K in average revenues (top left) and for vessels in the 2015 West Coast Fleet, broken out by state (top right), average gross revenue (bottom left), and vessel length (bottom right). Fishery diversification estimates were provided by Dr. Dan Holland and Dr. Stephen Kasperski (NOAA).

CCIEA Team Recommendations for Future Research in the CCE

In March 2015, the PFMC approved FEP Initiative 2, "Coordinated Ecosystem Indicator Review," by which the PFMC, advisory bodies, the public, and the CCIEA team would work jointly to refine the indicators in the annual CCIEA Ecosystem Status Report to better meet PFMC objectives. The Initiative was implemented by an ad-hoc Ecosystem Working Group (EWG). (See PFMC's Decision Summary Document.[8])

As part of the FEP Initiative 2 process, the EWG asked the CCIEA team to summarize their research recommendations in the 2017 ecosystem status report. The six recommendations below reflect our collective assessment of science products that a) we believe are important, b) we could provide to the PFMC in a reasonable time frame (e.g., 1–3 years, including technical review by the SSCES), c) should support regional implementation of the NOAA EBFM Policy and Road Map,[9] and d) would provide added value to the indicators as they relate to management of FMP stocks and protected species.

1. Continue an ongoing scoping process between the PFMC and the CCIEA.

The CCIEA team recognizes the necessity to partner directly with the PFMC on these research recommendations, in order for them to be effective and directly applicable to management. We greatly appreciated the time and effort the PFMC committed to scoping these indicators under FEP Initiative 2. An ongoing scoping process could give the CCIEA team clear direction on PFMC needs, and give the PFMC a clear sense of CCIEA capabilities and capacity. Therefore:

- The Research Recommendations below are based on our current work and interests, but we would appreciate an opportunity to further scope CCIEA work with the PFMC and its advisory bodies, to ensure that our work is aligned with the PFMC's ecosystem science needs.

2. Continue making improvements to indicator analysis.

The CCIEA team benefited greatly from working with the EWG on FEP Initiative 2, and from the complementary support of the SSCES in providing technical review of CCIEA indicators and activities. The CCIEA team recommends that this partnership continue, with emphasis on:

- Continued refining of the existing indicators in this report, to better meet PFMC needs.
- Identifying and prioritizing indicator gaps, such as CPS, HMS, groundfish, diet information, chlorophyll, harmful algal blooms, and socioeconomic data from underreported communities.
- Using MARSS models to estimate trends in our indicators, separate from the observation error inherent in field sampling.
- Analyzing time series to 1) determine if threshold relationships exist between stressors and indicators, thus informing risk assessments, and 2) to detect early-warning indicators of major shifts in ecosystem structure or function.

3. Assess the dynamics of fisheries adaptation to short-term climate variability.

The CCE is highly variable, driven by annual or decadal variations such as El Niño events, PDO shifts, and marine heat waves. The livelihoods of fishers in the CCE are heavily influenced by such variability. As fishers attempt to adapt to variability by switching among fisheries, their actions impact other fishers and fishing communities, and may actively influence ecosystem dynamics. This project will investigate how fisheries management and fishers' fishing strategies combine to affect social and ecological resilience to the short-term climate variability inherent to the CCE. We plan to:

- Analyze how productivity of key species varies with climate/ocean conditions.
- Survey CCE fishers to determine motivations for fishery participation, and use the data from the survey and fish tickets to fit statistical models of individual fishing participation choices.
- Construct an integrated model of several CCE fisheries (e.g., salmon, Dungeness crab, albacore [*Thunnus alalunga*], groundfish, and shrimp) that determines participation and effort in each fishery.
- Model how climate variability affects fisheries both directly, via environmental effects, and indirectly, via participation decisions, and explore what types of fishing portfolios, for individuals or ports, result in lower variation in income and higher quality of life.

4. Assess the vulnerability of communities at sea to long-term climate change.

Long-term climate change has already shifted distributions of marine species in the CCE, but the socioecological impacts of climate change on fishing communities over the next several decades are difficult to anticipate. A major challenge remains in linking vulnerability to predicted long-term changes in the marine seascape upon which each community depends, particularly because both target species and fleets from different ports form spatially and temporally dynamic "communities at sea" (e.g., Colburn et al. 2016). We plan to:

- Develop a composite index of vulnerability for each community at sea as a function of its exposure (changes in target species biomass) and sensitivity (dependence on each target species) to long-term climate change.
- Assess each community at sea's adaptive capacity (e.g., mobility and target switching).
- Set up Environmental Competency Groups throughout the CCE, so that scientists, fishers, and managers can together interrogate information about climate vulnerabilities and impacts, co-develop adaptation strategies, and proactively reveal barriers to adaptation.

5. Explore implementing Dynamic Ocean Management to reduce bycatch in HMS fisheries.

Traditional management measures for bycatch reduction are static in space and time, despite the fact that both marine species and human users rely on dynamic environmental features. Dynamic Ocean Management (DOM) offers an ecosystem-based management approach toward addressing these dynamic issues (Lewison et al. 2015). We define DOM as management of marine systems that can change in space and time with the shifting nature of the ocean and its users. We are exploring DOM for HMS, specifically to maximize swordfish (*Xiphias gladius*) catch in the California drift gillnet fishery while minimizing bycatch of key species including leatherback sea turtles (*Dermochelys* *coriacea*), blue sharks (*Prionace glauca*), and California sea lions; we will extend this to include marine mammals that are hard-cap species, i.e., species that are protected such that capture of a specific number will result in a fishery closure for the rest of the season. Our approach is to:

- Use species-specific bycatch risk profiles to create risk–reward ratios for swordfish vessels.
- Track spatiotemporal changes in risk ratios as a function of management strategies and dynamic environmental conditions in the area of the drift gillnet fishery.

6. Assess the ecological and economic impacts of ocean acidification.

The CCE is characterized by upwelling of deep, cold, nutrient-rich waters that support fish stocks and the human communities that rely on them, but that also make the area particularly at risk of OA. The CCIEA team is leading focused research to identify the species, fisheries, FMPs, and ports most vulnerable to OA. Specifically, we will:

- Apply an Atlantis ecosystem model, which was formally reviewed by a PFMC Methodology Review Panel and the Center for Independent Experts in July 2014, and presented to the full PFMC in November 2014 (Kaplan and Marshall 2016).
- Link the Atlantis model to 1) ensembles of future scenarios for OA, warming, and species range shifts, and 2) updated information about species exposure and sensitivity to OA.
- Identify FMPs, ecoregions, and ports most likely affected by OA, warming, and subsequent range shifts, including both direct and indirect (e.g., food web) effects and impacts on coastal economies, as explored by Marshall et al. (2017).
- Consider impacts on FMPs that result from changes in prey productivity, for instance impacts on rebuilding rockfish stocks.

Conclusions

Conditions in the CCE in 2016–17 suggest a transitional period from several years of anomalously warm temperatures, below-average precipitation, and poor coastal productivity into conditions more representative of long-term averages. Some species already appear to be responding to this shift, although the extent of species responses will require many years to understand: the CCE is a species-rich system, and the many species have developed a wide range of adaptations to deal with the highly variable environmental conditions that characterize the California Current. Some of these adaptations may manifest themselves quickly, but many species in the CCE have highly protracted life histories, which could result in lag times before the environmental effects are known. Many species are also highly mobile or migratory, making it difficult to monitor them and track their responses in real time. Finally, we simply do not fully understand the relationships between many species and their environment, particularly when their environment experiences such extreme anomalies as observed in the California Current from 2013–16.

The CCIEA team will collaborate with colleagues in NOAA and partner agencies and institutions to determine if, in fact, the recent anomalous conditions have resulted in negative impacts on forage species, salmon, and higher predators. We are likely to find unanticipated responses, such as the large numbers of YOY groundfish observed in 2015–16 that suggest favorable conditions for early life stages of those species despite environmental and lower trophic-level indicators to the contrary. We will also continue to study linkages between these dynamics and the equally dynamic human communities that rely on California Current marine resources.

Brian, Sam, and Others:

The ocean off Oregon is anything but "normal." Even though SST had cooled down a bit, we still have relatively warm/fresh water at depth as well as strong positive anomalies in copepod species richness and southern copepod biomass—all indicators that we still have a lot of "El Niño water" hanging around. And returns of adult spring Chinook past Bonneville Dam (Columbia River) are 10% of the ten-year average so far. Finally we are seeing small numbers of *Pseudo-nitzschia*. Nothing normal! The only good news is that *Euphausia pacifica* have returned.

Some years ago, we did a "warm in the north, cold in the south" (or was it the opposite title?).

Bill

ABSTRACT

This report examines the ecosystem state of the California Current System (CCS) from spring 2016–spring 2017. Basin-scale indices suggest conditions that would support average to below average coast-wide production across the CCS during this time period. Regional surveys in 2016 sampled anomalously warm surface and subsurface waters across the CCS. Chlorophyll concentrations were low across the CCS in 2016 and, concomitant with that, copepod communities had an anomalously high abundance of subtropical species. Early in 2017 conditions between northern, central, and southern CCS were dissimilar. Specifically, surface conditions north of Cape Mendocino remained anomalously warm, chlorophyll was very low, and subtropical copepods were anomalously abundant. Southern and central CCS surveys indicated that environmental conditions and chlorophyll were within normal ranges for the longer time series, supporting an argument that biophysical conditions/ecosystem states in the southern and central CCS were close to normal.

Epipelagic micronekton assemblages south of Cape Mendocino were generally close to longer-term average values, however the northern assemblages have not returned to a "normal" state following the 2014–15 large marine heatwave and 2016 El Niño. North of Cape Mendocino the epipelagic micronekton was largely composed of offshore and southern derived taxa. We hypothesize that stronger-than-typical winter downwelling in 2017 and a reduced spawning biomass of forage taxa are contributors to the anomalous forage community observed in the north. Also of note, surveys indicate northern anchovy (*Engraulis mordax*) abundance was greater than average (for recent years) and nearer shore in northern regions. Finally, record-low juvenile coho and Chinook salmon catches in the 2017 northern CCS salmon survey suggest that out-migrating Columbia Basin salmon likely experienced unusually high early mortality at sea, and this is further supported by similarities between the 2017 forage assemblage and that observed during poor outmigration survival years in 2004, 2005, and 2015.

Generally, the reproductive success of seabirds in 2016 (the most current year available) was low in the north but near average in central California. At Yaquina Head off Oregon and Castle Rock off northern California some of the lowest reproductive success rates on record were documented. In addition to reduced abundance of prey, there was a northward shift of preferred seabird prey. Seabird diets in northern areas also corroborated observations of a northward shift in fish communities. Nest failure was attributed to a combination of bottom-up and top-down forces. At Castle Rock, most chicks died of starvation whereas, at Yaquina Head, most nests failed (95% of common murre, *Uria aagle*) due to disturbance by bald eagles (*Haliaeetus leucocephalus*) seeking alternative prey. Mean bird densities at sea for the 2017 surveys between Cape Flattery Washington and Newport Oregon were the lowest observed and may indicate continued poor reproductive performance of resident breeders in 2017. South of Cape Mendocino, where forage availability was typical, seabird reproductive success was also below average for most species in 2016, but did not approach failure rates observed in the north. Finally, in 2017, abundances of seabirds observed at-sea off southern California were anomalously high suggesting an improved foraging environment in that area.

Marine mammal condition and foraging behavior were also impacted by the increased abundance and shifting distribution of the northern anchovy population. Increases in the abundance of northern anchovy in the Southern California Bight coincided with improved condition of sea lion (*Zalophus californianus*) pups in 2016. Namely, lipid-rich northern anchovy occurred in great frequencies in the nursing female diet. Increases in northern anchovy nearshore in the central and northern CCS may have also contributed to a shoreward shift in distribution of humpback whales (*Megaptera novaeangliae*) in these regions. These shifts along with recovering humpback whale populations contributed to recent increases in human-whale interactions (e.g., fixed-gear entanglements).

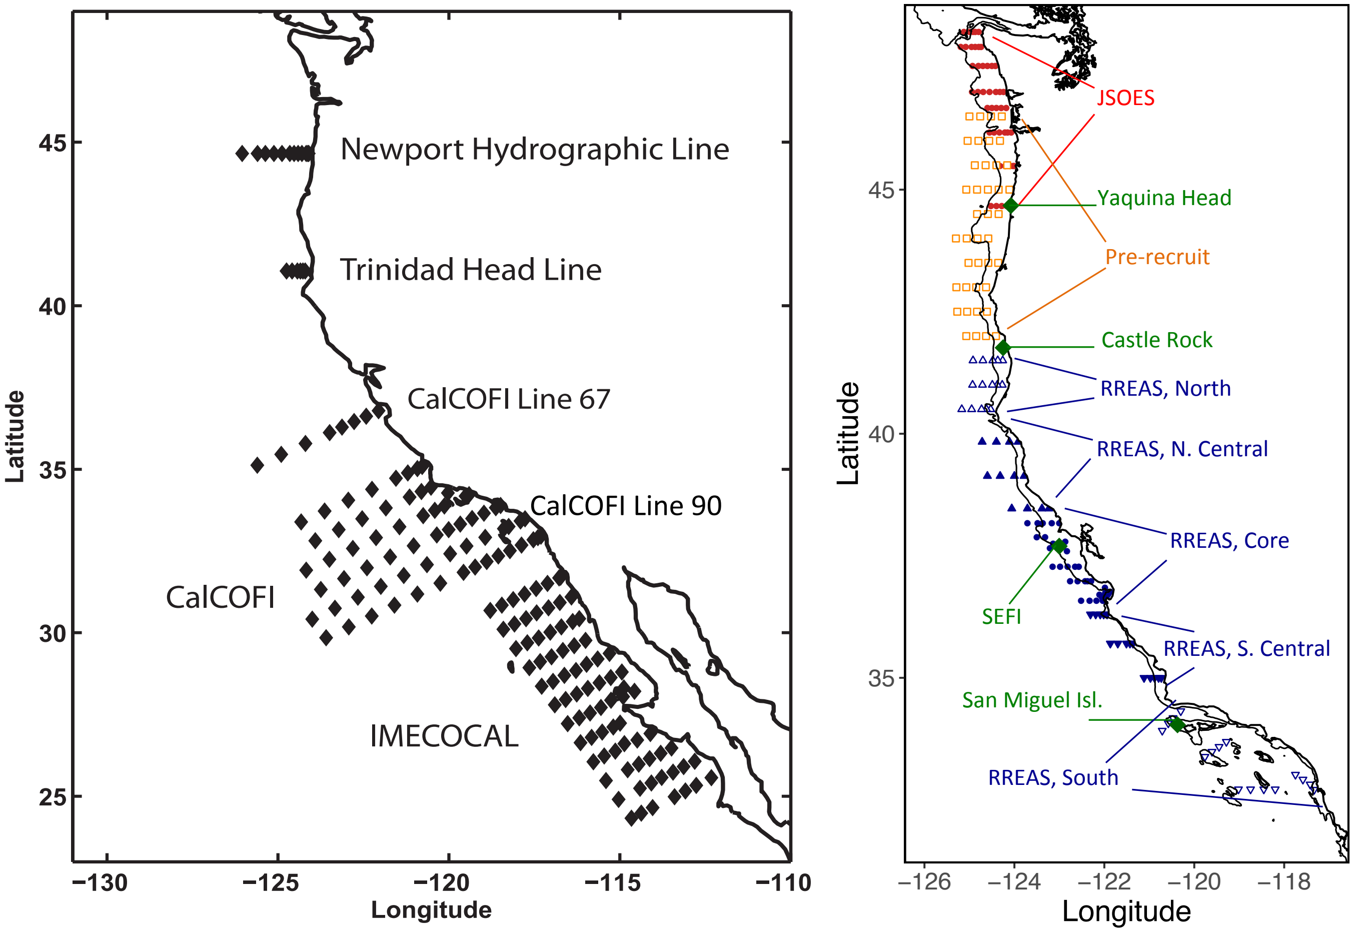

Figure 1. Left) Station maps for surveys that were conducted multiple times per year during different seasons to provide year-round observations in the California Current System. The CalCOFI survey (including CalCOFI Line 67 and 90) was occupied quarterly; the winter and spring CalCOFI survey grid usually extends just north of San Francisco. The IMECOCAL survey is conducted quarterly or semiannually. The Newport Hydrographic Line was occupied biweekly. The Trinidad Head Line was occupied at biweekly to monthly intervals. Right) Location of annual or seasonal surveys, including locations of studies on higher trophic levels, from which data were included in this report. Different symbols and colors are used to help differentiate the extent of overlapping surveys. Surveys used in this report include (Red) Juvenile Salmon and Ocean Ecosystem Survey (JSOES, NOAA/BPA rope trawl), (Orange) NWFSC Pre-recruit midwater trawl survey, and (Blue) SWFSC Rockfish Recruitment and Ecosystem Assessment Survey (RREAS) in five regions. SEFI indicates Southeast Farallon Island.

INTRODUCTION

From 2014 to 2017 the California Current System (CCS) had an unprecedented combination of warm-water conditions that may affect CCS marine life for a number of years, there was a large marine heat wave from 2014–16, influenced in part by anomalously warm conditions in the tropical Pacific that were punctuated by the 2015–16 El Niño (Leising et al. 2015; Jacox et al. 2016; Di Lorenzo and Mantua 2016; McClatchie et al. 2016; Frischkneckt et al. 2017; Peterson et al. 2017). This report revisits these years when applicable to current ecosystem conditions but primarily examines the state from spring 2016–spring 2017; this report is an extension of the previous State of the California Current report (McClatchie et al. 2016). Specifically, following on previous reports, we consolidate environmental and survey data from throughout the California Current (fig. 1). These data include indicators of basin-scale conditions, regional oceanographic conditions, and the food-web from primary production to top-predator foraging behavior, reproductive success, and condition. Although many results are preliminary and encompass dissimilar survey designs, synthesis of these diverse components provides a first approximation of the coast-wide and regional ecosystem conditions. Typical of these reports, we highlight emerging stories as supported by the available data and explore the connections between past, current, and future CCS ecosystem states. This year's report will focus on the clear disparity between ecosystem recoveries following the record 2014–16 warming of the CCS in northern and southern CCS subregions. Specifically, while the southern region trended toward a "normal" ecosystem state in 2016–17, the northern region did not (e.g., there was a persistence of the southern copepod community, limited forage availability, anomalously high salmon mortality,

TABLE 1
**State of various indicators along California Current System (CCS).
The status represents early 2017 unless otherwise stated. Grey font indicates average production/condition, red indicates below average production/condition, and green indicates above average production/condition. Italics represent data cited from elsewhere within this report or preliminary analyses discussed in this report. Abbreviations: Oceanic Niño Index (ONI), Pacific Decadal Oscillation (PDO), North Pacific Gyre Oscillation (NPGO), North Pacific High (NPH), and sea surface temperature (SST).**

Indicator	Basin	Northern CCS	Central CCS	Southern CCS
ONI	Average			
PDO	Above average			
NPGO	Near average			
NPH	Below average			
Upwelling		Below average	Average	Above average
Cumulative upwelling		Average	Below average	Average
SST		Above average	Average	Average

Harmful algal blooms		No	No	Yes
Copepods		Southern derived and rich	—	—
Forage		offshore and southern derived assemblage	Typical assemblage	Typical assemblage along with increased anchovy abundances
Salmon survival		Below average juvenile abundance at sea	*Ecosystem indicators related to salmon suggest average*	—
Seabird productivity (2016)		Reproductive failures	Below/near average	—
Seabird at-sea abundance		Well below average	*Below/near average*	Well above average
Sea lions (2016)		Signs of recovery after the 2013 unusual mortality event		
Whales			Humpback whales distributed shoreward	

unprecedented abundance of pyrosomes, and reduced reproductive success of seabirds) (table 1).

BASIN-SCALE CONDITIONS

North Pacific Climate Indices

The CCS experienced a marine heat wave that featured record-high sea surface temperatures (SST) in 2015, with 2014–16 the warmest 3-year period on record (Jacox et al. 2017). The exceptionally high SST anomalies declined from their peak values in spring/summer 2016. The marine heatwave was first evident in the Gulf of Alaska in late 2013 (Bond et al. 2015) and by the middle of 2014, anomalously high SST anomalies were also observed in the southern CCS as far south as Baja California (Leising et al. 2015).

El Niño/Southern Oscillation (ENSO) is a mode of interannual variability in the equatorial Pacific causing physical and ecological impacts throughout the Pacific basin and CCS, though the links between ENSO and the CCS are complex (Fiedler and Mantua 2017). The Oceanic Niño Index (ONI; http://www.cpc.ncep.noaa.gov/data/indices/), a three-month running mean of SST anomalies averaged over the NINO3.4 region of 5˚S–5˚N and 120˚W–170˚W, had values exceeding the 0.5˚C threshold that signifies an El Niño event from April 2015 through May 2016 (fig. 2). Peak ONI values in 2015–16 rivaled those of the record 1997–98 El Niño event, but this tropical climate event was perhaps not quite as extreme (Jacox et al. 2016). Negative ONI values, indicative of a tropical La Niña event, first appeared during July 2016, but declined only to –0.84˚C indicating a modest intensity La Niña during October–November 2016. By March 2017 the ONI had transitioned to ENSO-neutral conditions, with small positive values below the 0.5˚C threshold. NOAA's Climate Prediction Center[1] has issued a report stating that El Niño neutral conditions were present during the summer of 2017 and they predict that there are growing odds for a tropical La Niña event in winter 2017–18.

The Pacific Decadal Oscillation (PDO) index describes the temporal evolution of dominant spatial patterns of SST anomalies over the North Pacific (Mantua et al. 1997). Positive PDO values are also associated with a shallower upwelling cell in the northern CCS (Di Lorenzo et al. 2008). The PDO values from January 2015 to the spring of 2016 were exceptionally high. By summer of 2016 the PDO values dropped considerably and reached their lowest values since the spring of 2014 (fig. 2). However, the winter 2016–17 PDO values were slightly elevated from these, only to decline to near-zero values in July–August 2017 (fig. 2).

The North Pacific Gyre Oscillation (NPGO) is a low-frequency signal of sea surface height, indicating variations in the circulation of the North Pacific Subtropical Gyre and Alaskan Gyre (Di Lorenzo et al. 2008). Positive values of the NPGO are linked with increased equatorward flow in the California Current, along with increased surface salinities, nutrients, and chlorophyll values in the southern-central CCS (Di Lorenzo et al. 2009). Negative

---

[1] http://www.cpc.ncep.noaa.gov

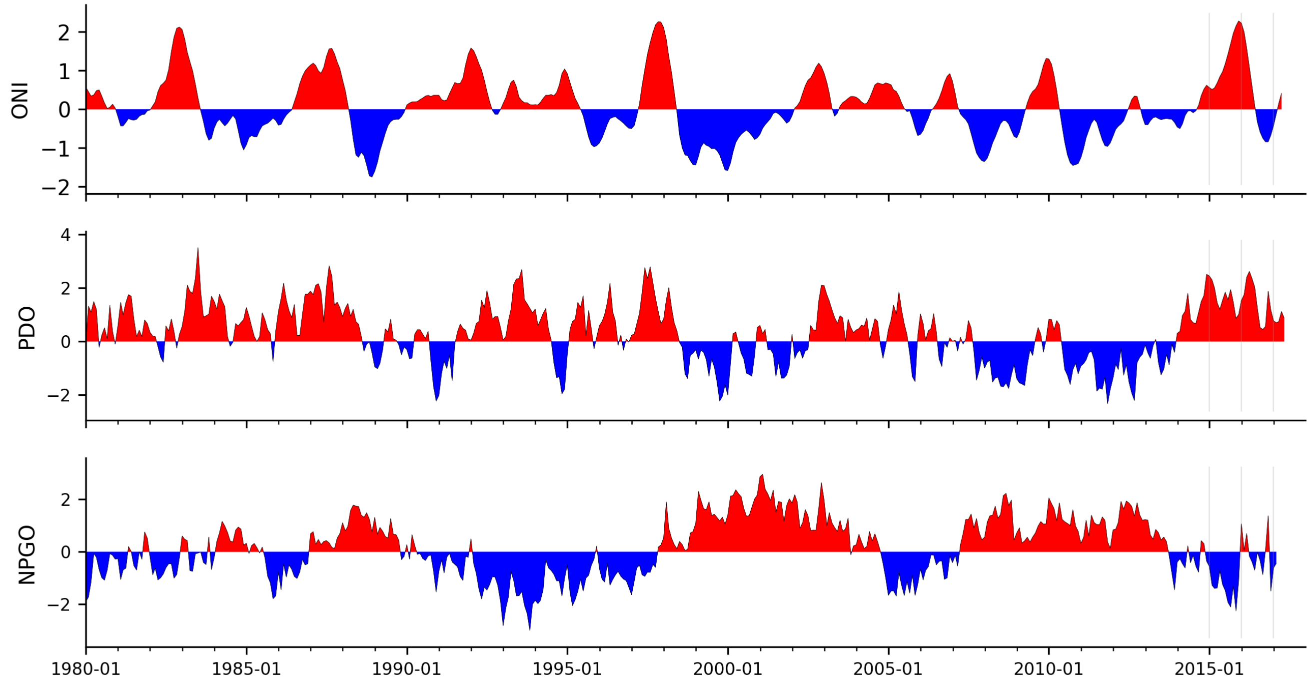

Figure 2. Time series of monthly values for three ocean climate indices especially relevant to the California Current: Oceanic Niño Index (ONI), the Pacific Decadal Oscillation (PDO), and North Pacific Gyre Oscillation (NPGO). Data are shown for January 1980 to July 2017. Vertical lines mark January 2015, 2016, and 2017.

NPGO values are associated with decreases in these variables, inferring less subarctic source waters, fewer nutrients, reduced upwelling and generally lower production in the CCS. The NPGO was negative for the entirety of 2015, with the largest negative values occurring in the fall (fig. 2). During 2016 the NPGO oscillated from positive to negative values that were very small in amplitude. The winter 2016–17 NPGO values were negative with December 2016 having the largest negative value of −1.5. Thus, NPGO index indicated that basin-scale gyre circulation favored low to neutral production across the CCS between spring 2016–spring 2017.

In summary, 2015–16 had extreme positive ONI and PDO index values, and extremely low NPGO index values, all pointing toward increased subtropical influences and reduced subarctic influences in the CCS. Summer 2016 to spring 2017 featured a modest La Niña event and reduced amplitudes in the PDO and NPGO indices, such that these basin-scale patterns were not indicating large fluctuations on the state of the CCS ecosystem over that period.

North Pacific Climate Patterns

A basin-scale examination of SST and surface wind anomalies allows for the interpretation of the spatial evolution of climate patterns and wind forcing over the North Pacific related to trends in the basin-scale and upwelling indices (figs. 3, 4). During July 2016, negative SST anomalies in the central and eastern Equatorial Pacific marked the transition between the El Niño event that peaked in winter 2015–16 and the La Niña event that peaked in winter 2016–17 (fig. 3). Tropical La Niña conditions dissipated by May 2017. During the summer of 2016, SST anomalies exceeding 1˚C were evident in the Bering Sea and the Gulf of Alaska. These positive anomalies persisted into the winter of 2016–17. The SST approached the long-term average by May 2017 in the central and southern CCS but remained warmer than average along the northern CCS.

Wind anomalies over the Bering Sea and Gulf of Alaska were anomalously eastward in July and December 2016 and a large anti-cyclonic pattern was centered at 42˚N, 160˚W due to higher than average sea level pressures during July and December 2016 (fig. 3). High SST anomalies associated with the marine heatwave had dissipated along the west coast of North America by July 2016, with only the Southern California Bight and along the Baja Peninsula showing SST anomalies greater than 1˚C. From December 2016 to May 2017 SST along the West Coast were near the long-term mean, with slightly elevated temperatures along the Washington and Oregon coasts and southern Baja California, Mexico (figs. 3, 4). Alongshore winds were average during July 2016, but strengthened in December 2017. February 2017 winds were anomalously northward, associated with an unusual number of winter storms and excessive rainfall along the West Coast (fig. 3)[2]. Upwelling-favorable (southward) winds resumed by May 2017.

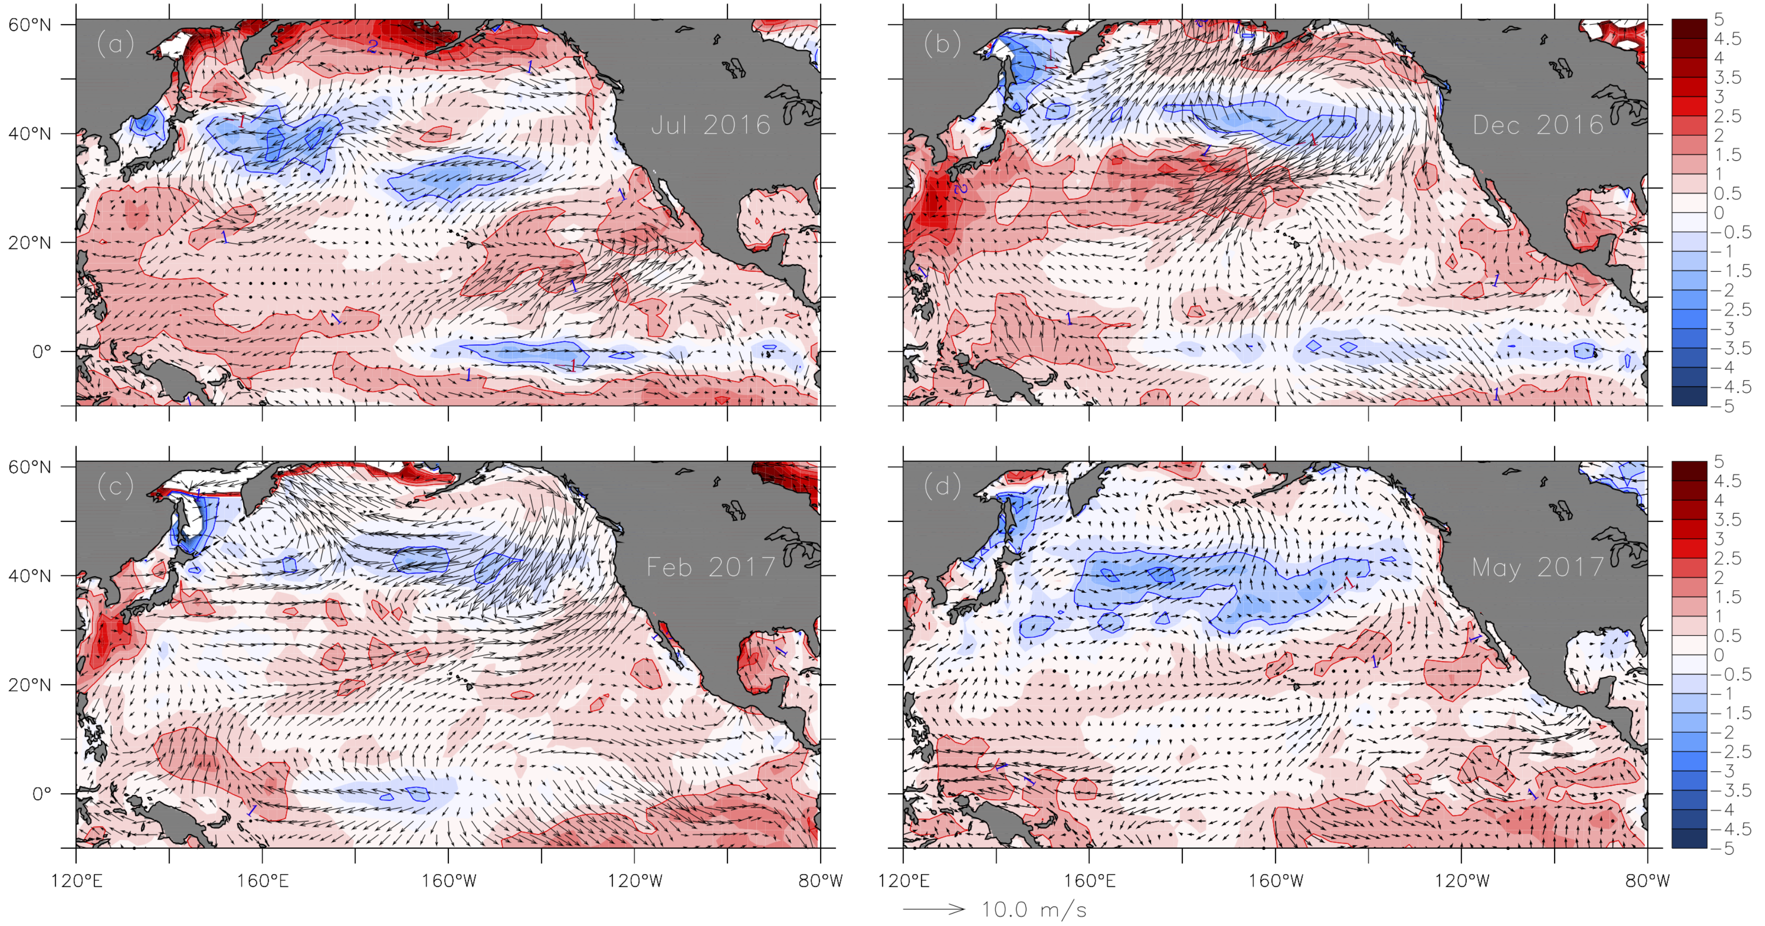

Figure 3. Anomalies of surface wind velocity and sea surface temperature (SST) in the North Pacific Ocean for July 2016, December 2016, February 2017, and May 2017. Arrows denote magnitude and direction of wind anomaly (scale arrow at bottom). Contours denote SST anomaly. Shading interval is 0.5°C and contour intervals of 1 and 2°C are shown. Negative (cool) SST anomalies are shaded blue. Wind climatology period is 1968–96. SST climatology period is 1950–79. Both SST and wind data are from NCEP/NCAR Reanalysis and were obtained from http://www.esrl.noaa.gov.

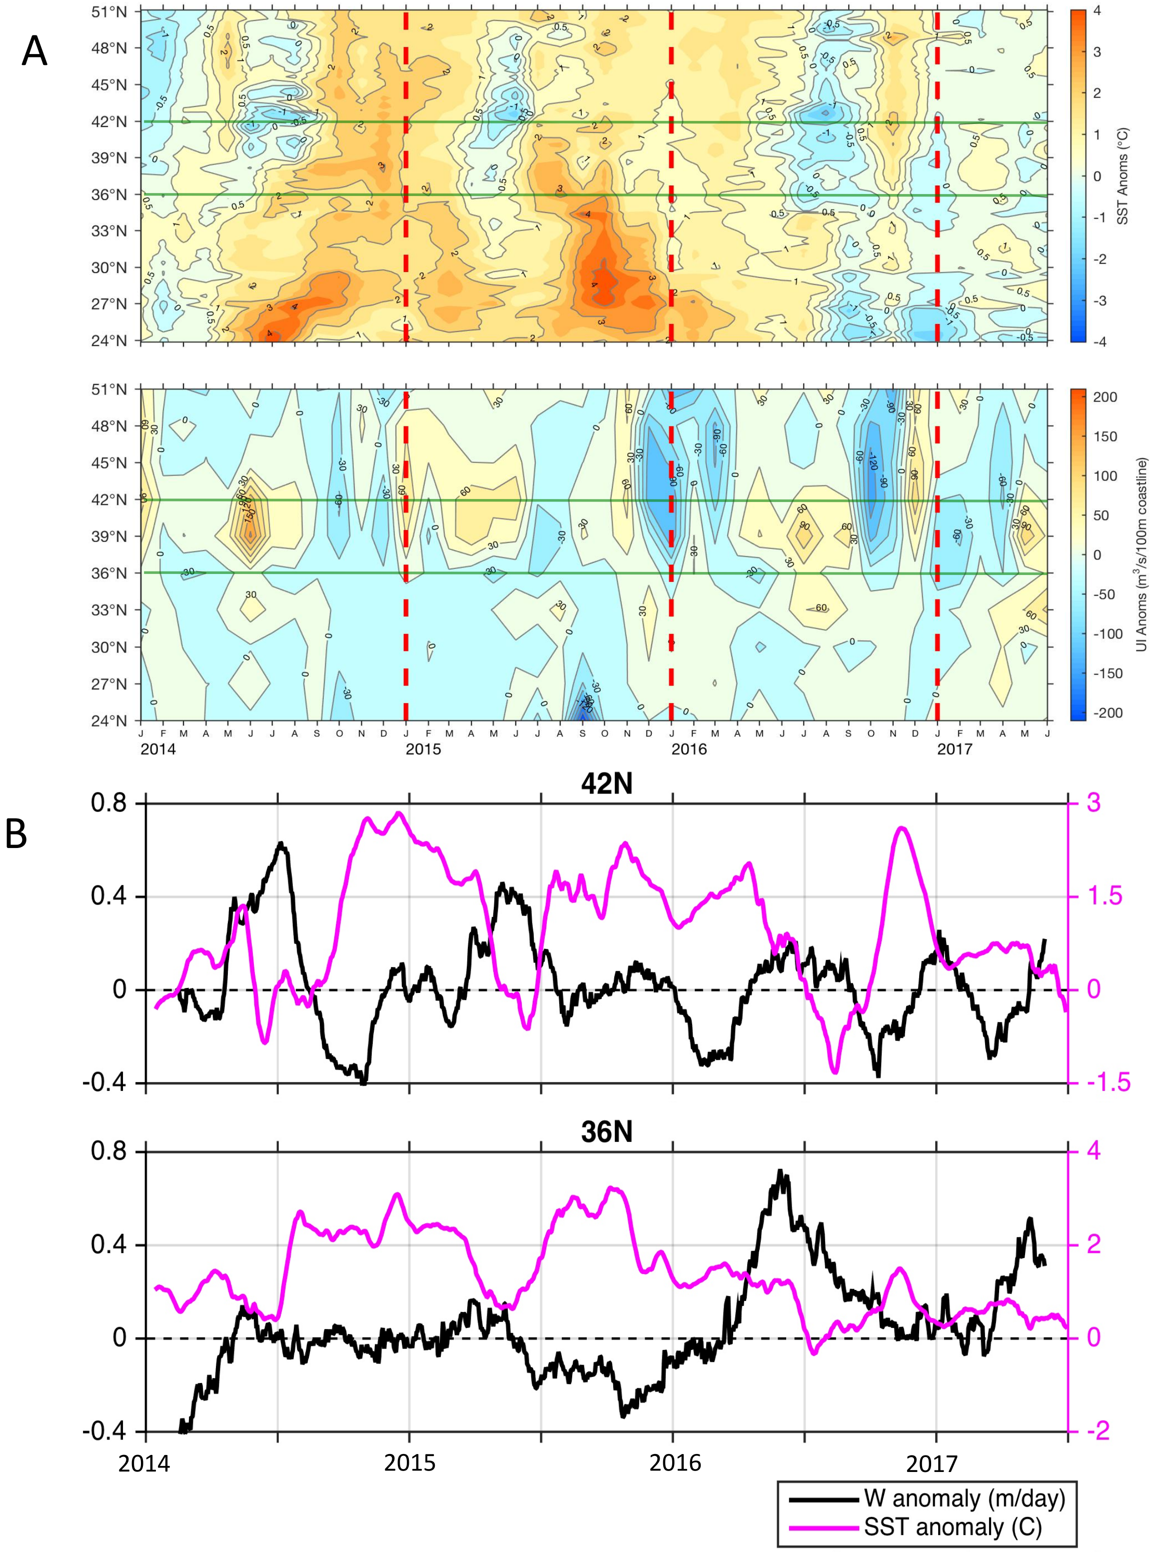

Figure 4. A) Monthly sea surface temperature (SST) anomalies (top) and upwelling index (UI) anomalies (bottom) for January 2014–June 2017. The SST anomalies are averaged from the coast to 100 km offshore. Positive and negative upwelling anomalies denote greater than average upwelling or downwelling (usually during the winter), respectively. Anomalies are relative to 1982–2017 monthly means. Daily optimum interpolation AVHRR SST data obtained from http://coastwatch.pfeg.noaa.gov/erddap/griddap/ncdcOisst2Agg. Six-hourly upwelling index data obtained from http://oceanview.pfeg.noaa.gov/erddap/tabledap/. B) Upwelling anomalies (black) and SST anomalies (magenta) relative to the 1999–2011 climatology, derived from a data assimilative ocean reanalysis of the California Current System (http://oceanmodeling.ucsc.edu/ccsnrt/), are shown at two latitudes off the US West Coast; 36°N and 42°N (indicated by horizontal green lines in A). Values are averaged from the coast to 100 km offshore. SST is smoothed with a 30-day running mean; upwelling, which is much noisier, is smoothed with a 90-day running mean.

COAST-WIDE CONDITIONS

Upwelling in the California Current

Monthly anomalies of SST (averaged from the coast to 100 km offshore) and upwelling are used to examine anomalous coastal upwelling conditions within the CCS from January 2014 to July 2017 (fig. 4). Upwelling estimates come from two sources: the Bakun upwelling index (UI; fig. 4a; Bakun 1973; Schwing et al. 1996), and a data-assimilative regional ocean model (W; fig. 4b; Jacox et al. 2014)[3]. We take this approach as the UI has long been used in studies of the California Current, but in some places, particularly south of 39°N, it is a less reliable indicator of upwelling due to relatively poor estimation of the wind stress and modulation of upwelling by the cross-shore geostrophic flow (Bakun 1973; Jacox et al. 2014). SST anomalies along the coast are driven by upwelling, especially in northern latitudes due to a strong coupling between local winds and SST (Frischknecht et al. 2015). High SST anomalies due to the marine heat wave are evident in 2014 and 2015. Positive SST anomalies (>1°C) during the 2015–16 El Niño event persisted during the winter and spring of 2016 especially for locations north of 42°N. From January to May of 2017, SST anomalies north of 42°N were near the long-term average, with the exception of a few localized periods of ~0.5°C anomalies. UI anomalies from 39° to 45°N were positive during the spring and summer of 2015, but anomalously strong downwelling occurred in the winter of 2015–16 (typical of past El Niño winters). The longest period of sustained positive upwelling anomalies during 2016 occurred from July to September for latitudes between 36° and 42°N. October and November 2016 upwelling anomalies were negative north of 36°N, followed by positive anomalies (weaker downwelling) in December. On the whole, upwelling during 2017 has been about average from 39° to 42°N, weaker than average farther north, and stronger than average farther south.

The cumulative upwelling index (CUI) is the cumulative sum of the daily UI values starting January 1 and ending on December 31, and it provides an estimate of the net influence of upwelling on ecosystem structure and productivity over the course of the year (Bograd et al. 2009). In general, upwelling has been weaker for the last two years, 2016–17, than the previous two years, 2014–15 (fig. 5). During the 2016 winter, upwelling north of 39°N was low due to the El Niño and strong upwelling only began by the summer. South of 39°N, upwelling anomalies were neutral to positive in early 2016, counter to what would be expected from a strong El Niño (Jacox et al. 2015). Upwelling during 2017 was near the long-term average for the whole coast except for the latitudes between 36°–42°N. For these latitudes, the CUI curves during the winter were below the climatological curve and stronger upwelling began by the beginning of May.

Periods of upwelling or, farther north, reduced downwelling during the winter can limit stratification and facilitate introduction of nutrients to the surface acting to precondition the ecosystem for increased production in the spring (Schroeder et al. 2009; Black et al. 2010). The area of the surface atmospheric pressures associated with the North Pacific High (NPH) can be used as an index of this winter preconditioning (Schroeder et al. 2013). Since 2014 there has been a continual weak NPH during the winter (fig. 6). The January–February mean of the NPH area has been very small since the exceptionally large area during 2013, and the 2017 area was the smallest size since 2010.

Coastal Sea Surface and Subsurface Temperatures

SSTs measured by National Data Buoy Center buoys along the West Coast were mostly above long-term averages during summer of 2015 through spring of 2016 (fig. 7). For the northern buoys, this period of warm temperature was briefly interrupted by a decrease in temperatures during August or September that coincided with a strong period of upwelling favorable winds. The decrease in temperatures associated with upwelling was also evident in April and May 2016 for the buoys located off California. For all buoys, warm to exceptionally warm temperatures were recorded during October and November 2016, which decreased greatly in December and January 2017 during a period of strong southward winds. The winter storms that brought excessive rainfall to the West Coast January–February 2017 were accompanied by episodes of strong northward winds lasting approximately a week at a time (fig. 7).

Figure 8 shows January 2014–May 2017 upper ocean temperature anomalies from ROMS averaged from the coast to 100 km offshore at latitudes of 33, 36, 39 and 42°N. From Cape Blanco (42°N) to central California (36°N) near-surface temperature was above average from the summer of 2014 through spring of 2016; yet, at depths greater than ~50 m, cool anomalies were often present. The exception of the warm surface and cool subsurface conditions was during winter 2015–16 when above average temperatures existed throughout the entire water column. This is

[3] A data-assimilative configuration of the Regional Ocean Modeling System (Shchepetkin & McWilliams 2005; Haidvogel et al. 2008) has been used to produce a reanalysis of the California Current circulation extending back in time to 1980 (Neveu et al. 2016) and continuing to present in near real time (http://oceanmodeling.ucsc.edu/ccsnrt).

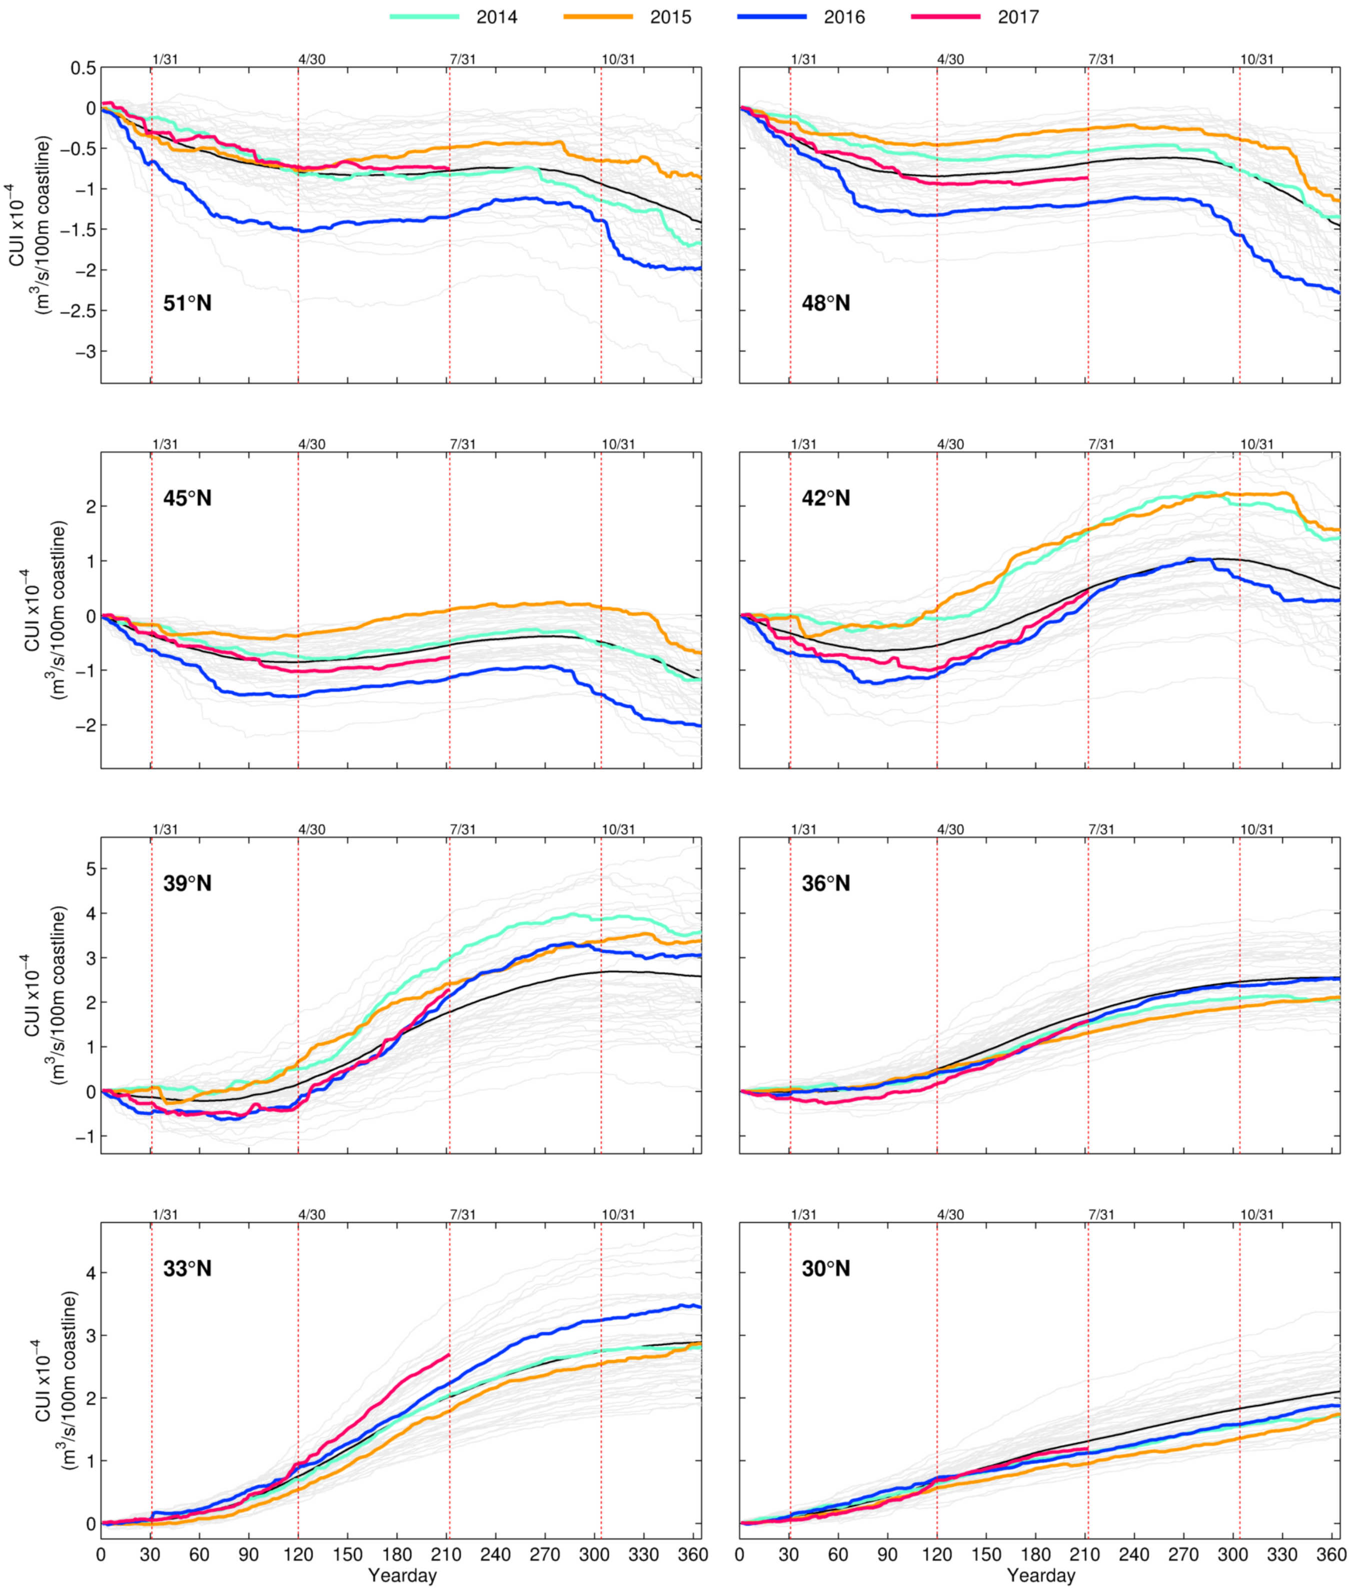

Figure 5. Cumulative upwelling index (CUI) starting on January 1 calculated from the daily upwelling index at locations along the west coast of North America. Grey lines are all yearly CUI for 1967–2016, colored CUI curves are for the years 2014–17. The climatological mean CUI is the black line. The red dashed vertical lines mark the end of January, April, July and October. Daily upwelling index data obtained from http://upwell.pfeg.noaa.gov/erddap/.

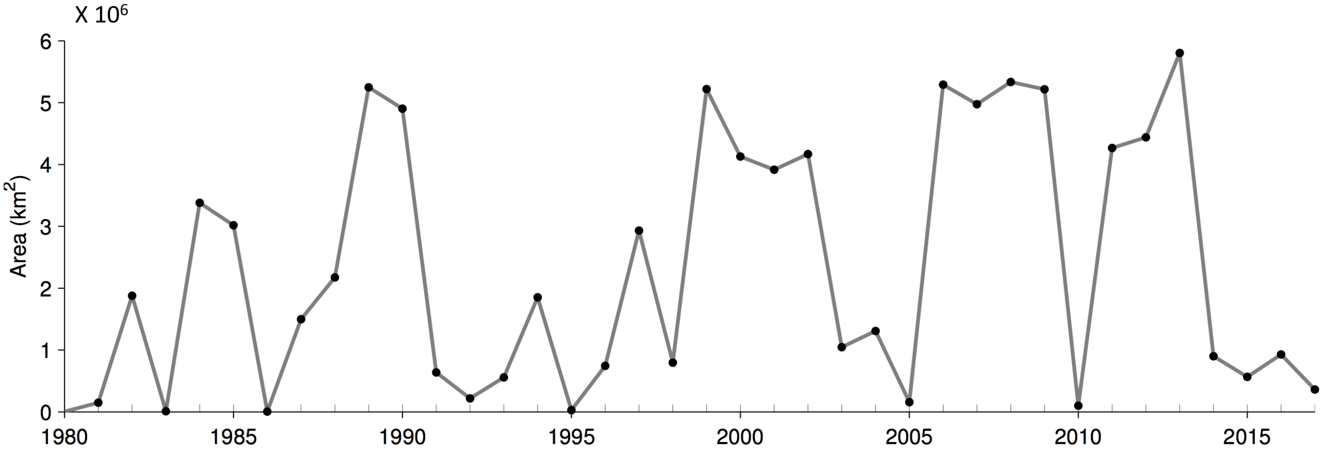

Figure 6. The area of high atmospheric pressure of the North Pacific High averaged over January and February each year (Schroeder et al. 2013). The area is the areal extent of the 1020 hPa isobar located in the eastern North Pacific.

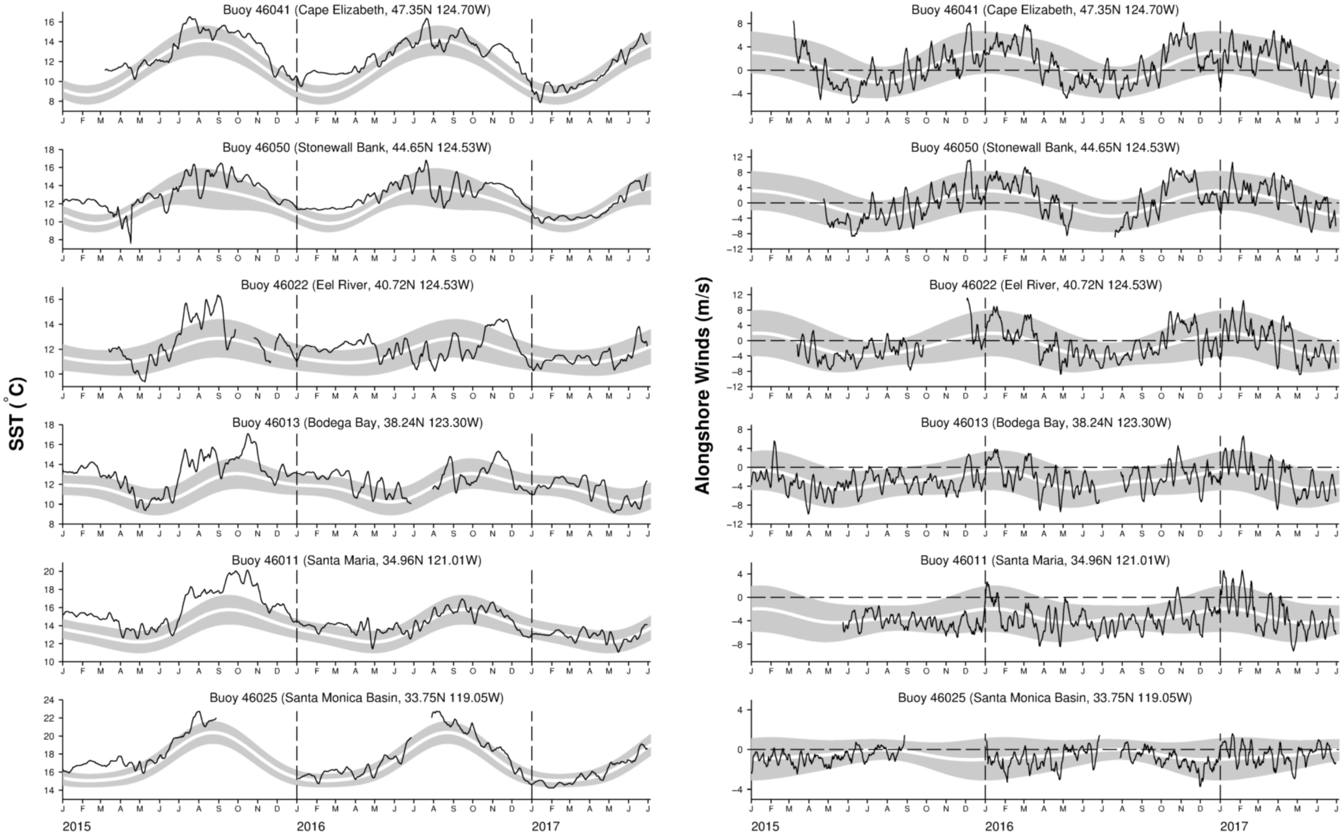

Figure 7. Time series of daily sea surface temperatures (left) and alongshore winds (right) from various National Data Buoy Center (NDBC) coastal buoys along the CCS for January 2015 to June 2017. The wide white line is the biharmonic annual climatological cycle at each buoy. Shaded areas are the standard errors for each Julian day. Series have been smoothed with a 7-day running mean. Data provided by NOAA NDBC. Additional buoy information can be found at http://www.ndbc.noaa.gov/.

especially evident in the southern bight and latitudes south of 39°N during the summer of 2015 and winter of 2015–16. In fact, for the line at 33°N the subsurface temperatures were anomalously high for the whole water column from spring of 2014 to the winter of 2016. During the winter and early spring of 2017, near-surface temperatures (0–50 m) for all the lines were slightly above average, turning below average by the late spring for depths between the surface and 150 m.

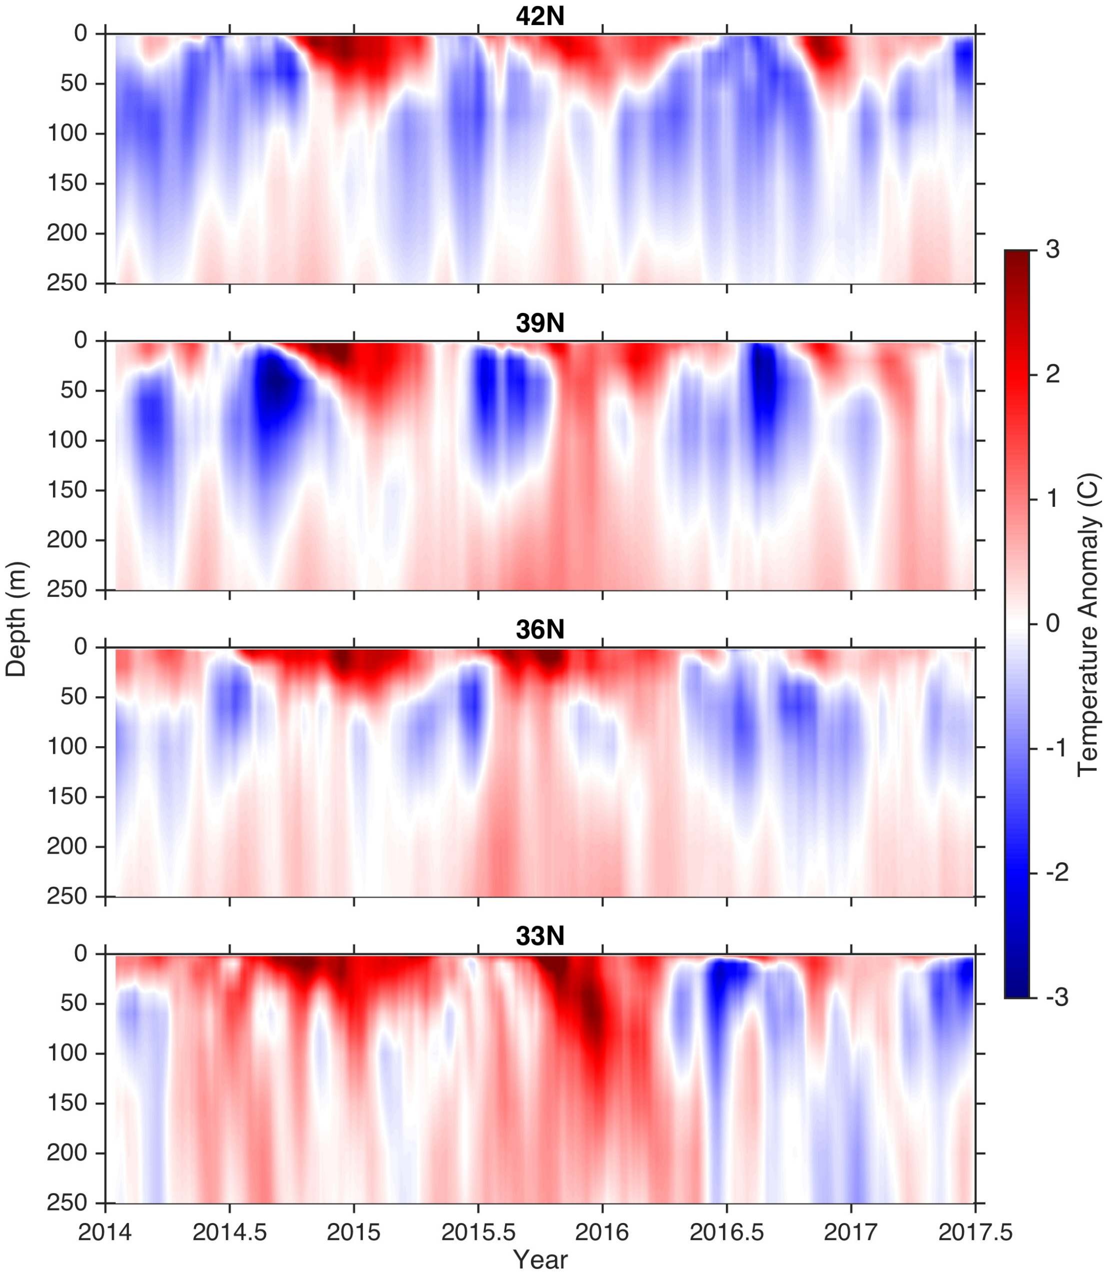

Figure 8. Temperature anomalies relative to the 1999–2011 climatology, derived from a data assimilative ocean reanalysis of the California Current System (http://oceanmodeling.ucsc.edu/ccsnrt/), are shown at four latitudes off the US West Coast. Temperatures are averaged from the coast to 100 km offshore and smoothed with a 30-day running mean.

Primary Production in the California Current System

Anomalously high chlorophyll during the spring occurred along Central California in 2014 and along the whole coast from northern Washington to Point Conception in 2015, which likely represents, to a degree, *Pseudo-nitzschia* (see McClatchie et al. 2016 for more complete description) (fig. 9)[4]. However, during these two years chlorophyll levels were below average off southern California. Spring chlorophyll levels in 2016 were below average for the whole coast except for a few localized increases along Washington and central California coasts (McClatchie et al. 2016). Spring 2017 chlorophyll values were lower than average for the majority of the CCS but showed increases in central California and around the Channel Islands. The elevated chlorophyll in spring 2017 for the Channel Islands corresponded to significant toxin event caused by *Pseudo-nitzschia* (modeled data shown in lower panels of fig. 9).

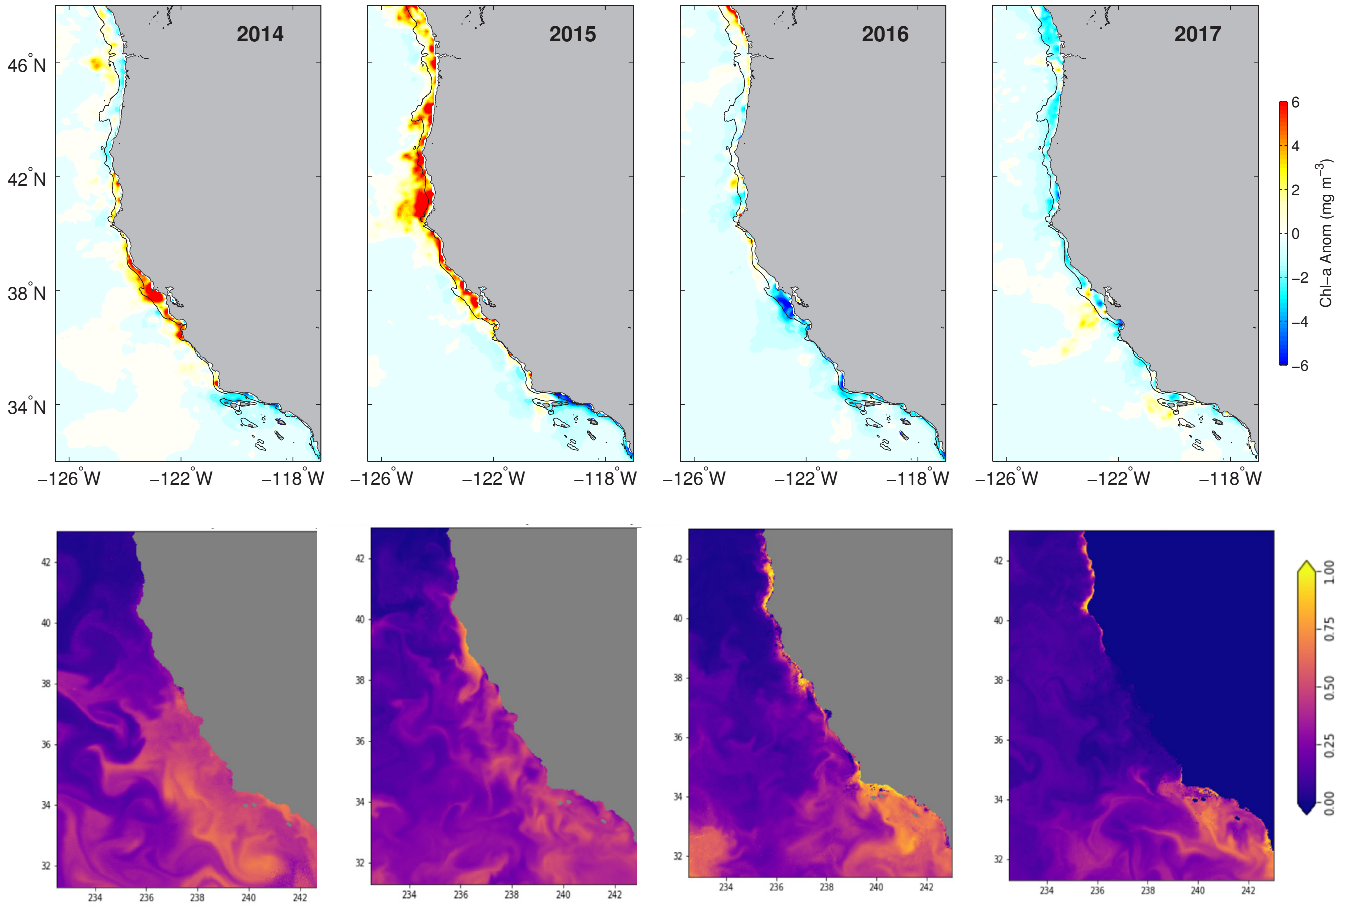

Figure 9. Top) Chlorophyll *a* anomalies from Aqua MODIS for: spring (March–May) of 2014–2017. Monthly anomalies were averaged onto a 0.1° x 0.1° grid and the climatology was based on the time period from 2002–17. The data were obtained from http://coastwatch.pfel.noaa.gov/. Bottom) predicted probability of domoic acid > 500 nanograms/L, during the same times periods as the top pane from http://www.cencoos.org/data/models/habs/previous.

REGIONAL OBSERVATIONS OF ENVIRONMENT AND LOWER TROPHIC LEVELS

Northern California Current: Oregon (Newport Hydrographic Line)

The warm anomalies that intruded onto the Oregon shelf surface waters in September 2014 remained throughout 2015, 2016, and continued into 2017, dominating the local hydrography and impacting pelagic communities. The upwelling season (spring transition) began early on 27 March 2016 and ended on 29 September 2016 (fig. 4), resulting in an upwelling season that was eight days longer than the 40-year climatology. Upwelling in 2016 cooled the warm temperatures that began during the winter of 2015–16 and continued into spring of 2016, resulting in neutral sea surface and deeper water temperatures on the shelf from June through September (figs. 7, 10). During this upwelling period, shelf waters were slightly saltier while deep waters on the slope were mostly neutral throughout 2016 and into 2017. Despite above average upwelling (fig. 4), nitrogen concentrations remained below average throughout 2016 and into 2017 (fig. 10). Following the upwelling season in 2016, the shelf waters returned to anomalously warm and fresh conditions, which were similar to the previous two years.

The zooplankton community remained in a lipid-depleted state throughout 2016 and into 2017. The zooplankton community was dominated by lipid-poor tropical and subtropical copepods and gelatinous zooplankton that generally indicate poor feeding conditions for small fishes. Pyrosomes (*Pyrosoma atlanticum*), a tropical species, were first observed in the fall of 2016 and their biomass increased greatly in the spring of 2017. With the exception of the upwelling months in 2016, the biomass of lipid-rich northern ("cold water") copepods was the lowest observed in the 21-year time series (fig. 10). During June through September, the biomass anomalies of the northern copepods were reduced slightly in response to upwelling, however the anomalies still remained strongly negative. The biomass of southern ("warm water") copepods fluctuated greatly, with

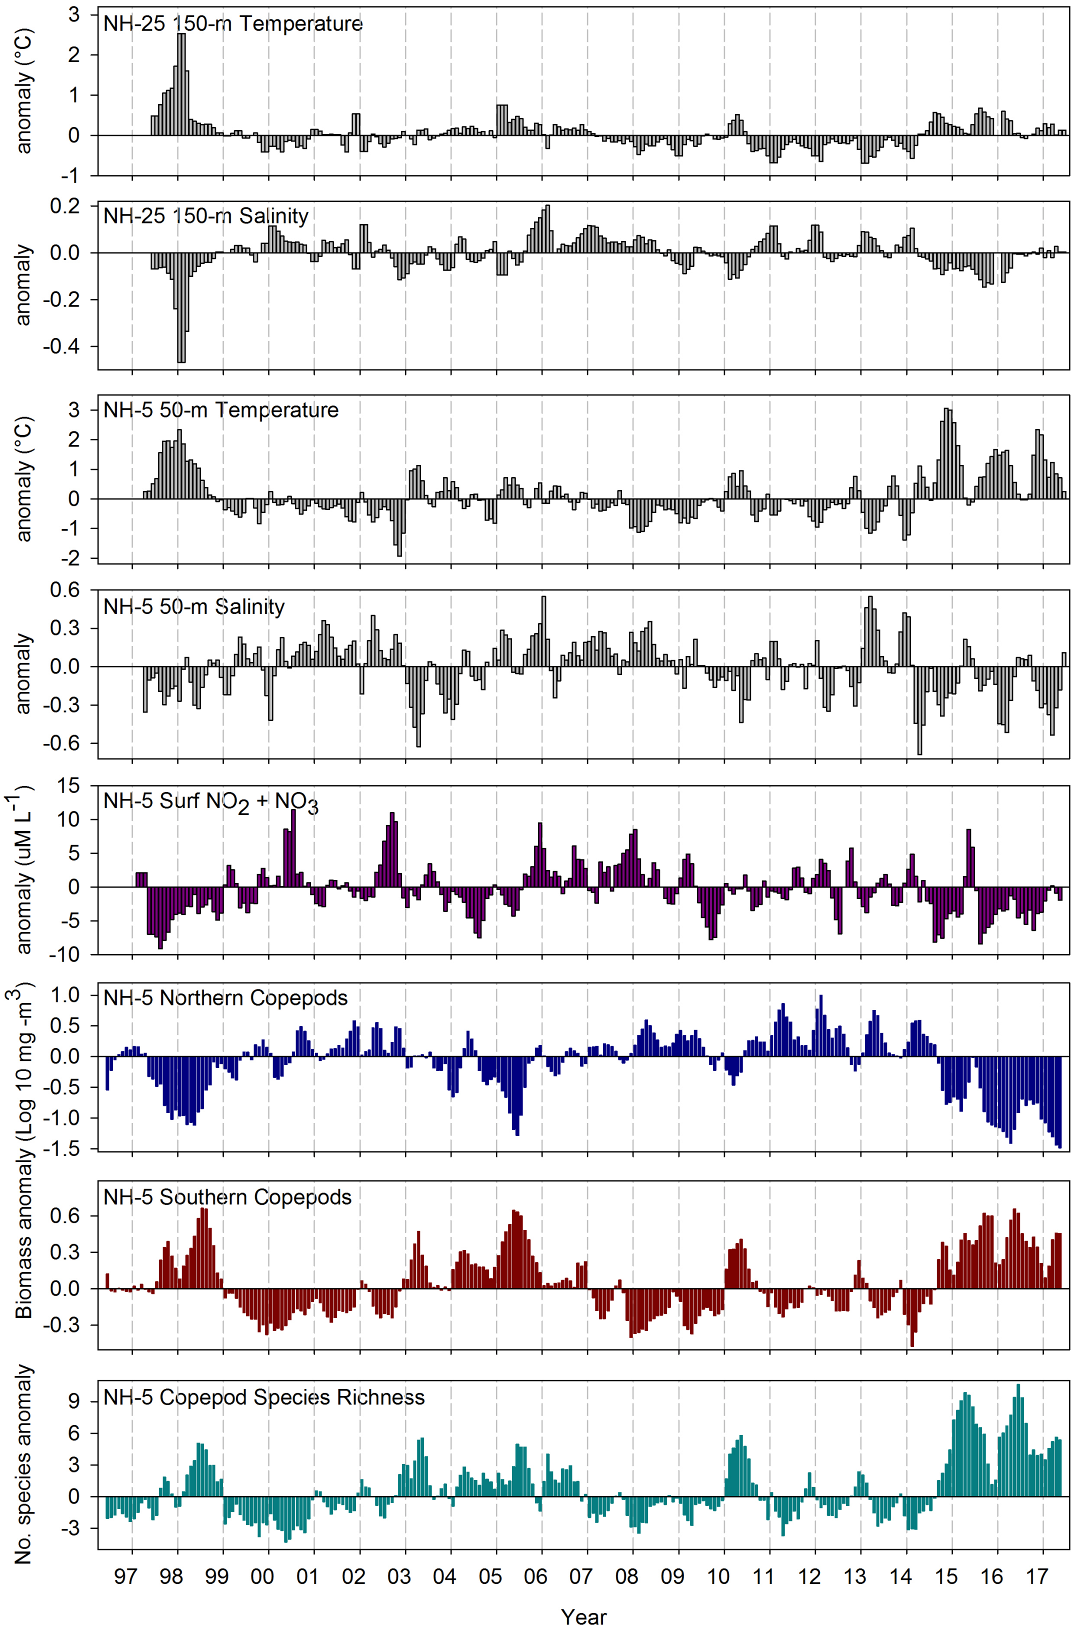

Figure 10. Time series plots of local physical and biological anomalies (monthly climatology removed) from 1997–2017 at NH-25 (Latitude: 44.6517 N Longitude: 124.65 W; top two panels) NH-5 (Latitude: 44.6517 N Longitude: 124.1770 W; lower six panels) along the Newport Hydrographic Line. Temperature and salinity from 150 m and 50 at NH-25 and NH-5 respectively, NO2 + NO3 from the surface, and copepod biomass and species richness anomalies are integrated over the upper 60 m. All data were smoothed with a 3-month running mean to remove high frequency variability.

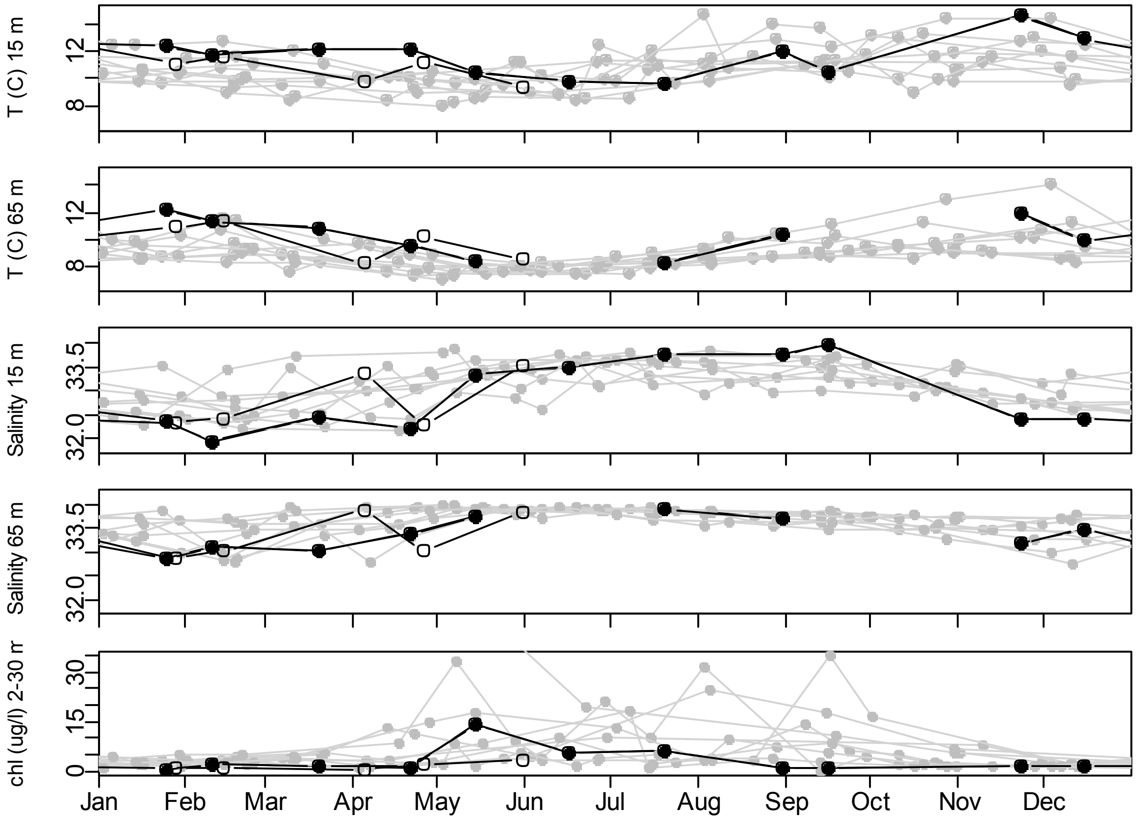

Figure 11. Hydrographic observations along the Trinidad Head (TH) Line at station TH02. Panels from top to bottom show temperature at 15 m, temperature at 65 m (near the sea floor), salinity at 15 m, salinity at 65 m, and mean (uncalibrated) chlorophyll *a* concentration from 2–30 m. Closed black circles represent 2016, open circles represent 2017, and grey time series represent previous years.

the highest biomass anomalies occurring during the upwelling months and lower anomalies during the winter (fig. 10). In 2015 and in 2016, the seasonal shift from a winter copepod community to a cold summer community that results from the Davidson Current in winter and its disappearance in spring did not happen (data not shown). This transition in the copepod community also did not occur during 1998, however it is unusual to remain in a warm-water copepod community for two consecutive years. This last occurred in 2003, 2004, and 2005 (fig. 10).

Copepod species richness was the highest in the time series during the summer of 2016[5]. Many of the rare species observed during this period had Transition Zone and North Pacific Gyre affinities and many of the species have never (or rarely) been observed off Newport since sampling began in 1969 (Peterson et al. 2017). The presence of these species greatly increased the species richness, which exceeded the number of species observed during the strong El Niño in 1998 (fig. 10). Like cold-water copepods, euphausiid biomass during 2016 was among the lowest in 21 years and the coastal euphausiid, *Thysanoessa spinifiera*, was largely absent (data not shown; Peterson et al. 2017).

Northern California Current: Northern California (Trinidad Head Line)

Coastal waters off northern California were warmer and fresher than usual during early 2016, but cooled in response to strong upwelling during summer. Warmer, fresher water was again observed over the shelf following relaxation from upwelling in early fall 2016. Coastal waters were slightly cooler in early 2017 relative to early 2016 (figs. 8, 11), yet remained higher than most previous observations in the record, which is consistent with larger scale patterns in the CCS (figs. 3, 8). These patterns manifested throughout the water column over the inner to midshelf (fig. 11), and extended to surface waters offshore, but did not have a strong signal at depth over the outer shelf (fig. 8). Upwelling in spring 2016 led to a phytoplankton bloom that peaked in late spring and persisted through the summer (figs. 9, 11). *Pseudo-nitzschia* were a major component of this bloom, leading to low to moderately high concentrations of particulate domoic acid (the neurotoxin produced by

---

[5] Copepod data were based on samples collected with a 0.5 m diameter ring net of 202 μm mesh, hauled from near the bottom to the sea surface. A TSK flowmeter was used to estimate volume of water sampled.

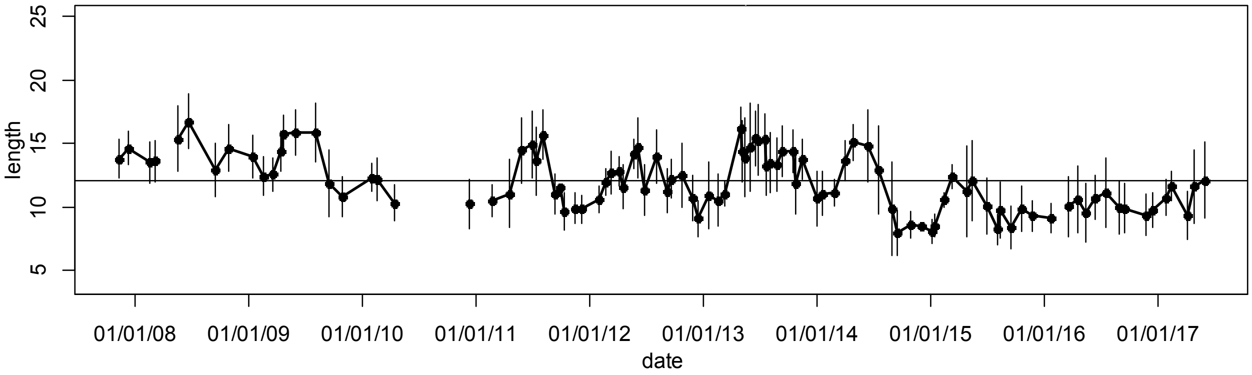

Figure 12. Density-weighted mean (points) and standard deviation (whiskers) of rostral-dorsal length of adult *Euphausia pacifica* collected along the Trinidad Head Line (aggregated over stations TH01 to TH05). Horizontal line indicates mean length taken over entire time series. Samples are collected by fishing bongo nets (505 µm mesh) obliquely from a maximum depth of 100 m (or within a few meters of the sea floor in shallower areas) to the surface.

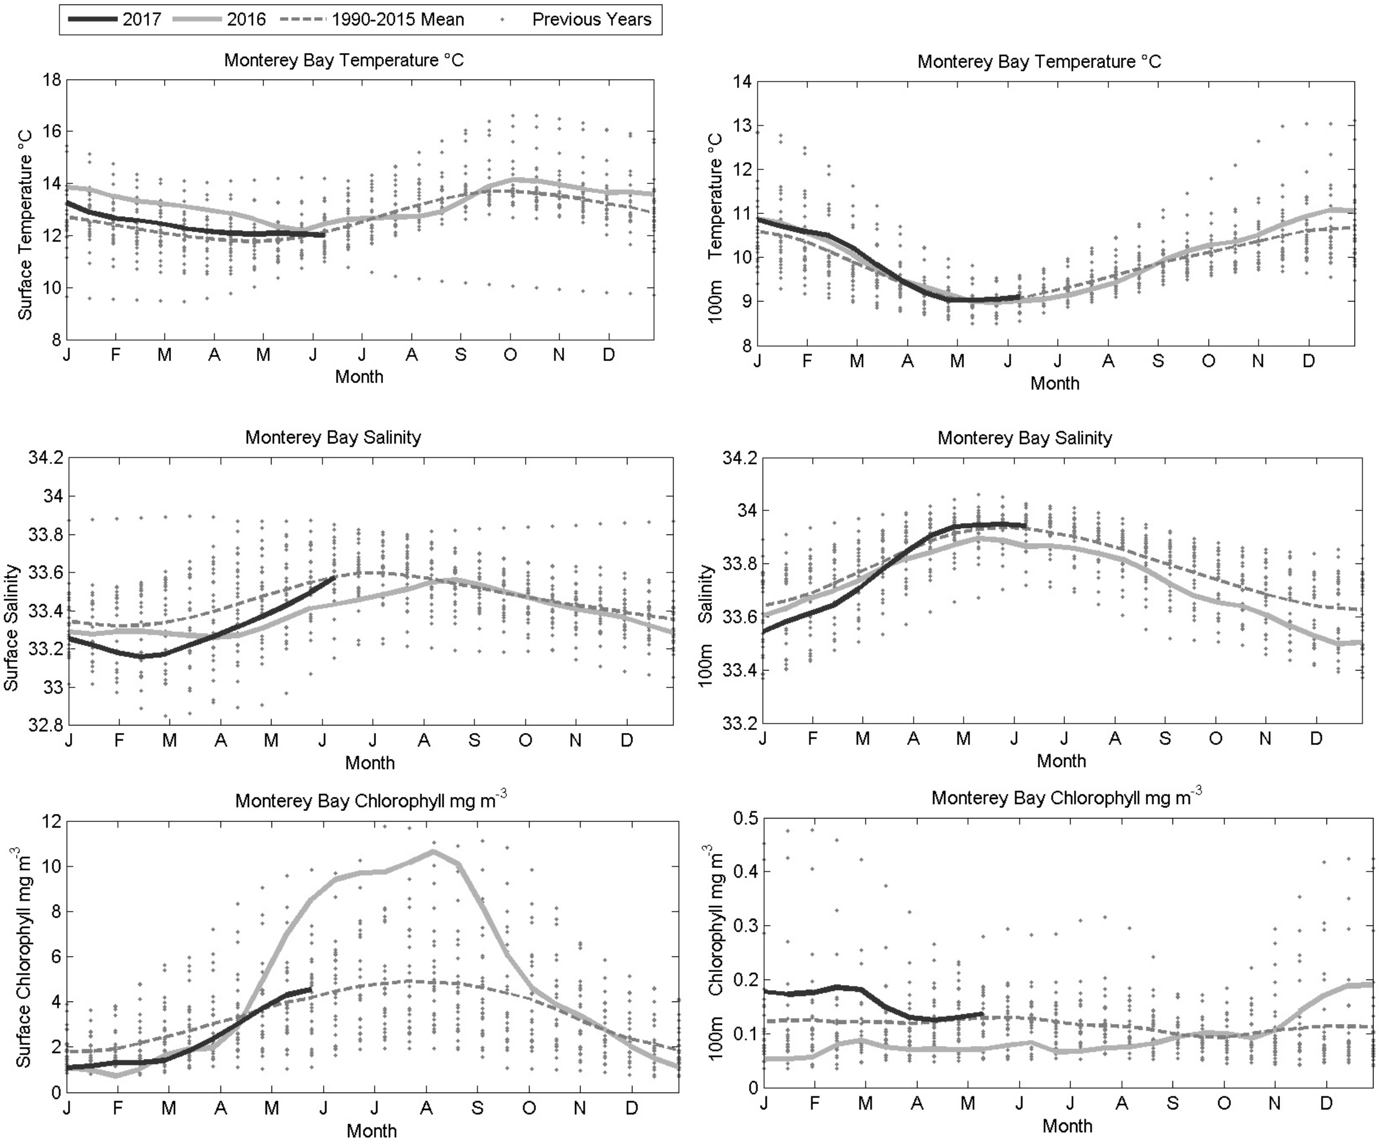

Figure 13. Temperature (top panels), salinity (middle panels) and chlorophyll *a* concentration (bottom panels) at the surface (left-hand column) and at 100 m (right hand column) observed at the M1 mooring in Monterey Bay, CA.

Pseudo-nitzschia; 0 to > 16,000 ng l^{-1}) in June 2016 that declined over the course of the summer. Chlorophyll concentrations have remained low through spring 2017 (figs. 9, 11). No hypoxic events were observed during 2016 and early 2017.

Zooplankton population and community data reflected the ongoing biological response to the persistence of warmer-than-usual water masses off northern California. For example, mean length of adult *Euphausia pacifica* collected along the Trinidad Head Line has remained consistently smaller than usual (fig. 12). Larger individuals were captured during periods of upwelling-driven cooling, and have been more consistently encountered during 2016 and early 2017, but the population continues to be dominated by smaller adults. The warm-water euphausiids *Euphausia recurva* and *Nyctiphanes simplex* were captured during winter and early spring 2016. Both species also occurred in winter samples from 2016–17, suggesting that warm-water zooplankton communities remained in the region but were displaced from coastal waters during periods of sustained upwelling. Copepod community data have not been updated through this period, but cursory inspection of samples and anecdotal observations made during analysis of krill samples suggest that cold-water copepods remain relatively rare or absent. Pyrosomes were present at unusually high densities throughout 2016 and early 2017, with the greatest abundance occurring during spring 2017. Large pyrosomes (i.e., individuals too large to be retained in preserved samples) were much more frequently and consistently encountered during 2016 and early 2017 than in previous years. Salps were abundant for a brief time during summer and fall 2016.

Central California Current: Monterey Bay

Temperatures at the surface and 100 m recorded at M1 (36°45'0" N 122°1'48" W) mooring in Monterey Bay were near average in 2017 and similar to the values from 2016. Surface salinities were also near the climatological average during this time period, although in early 2017 surface waters were somewhat fresher (fig. 13). Chlorophyll at the surface was low during winter 2016 but increased concomitantly with increased upwelling during summer and stayed elevated until October when upwelling weakened (fig. 4). Chlorophyll remained slightly below average until May 2017. At 100 m, chlorophyll remained below average during 2016 through November, at which point, it was near average until April 2017. Generally, aside from extremely elevated surface chlorophyll during June–September 2016 associated with anomalously strong upwelling (fig. 4), conditions at M1 were typical. In contrast to other regions, there were no significant toxic blooms in Central California, but there were a series of "red tide" events in the nearshore caused by the dinoflagellate *Akashiwo sanguinea*.

Southern California Current: CalCOFI Survey[6]

Over the last 12 months, mixed layer temperature anomalies remained above the long-term average (fig. 14) but were 1 to 1.5°C cooler than those observed during the marine heatwave in 2014–15. The cooling of surface waters since 2015–16 is clearly shown in the Hovmoeller plots of 10 m temperatures along CalCOFI line 90, and temperatures at 100 m depth had returned to the long-term average (figs. 8, 15).

Over the last three years water column stratification in the upper 100 m was primarily driven by high surface ocean temperatures (McClatchie et al. 2016), and this trend continued over the last year (fig. 14). Mixed layer salinity was slightly below long-term averages for the last three years (fig. 14). Temperature-salinity distributions for the offshore, California Current, upwelling, and Southern California Bight areas were not dramatically different from previous years, and neither region showed the pronounced warming of the surface layer seen in 2015–16.

The depth of the σ_t 26.4 isopycnal (fig. 16), which can indicate nutrient availability and transport, was close to its long-term average over the last 12 months, contrasting with high (deep) values observed during the previous two years. Bjorkstedt et al. (2012) speculated that concentrations of oxygen at depth had been declining since the year 2000 to values not observed previously. It appears that this trend has ended (fig. 16). Indeed, one could argue that there is no trend in the O_2 time series at σ_t 26.4 from 2003 until the present (fig. 16). The same is true for the nitrate time series (fig. 16). Changes in N*, which is a biogeochemical indicator which reflects the deficit of nitrate in a system relative to concentrations of phosphate, over the last year have also been small (fig. 16).

Mixed layer concentrations of chlorophyll were extremely low during the marine heat wave and the 2015–16 El Niño. Chlorophyll concentrations returned

---

[6] These results are based on four seasonal CalCOFI cruises (Ohman and Venrick 2003) in July and November of 2016 and January and April of 2017. The sampling domain encompasses the southern California Current, the Southern California Bight, the coastal upwelling region at and north of Pt. Conception and an offshore area at the edge of the North Pacific Gyre.

Results are presented as time series of averages over all 66 standard CalCOFI stations covered during a cruise or as anomalies of such values with respect to the 1984–2012 time period. When appropriate, averages from selected regions are used based on a subset of the 66 standard CalCOFI stations. The buoyancy frequency was calculated for all depths and averaged for the upper 100 m of the water column. The nitracline depth is defined as the depth where concentrations of nitrate reach values of 1 µM, calculated from measurements at discrete depths using linear interpolation. Mesozooplankton displacement volumes for the last 12 months are not yet available. Methods used to collect and analyze samples are described in detail at www.CalCOFI.org/methods. At each station a CTD cast and various net tows were carried out. This report focuses on the hydrographic, chemical and biological data derived from ~20 depths between the surface and ~515 m, bottom depth permitting.

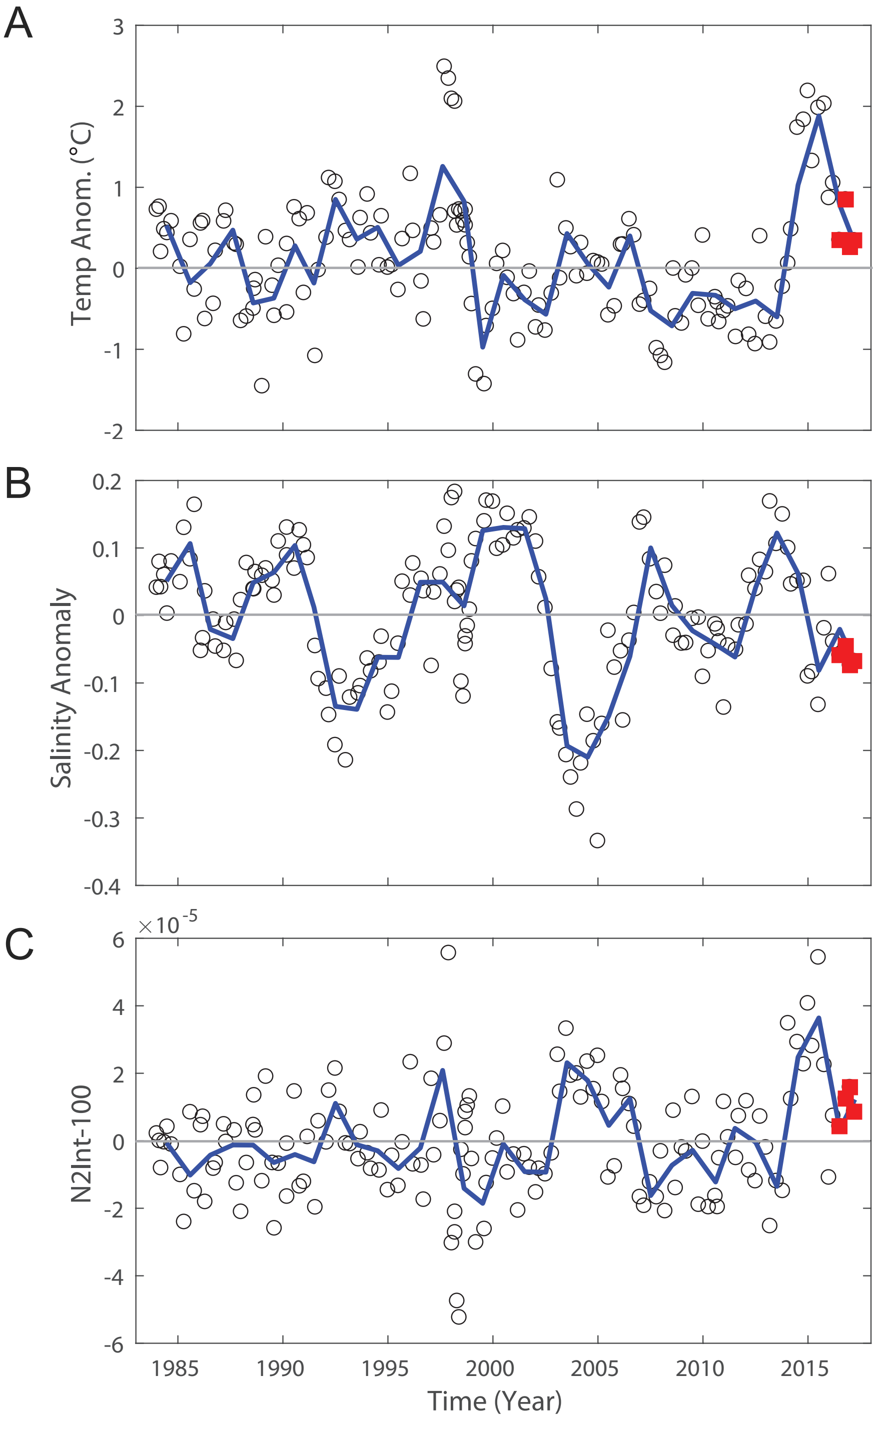

Figure 14. Cruise averages of property anomalies for the mixed layer (ML) of the 66 standard CalCOFI stations (Figure 1) for 1984 to the spring of 2017. A) ML temperature, B) ML salinity. C) buoyancy frequency squared (N2) in the upper 100 m. Data from individual CalCOFI cruises are plotted as open circles; data from the four most recent cruises, 201607 to 201704, are plotted as solid red symbols. Blue solid lines represent annual averages, grey horizontal lines the climatological mean, which is zero in the case of anomalies. Anomalies are based on the 1984 to 2012 time period.

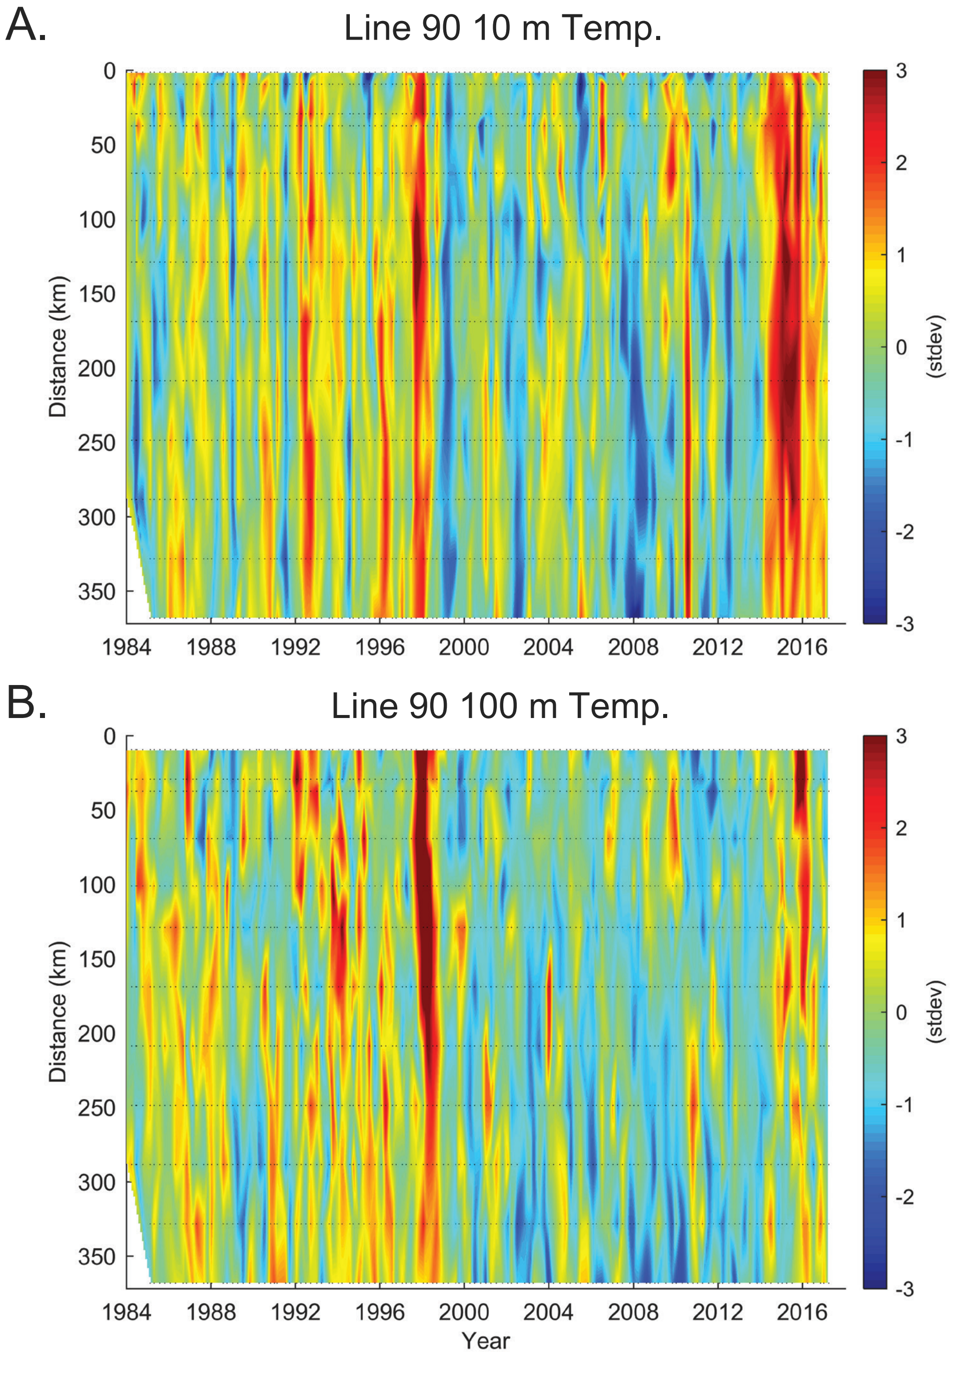

Figure 15. Standardized temperature anomalies for CalCOFI line 90 plotted against time and distance from shore for a depth of 10 m (A) and 100 m (B). Plotted data are deviations from expected values in terms of standard deviations in order to illustrate the strength of the relative changes at different depths.

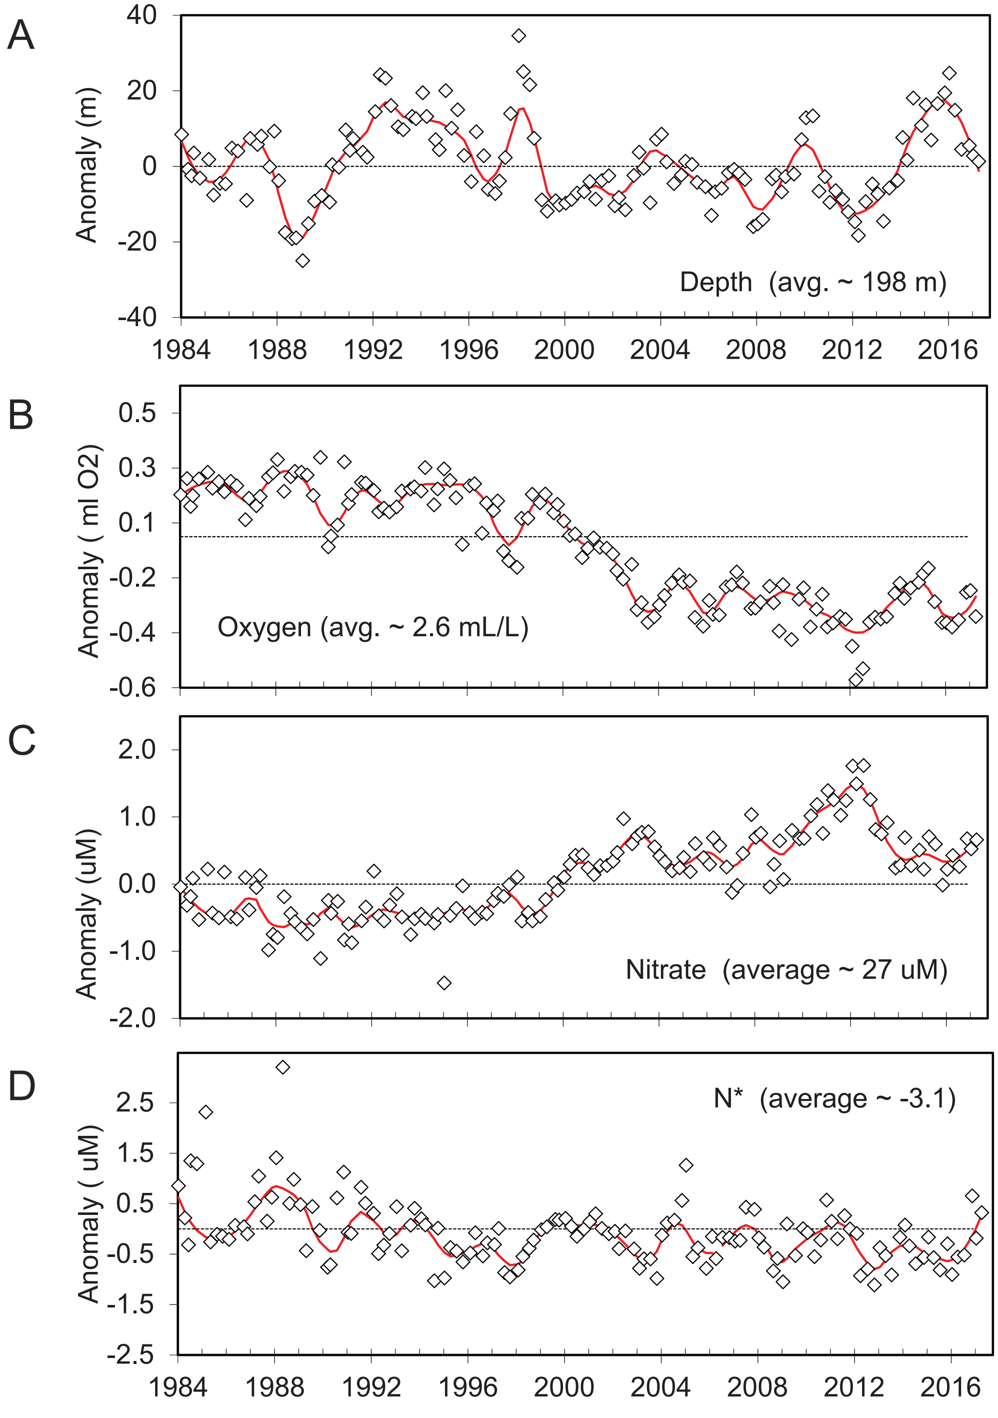

Figure 16. Anomalies of hydrographic properties at the σt 26.4 isopycnal (open diamonds) averaged over the 66 standard CalCOFI stations. Shown are anomalies of isopycnal depth, oxygen, nitrate, and N*, which is a biogeochemical indicator which reflects the deficit of nitrate in a system relative to concentrations of phosphate (Gruber & Sarmiento 1997). The solid red line represents a LOESS fit to the data; average values for the properties are listed. Anomalies are based on the 1984 to 2012 time period.

to the long-term average over the last 12 months (fig. 17). Values of mixed layer nitrate concentrations and nitracline depth (fig. 17) were also close to their long-term average, consistent with the hypothesis that phytoplankton biomass in the CalCOFI study area is primarily controlled by the availability of inorganic nutrients such as nitrate, which in turn is controlled by stratification. The depth distributions of chlorophyll in the offshore, California Current, and upwelling areas were similar to those observed between 1984 and 1997 (http://calcofi.

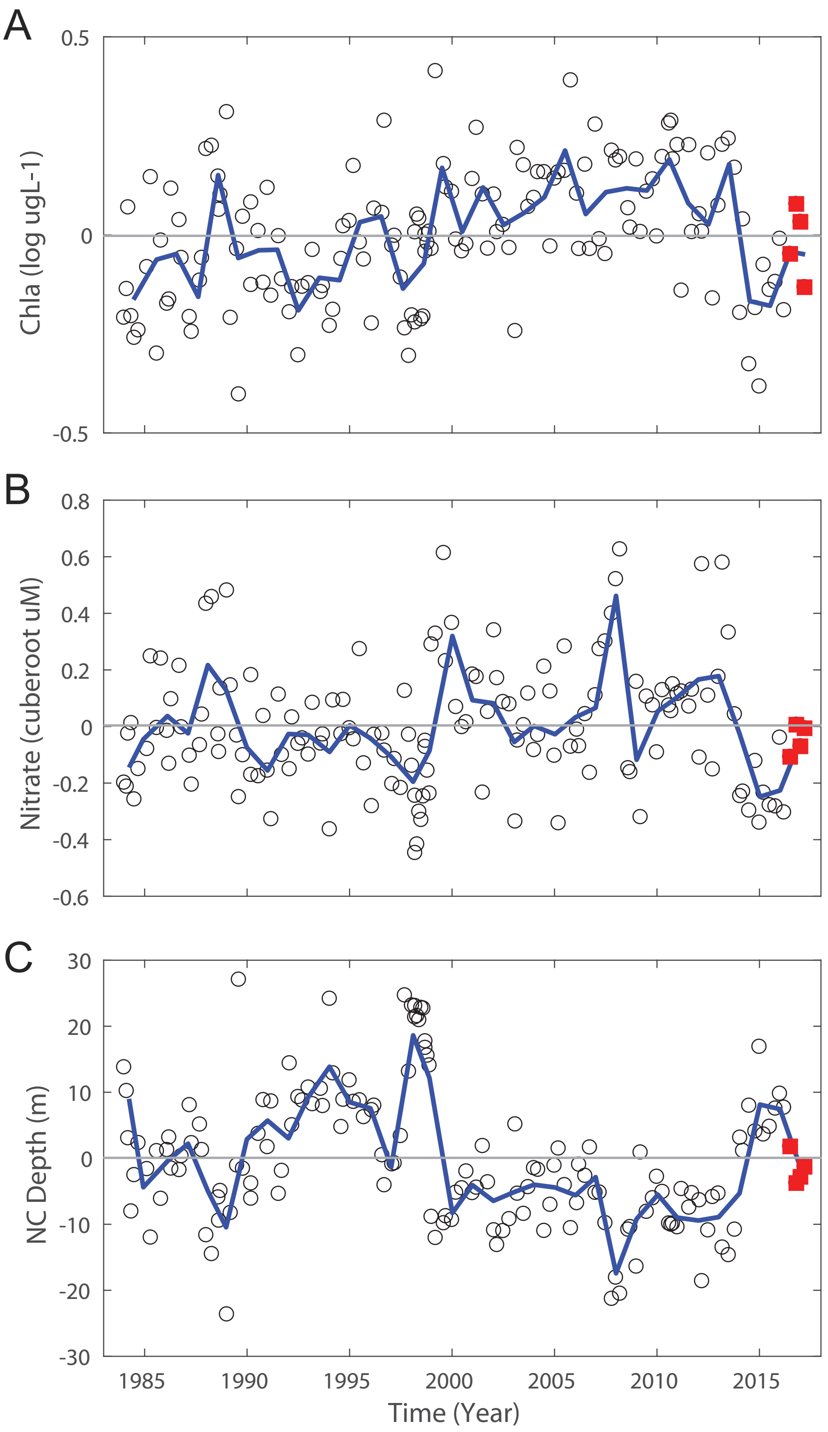

Figure 17. Cruise averages of properties for a depth of 10 m for the CalCOFI standard grid plotted as anomalies relative to the mean of the time series. A) The log10 of chlorophyll *a*, B) the cube root of nitrate, and C) nitracline depth.

org/cruises.html). The chlorophyll maximum in the offshore and California Current region was 10 to 20 m deeper than during the last decade. In the Southern California Bight the chlorophyll maximum was substantially stronger than maxima observed over the last 15 years but the mechanism driving these changes is unknown.

Southern California Current: Harmful Algal Blooms (HAB)

As part of the 2016 CalCOFI surveys, near-surface samples were collected for domoic acid to see if there would be an HAB response to the El Niño conditions. Toxin concentrations were negligible during 2016. In

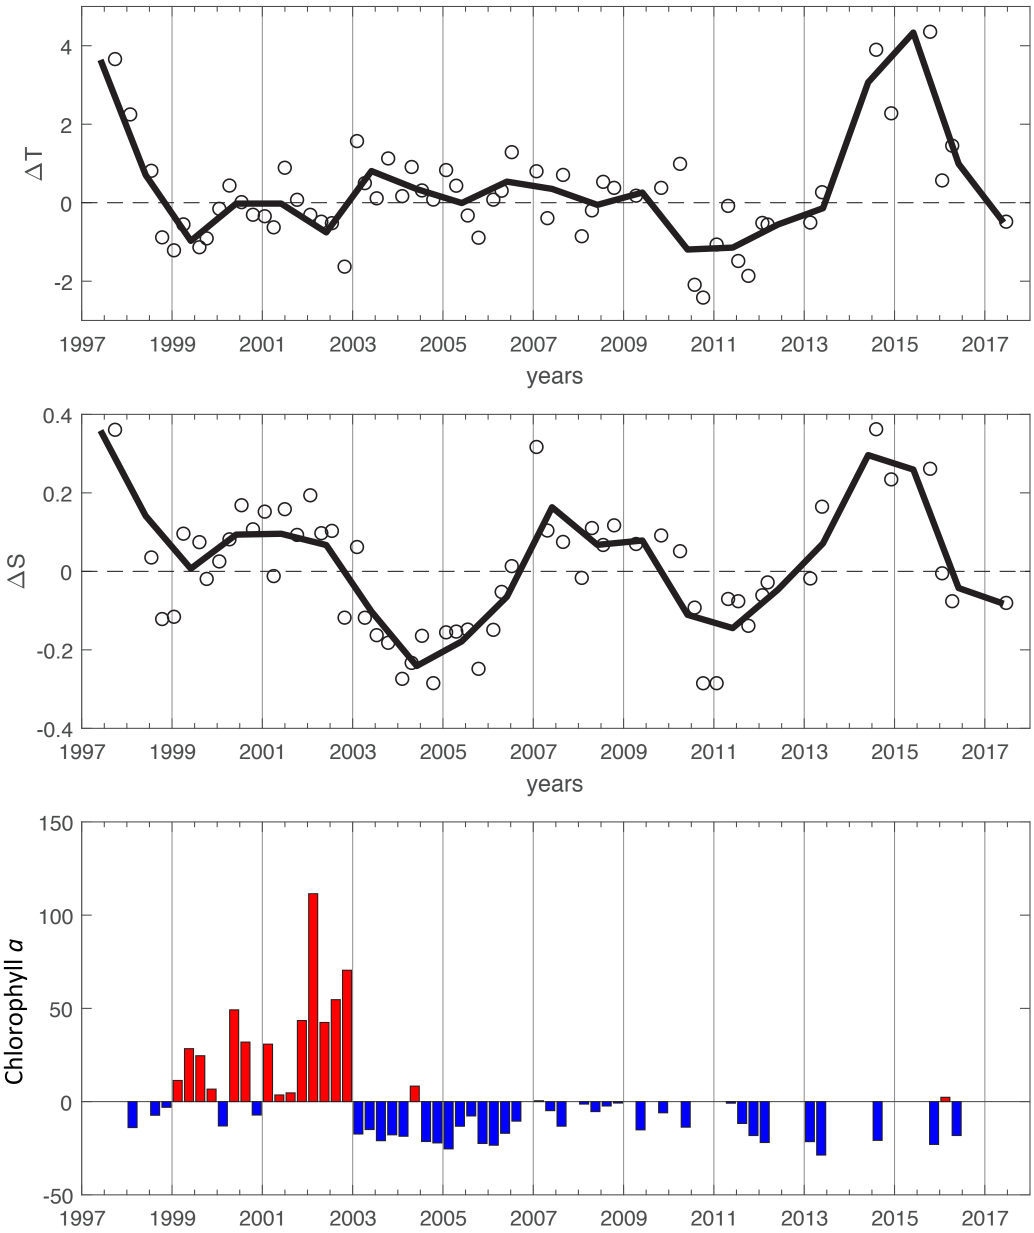

Figure 18. Interannual variability of the mixed layer temperature anomalies (°C) and salinity anomalies in the IMECOCAL region for the period 1997–2017 (white circles) and the mean of each year (thick line). Depth-integrated (0–100 m) chlorophyll *a* anomalies (mg m^{-2}) in the IMECOCAL region.

contrast, a significant bloom developed in April–May 2017, with numerous bird mortalities and marine mammal strandings. The bloom was localized to the Southern California Bight region, but achieved very high particulate domoic acid concentrations (exceeding 50,000 ng/L). This caused an unusual mortality event for multiple marine bird species, dominated by loons (*Gavia* spp., 75% of strandings). Sixteen loons were sampled for toxins, and all were positive for domoic acid. One loon had a sardine in its gullet at the time of death, which contained 681 ppm domoic acid. Concentrations in the loons (liver, kidney, bile) tested as high as 88 ppm (the regulatory limit for human consumption of fish and shellfish is 20 ppm). The bloom region corresponded to the elevated chlorophyll in Figure 9.

Southern California Current: Baja California (IMECOCAL)[7]

Similar to other areas in the California Current, the magnitude of anomalously warm conditions of 2014–

---

[7] The IMECOCAL program conducts quarterly cruises off the Baja California peninsula since 1997–98 El Niño. However, during 2012–17 the sampling frequency has been more sporadic and the last two years the surveys have been carried out exclusively off north Baja California.

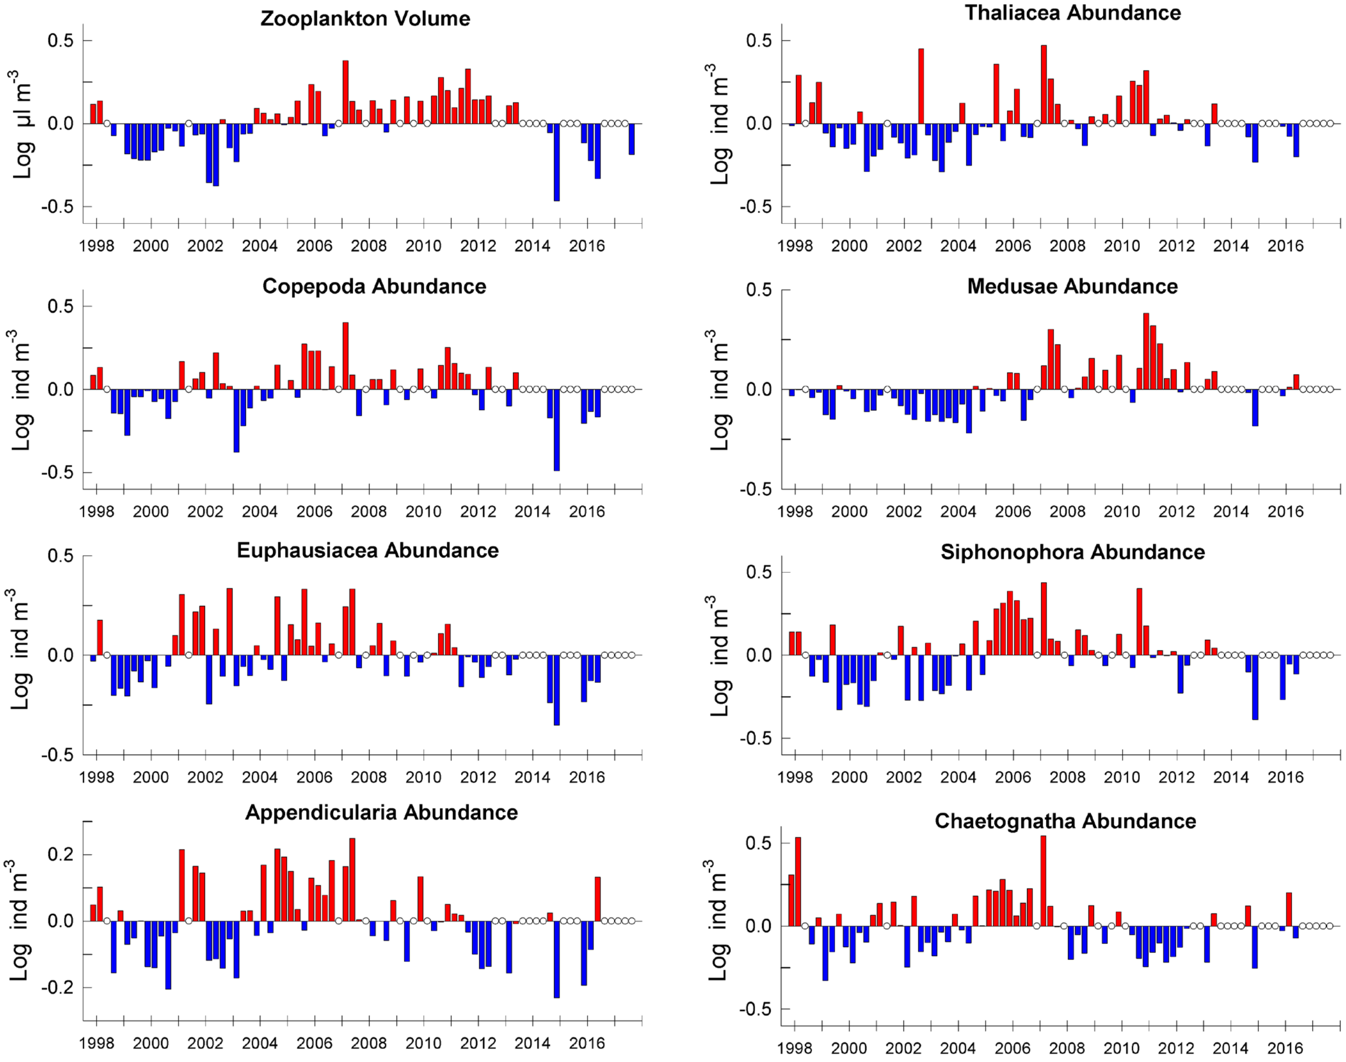

Figure 19. Zooplankton volume anomalies and abundance anomalies of zooplankton groups for the Baja California Peninsula (IMECOCAL) region. Each bar represents a single cruise and open circles represent cruises that did not take place or were omitted due to limited sampling. Data were converted to logarithms.

15 was reduced in 2016 off Baja California (fig. 18)[8]. By June 2017, surface waters transitioned to slightly cooler than average. The last result should be taken with caution because the cruise was carried out in early summer during overcast conditions. Similar to temperature, salinity anomalies of the mixed layer in April 2016 shifted from more saline waters associated with 2014–15 to fresher than average water, and remained this way into 2017 (fig. 18).

Chlorophyll from 2003-2016 remained anomalously low (fig. 18)[9]. However, there were data missing for the most productive season (spring) in recent years 2015–17. It is worth noting that anomalies presented in this updated figure differ from the figure reported in McClatchie et al. (2016) for the time interval 2008–16. This is due to a methodological error found and the application of a correction factor to values collected after 2008.

Zooplankton biomass anomalies have only recently tracked chlorophyll anomalies in this region (fig. 19)[10].

---

[8] The hydrographic data were collected using seabird sensors factory calibrated prior to each cruise. CTD data were computed by Seasoft based on EOS-80. After that, the thermodynamic variables were processed using Matlab functions from SEA-MAT. The mixed layer depth was estimated following the methodology by Jeronimo and Gomez-Valdes (2010) for the IMECOCAL grid. Harmonics were computed for mixed layer properties for all stations for which sufficient data exists. Our approach to obtain the long-term variability follows that of Bograd and Lynn (2003).

[9] Phytoplankton chlorophyll-*a* data were analyzed from water collected at discrete depths in the upper 100 m, filtering water onto Whatman GF/F filters, following the fluorometric method. Integrated chlorophyll anomalies were estimated removing seasonal means. Chlorophyll was not measured in the cruise performed in 2017.

[10] Zooplankton was sampled with oblique tows of a bongo net (500 µm of mesh width) from 210 m to the surface. Displacement volume was measured in all samples and zooplankton taxa were counted in nighttime samples only. For more reference about water samples collections and zooplankton techniques visit the IMECOCAL Web page: http://imecocal.cicese.mx.

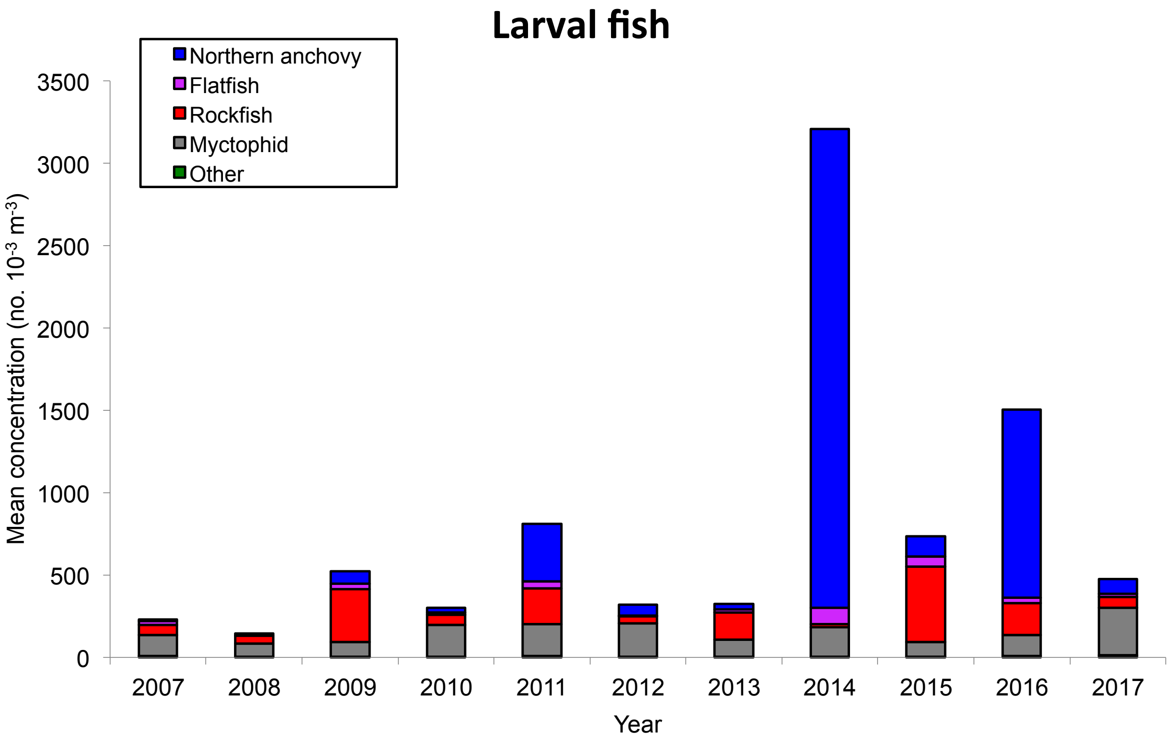

Figure. 20. Mean concentrations (no. 10^{-3} m^{-3}) of the dominant larval fish taxa collected during June–July in 2007–17 along the Newport Hydrographic (NH; 44.65°N, 124.35–125.12°W) and Columbia River (CR; 46.16°N, 124.22–125.18°W) lines off the coast of Oregon.

During 2014–16, an anomalously low biomass of zooplankton coincided with low chlorophyll concentrations. Prior to this (2003–13), zooplankton biomass tended be greater than average despite the anomalously low concentration of chlorophyll over this same period. In June 2017, zooplankton biomass remained anomalously low despite cooling water temperatures. The main crustacean grazers (copepods and euphausiids) as well as gelatinous groups (tunicates, siphonophores, and medusae) may have contributed to the extremely low biomass of zooplankton observed (fig. 19). The negative anomalies of zooplankton biomass and abundances of functional groups during El Niño 2015–16 are in contrasts with El Niño 1997–98 when positive anomalies of copepods, euphuausiids, tunicates, and siphonophoes were observed. The unique coincidence between zooplankton in the two periods were positive anomalies of chaetognaths abundance during both the 2015–16 and the 1997–98 El Niño.

It is difficult to distinguish the contribution of the marine heat wave or El Niño on the low abundance of zooplankton in the Baja California. An increase in temperature could be the result of either, producing a similar effect on subtropical species, which usually are dominant in the region (Jiménez-Pérez and Lavaniegos 2004; Lavaniegos and Ambriz-Arreola 2012). Also, negative anomalies in some groups, such as euphausiids, appendicularians, and chaetognaths, occurred since 2011, previous to the marine heat wave event.

REGIONAL EPIPELAGIC MICRONEKTON AND SALMON OBSERVATIONS

Northern California Current: Washington and Oregon

Newport Hydrographic Line and Pre-recruit Survey The larval epipelagic micronekton community along the central-northern coast of Oregon in June 2017 was similar to the average community structure found in the same area and season during the previous ten years in terms of composition and relative concentrations of the dominant taxa (fig. 20)[11]. The exception was unusually

---

[11] Micronekton samples were collected from 3–4 stations representing coastal (<100 m in depth), shelf (100–1000 m), and offshore (>1000 m) regions along both the Newport Hydrographic (NH; 44.65°N, 124.35–125.12°W) and Columbia River (CR; 46.16°N, 124.22–125.18°W) lines off the coast of Oregon during June–July in 2007–17 (See Auth 2011 for complete sampling methods). In addition, post-larval (i.e., juvenile and adult) fish were collected using a modified-Cobb midwater trawl (MWT) with a 26 m headrope and a 9.5 mm codend liner fished for 15 min at a headrope depth of 30 m and ship speed of ~2 kt. MWT collections were made at 4–6 evenly-spaced, cross-shelf stations representing coastal, shelf, and offshore regions along nine (five in 2017) half-degree latitudinal transects between 42.0 and 46.0°N latitude in the northern California Current region during June–July in 2011–17 (although no sampling was conducted in 2012). Sampled volume was assumed to be uniform for all hauls. All fish collected were counted and identified to the lowest taxonomic level possible onboard, although pre-recruit rockfish were frozen and taken back to the lab for identification using precise meristic and pigmentation metrics.

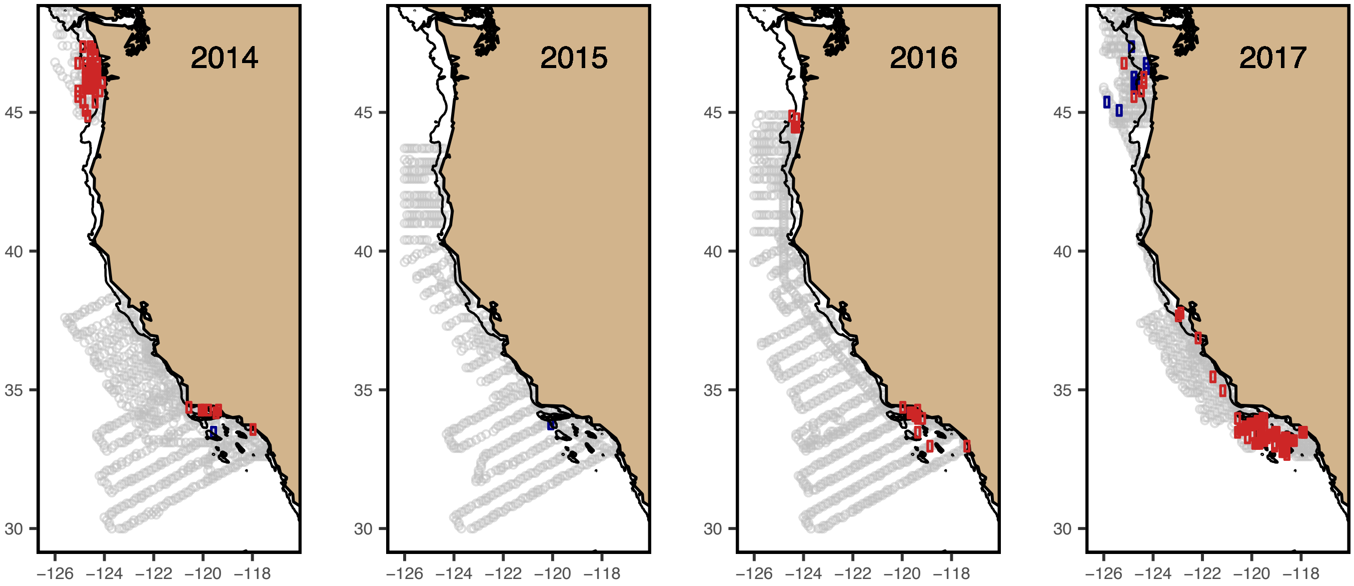

Figure 21. Northern anchovy egg density anomalies from continuous underway fish egg sampler (CUFES) surveys March–July 2014–17. Anomalies are shown for values greater than 2 eggs/m^3 (red, Observation – Mean) or less than –2 eggs/m^3 (blue) based on 0.1˚ bin spatial averages. North of 44˚N there were only 12 years of data: 2003, 2004, 2006, 2007, 2008, 2010, 2011, 2012, 2013, 2014, 2016, and 2017. Note that central California southward has been surveyed since 1997.

high concentrations of larval northern anchovy (*Engraulis mordax*) in 2014 and 2016 resulting from anomalously high spawning activity in the region (fig. 21)[12]. Total mean larval concentration was near average based on the 11-year time series. Larval myctophids in 2017 were found in the highest concentration since sampling began in 2007 as were "other" taxa, although other taxa still only accounted for <3% of the total mean larval concentration.

The post-larval fish community in the northern California Current in June 2017 was similar to the community structure found in the same area and season during the previous two years primarily due to the continued dominance of Pacific hake (*Merluccius productus*), which comprised 83% of the mean abundance of "other" taxa and ~ 60% of the total mean abundance of all post-larval fish (fig. 22). The abundance of smelt in 2017 was tied with that in 2016 for the lowest of the six-year time series, while the abundance of clupeiformes in 2017 was tied with that in 2016 for the highest, primarily due to the high concentration of northern anchovy collected just off the mouth of the Columbia River. Rockfish abundance in 2017 was the second highest of the time series, with the dominant species consisting of shortbelly (*S. jordani*; 50% of total rockfish), blue (*S. mystinus*), darkblotch (*S. crameri*), and widow (*Sebastes entomelas*). In addition, medusafish (*Icichthys lockingtoni*) were collected in far higher numbers than ever before in the six-year time series, probably due to their affinity for pyrosomes which were present in unprecedented numbers throughout the sampling area.

Columbia River plume region: Juvenile Salmon and Ocean Ecosystem Survey The June fish and invertebrate assemblage in the northern California Current during 2017 was unusual and dominated by species that normally occur in warmer ocean waters to the south of the study area[13]. A nonmetric multidimensional scaling (NMDS) ordination clearly showed that the 2015–17 assemblages were outliers, distinct not only from the 1999 La Niña assemblages, but also from the assemblage sampled during the 2005 warm event in the northern California Current (fig. 23).

The fish and invertebrate community in 2017 was similar to the past two warm years of 2015 and 2016 (fig. 23). Taxa indicative of 2017 included the pyrosome, Pacific pompano (*Peprilus simillimus*), Pacific chub mackerel (*Scomber japonicus*), and jack mackerel (*Trachurus symmetricus*). Pyrosomes are tunicates that are normally

---

[12] Egg data is from continuous underway fish egg sampler (CUFES). While the southern/central region has been surveyed since 1997, the survey expanded north of 44˚N only in 12 years: 2003, 2004, 2006, 2007, 2008, 2010, 2011, 2012, 2013, 2014, 2016, and 2017. Spatial anomalies are estimated on 0.1˚ bins.

[13] Pelagic fish and invertebrate catch data were collected by the Juvenile Salmon and Ocean Ecosystem Survey (JSOES, NWFSC NOAA/Bonneville Power Administration) surveys using surface trawls on standard stations along transects between northern Washington and Newport, OR, in June from 1999 to 2016. All tows were made during the day at predetermined locations along transects extending off the coast to the shelf break (Brodeur et al. 2005). We restricted the data set to stations that were sampled consistently over the sampling time period (>9 y). Numbers of individuals were recorded for each species caught in each haul and were standardized by the horizontal distance sampled by the towed net as CPUE (number/km towed). A log(x+1) transformation was applied to the species at each station and then averaged by year for each species. The species data matrix included the 27 most abundant species captured over the 18 years sampled years (27 species x 18 years). A nonmetric multidimensional scaling (NMDS) ordination was used to describe the similarity of each year's community in species space.

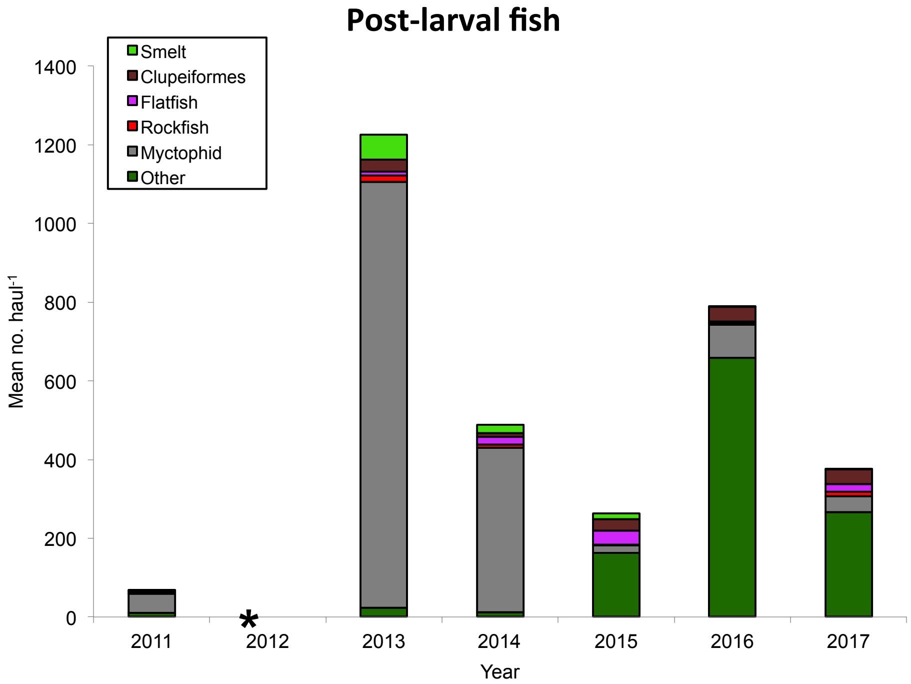

Figure 22. Mean catches (no. haul^{-1}) of the dominant post-larval fish taxa collected during June–July in 2011–17 along nine half-degree latitudinal transects between 42.0° and 46.0°N latitude in the northern California Current region. * = no samples were collected in 2012.

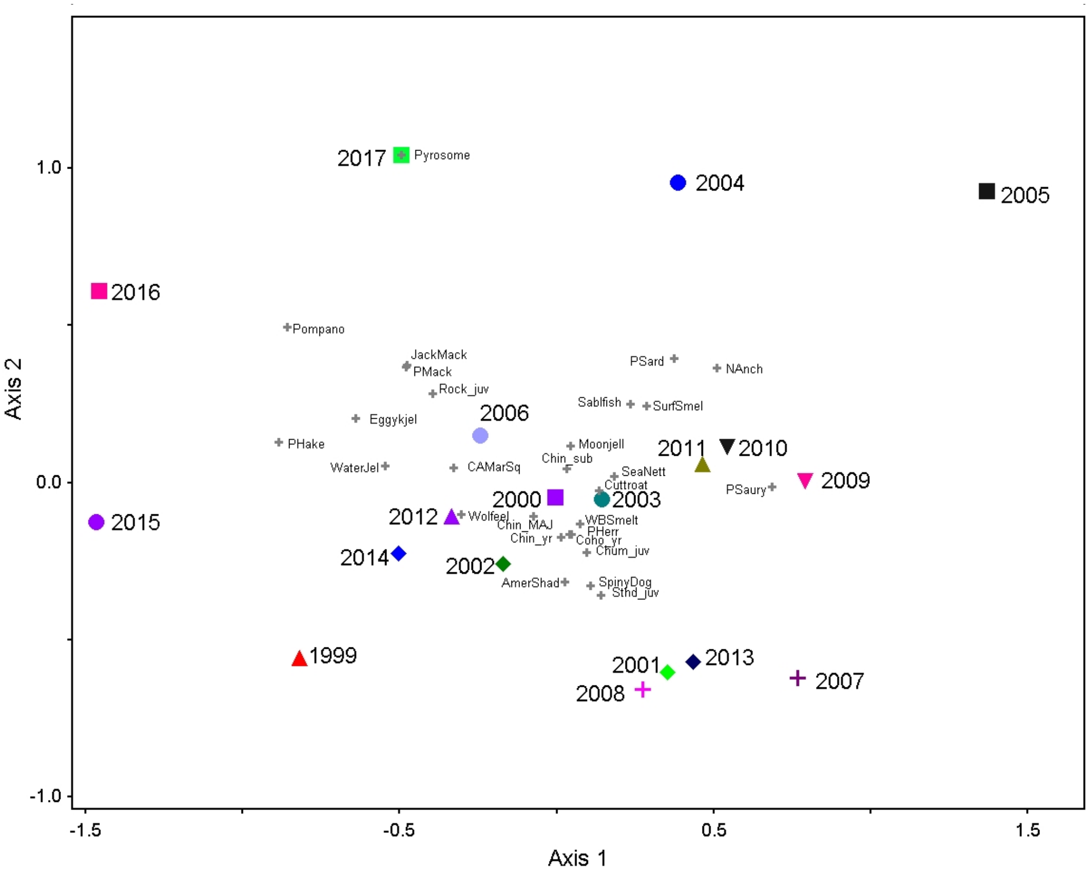

Figure 23. NMDS ordination of northern California Current pelagic assemblages. The NMS ordination explained 80.8% of the total variability in the first two dimensions. Pelagic fish and invertebrate catch data were collected by the NWFSC NOAA/Bonneville Power Administration surveys using surface trawls on standard stations along transects between northern Washington and Newport, OR, in June from 1999 to 2016. All tows were made during the day at predetermined locations along transects extending off the coast to the shelf break (Brodeur et al. 2005).

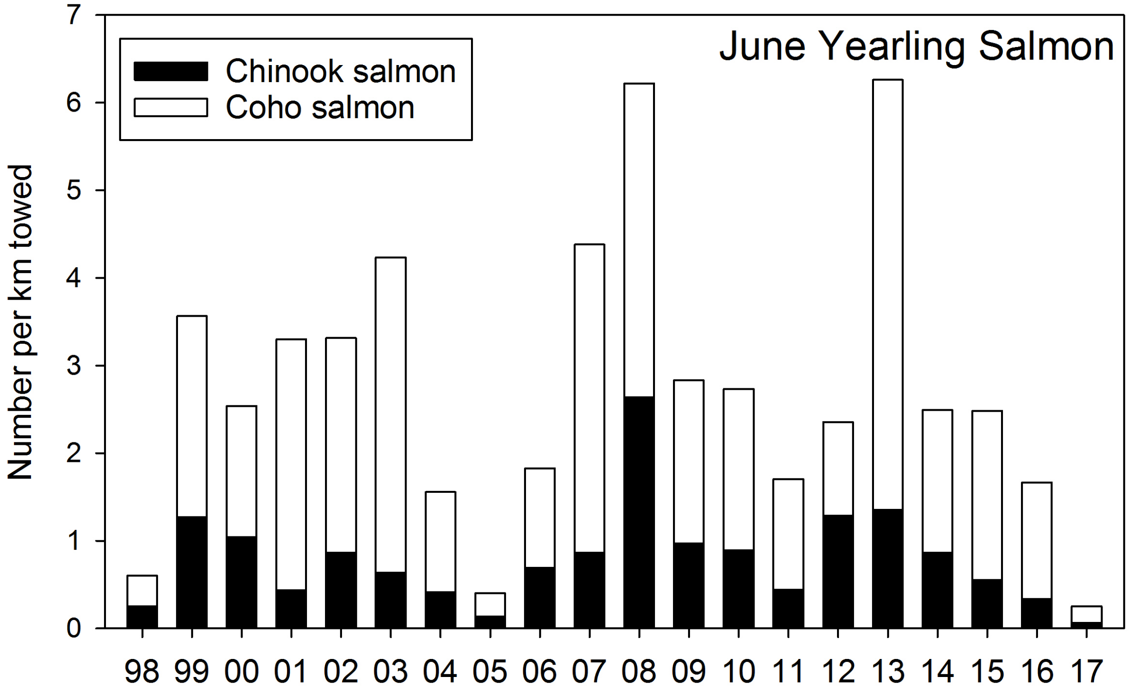

Figure 24. Catches of juvenile coho (black bars) and Chinook (white bars) salmon off the coast of Oregon and Washington in June from 1998–present.

found in the tropics, and have never been captured on the continental shelf during this survey or any previous surveys off central Oregon to northern Washington to our knowledge, although in recent years it has been found increasingly farther north off the shelf in other surveys[14]. But during June 2017 pyrosomes were present in 37% of the hauls, sometimes exceeding hundreds of individuals.

The jellyfish community off Washington and Oregon was also quite different than previous years. The usual numerically dominant large jellyfish is a cool-water associated scyphozoan species, sea nettle (*Chrysaora fuscescens*). However, during the warm ocean years of 2015 and 2016, the more offshore taxa of Hydromedusae, the water jelly (*Aequorea* spp.) was much more abundant and densities of *Chrysaora* were low. In June 2017 both *Chrysaora* and *Aequorea* were caught in average densities.

Salmon and salmon forage indicators in northern California Current Catches of yearling salmon off Washington and Oregon in June may be a good indicator of early ocean survival of yearling Chinook (*Oncorhynchus tshawytscha*) and coho salmon (*O. kisutch*). The abundance of yearling Chinook salmon during June is positively related to spring Chinook jack and adult salmon counts at the Bonneville Dam (with 1 and 2 year lags, respectively), as does the abundance of yearling coho salmon to subsequent coho smolt to adult survival[15] (Morgan et al. 2017). Catch per unit effort (number per km trawled) of both yearling Chinook and coho salmon during the June 2017 survey was the lowest of the 20-year time series from 1998 to 2017 (fig. 24). This suggests that adult returns of both spring Chinook in 2019 and coho salmon in 2018 will be significantly lower than average.

The biomass of fish larvae in late winter from the Newport Hydrographic Line provides an index of fish that are the common prey of juvenile salmon when they enter the ocean in spring and summer, and correlates with juvenile salmon survival and return as adults (Daly et al. 2013, 2017)[16]. The food biomass for out-migrating juvenile salmon in winter (January–March) 2017 was the highest in the 20-year time series (fig. 25), largely attributable to presence of young-of-the-year (YOY) rockfishes.

In addition to the increased biomass of fish prey potentially available to out-migrating juvenile salmon, the type of fish prey (assemblage) that are available for salmon also influences salmon survival. Importantly, the overall community composition of winter ichthyoplankton in 2017 was similar to 2015 and 2016 and predicted a poor food community for the salmon (fig. 26).

---

[14] http://news.nationalgeographic.com/2017/06/pyrosome-fire-body-bloom-eastern-pacific-warm-water

[15] https://www.nwfsc.noaa.gov/oceanconditions/Juvenile Salmon Catch

[16] Ichthyoplankton samples were collected from 5 stations spaced ~9 km apart along the NH line. Sampling was conducted approximately every 2 wk between January and March. Only samples from January–March were used, assuming that larvae collected during these months would have had sufficient time to grow to the average size of prey eaten by juvenile salmon in late spring and early summer.

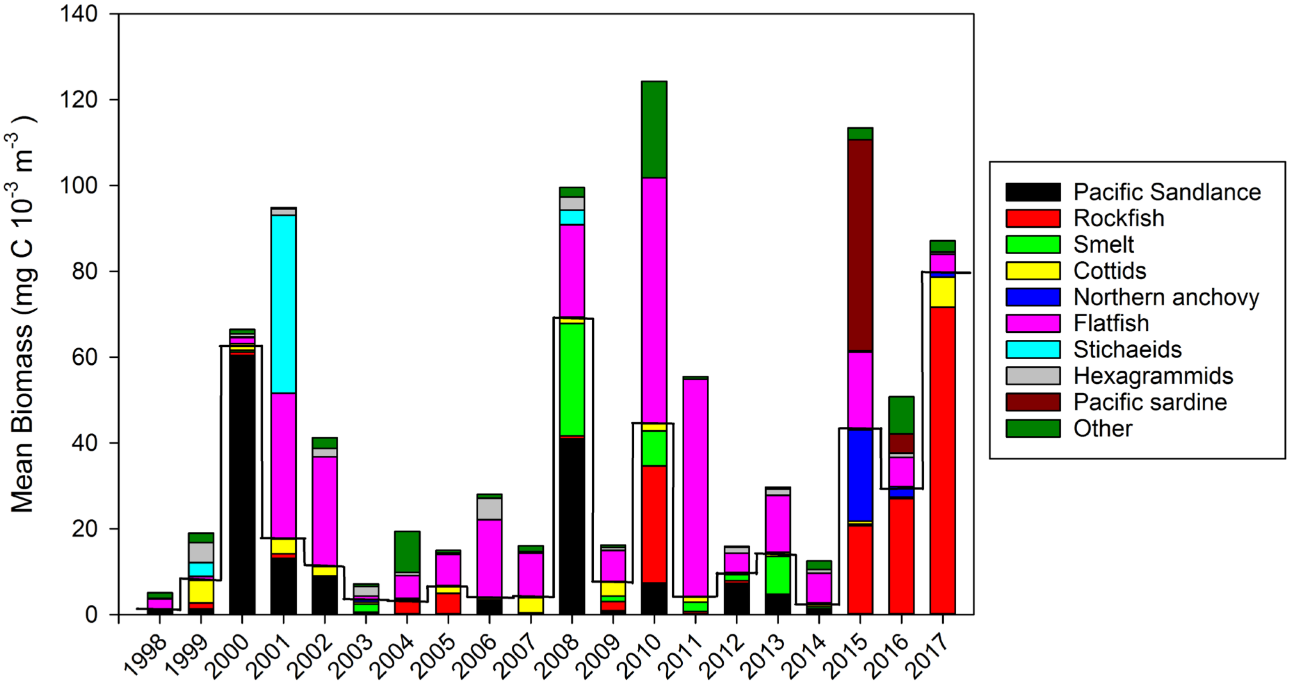

Figure 25. Annual mean biomass (mg C 10^{-3} m^{-3}) of the five important salmon prey taxa (below solid line) and five other dominant larval fish taxa (above solid line) collected during winter (January–March) in 1998–2017 along the Newport Hydrographic line off the coast of Oregon (44.65°N, 124.18–124.65°W). Figure expanded from one presented in Daly et al. (2013).

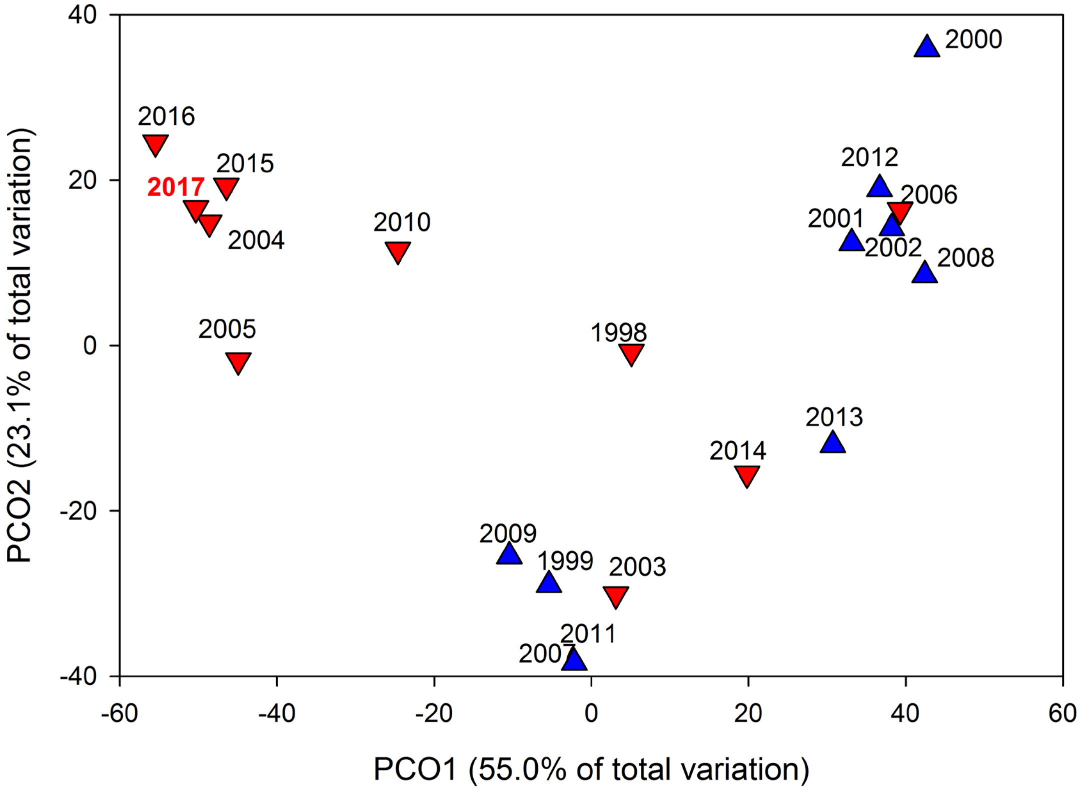

Figure 26. Principal coordinate analysis of the prey composition of winter ichthyoplankton that are important prey for out-migrating juvenile salmon (Pacific sand lance, osmerids, cottids, northern anchovy, and rockfishes). Red symbols indicate positive winter PDO (warm ocean temperatures) and blue indicates negative winter PDO (cold ocean temperatures). The larvae were collected during winter (January–March) in 1998–2017 along the Newport Hydrographic line off the coast of Oregon (44.65°N, 124.18–124.65°W). Figure expanded from one presented in Daly et al. (2017).

Based on axis 1 values (55% variance explained along this axis) from principal coordinate analysis of the prey composition of winter ichthyoplankton, the index of the 2017 prey composition predicts poor prey conditions for currently out-migrating juvenile salmon. In 2017, 90% of the winter ichthyoplankton composition was warm ocean condition taxa consisting of rockfishes and northern anchovy larvae. The relationship between the principle component 1 (PC1) axis values (prey composition) with spring Chinook salmon adult returns to Bonneville Dam two years later is: $P = 0.003$; $R^2 = 48.0\%$ (1998–2014; 1999 outlier year excluded). The biomass of ichthyoplankton in winter predicts returns of spring Chinook salmon to Bonneville Dam in 2019 to be just below ~230,000, and the prey composition prediction is one of the lowest of the time series at ~74,000.

Higher than average ichthyoplankton biomass but poor ichthyoplankton composition occurred in the warm ocean years 2015–17. Of particular note during January–March 2017, southern California winter-spawned larvae were present for the third winter in a row (e.g., Pacific hake and Pacific sardine [*Sardinops sagax*]; Auth et al. 2017). Sardine larvae were present in winter 2017, but not in high amounts, and were located at inshore stations (NH 1 and 10) and some were >10 mm long (Auth unpublished data). Of note, juvenile sardine were eaten for the first time in the time series by coho and Chinook salmon in May and June 2016 (Daly and Brodeur unpublished data), indicating that sardine are a new prey resource for the salmon in warm ocean conditions.

Summary of epipelagic micronekton and salmon in northern CCS Taken as a whole, the micronekton community and juvenile salmon abundance during winter to June 2017 off Washington and Oregon indicate continued perturbation from "normal" conditions. The abundance of pyrosomes may have indicated abnormal water transport in 2017. It is not yet clear whether the findings of 2017 are a result of the marine heat wave combined with the 2015–16 El Niño or whether ocean processes unique to 2017 combined with the previous warm years resulted in the altered community structure.

Central California[17]

Above average catches of YOY rockfishes were observed off central California in late spring 2017, although these catches were lower than the high catches observed in 2015 and 2016 (fig. 27). Catches in the southern region increased from below average values in 2016 to the greatest values in the (shorter) 13-year record in that region in 2017. Catches of YOY rockfish in north-central California were below average, such that there was a gradient in relative catch rates from record highs in the Southern California Bight to below average (but above historic low levels) in northern California.

In the Southern California Bight during 2017, catches of adult northern anchovy were comparable to past (2004) high levels, while catches continued to be very sparse in other regions of the California Current sampled by this survey (fig. 27). The survey also samples YOY northern anchovy and YOY Pacific sardine, for which catches of both increased during the 2015–16 warm event, and, in 2017, stayed above previous low levels in northern and central areas while continuing to increase to very high levels in the Southern California Bight (data not shown, but see Sakuma et al. 2016). Although the sparse catches for adult Pacific sardine and adult northern anchovy north of Southern California Bight indicate that the biomass of each may be too low to be meaningfully indexed by the survey, the increase in catches of YOY northern anchovy, in particular, are consistent with an increase in that population which is likely more concentrated in nearshore habitats not sampled by the survey. An increase in adult northern anchovy nearshore is also consistent with the egg enumeration data in 2017 (fig. 21) and seabird diets (presented below), both of which indicated above average adult northern anchovy abundance in the region. The abundance of both krill and market squid (*Doryteuthis opalescens*), increased significantly in all regions in 2017, both ranked at the third highest value since 1990 in the core region (fig. 27).

Thetys as well as other salps were less abundant than recent years in all but the southern region, where other salps increased relative to 2016 (fig. 28). Pyrosomes continue to be caught in very large numbers across all regions (fig. 28), with particularly high catches (of primarily very small pyrosomes) in the southern region. Catches of scyphozoan jellyfish (primarily *Aurelia* spp. and *Chrysaora* spp.) continued to be unusually low in 2017, a pattern that emerged in 2015 (fig. 28). The high numbers of pelagic red crabs (*Pleuroncodes planipes*) and California lizardfish observed in 2015 and 2016 (Leising et al. 2015; McClatchie et al. 2016) were not observed in 2017 possibly indicating cooler water regionally.

There are sharp differences in principal component (PC) loadings between coastal pelagic (Pacific sardine, northern anchovy) and mesopelagic species (myctophids) relative to most of the YOY groundfish, krill, and cephalopods. The two leading PCs for the assemblage are shown in a phase plot (fig. 29). The dramatic separation of the 2013–16 period was apparent as those years were

---

[17] Epipelagic micronekton samples were collected during May and June by the Southwest Fisheries Science Center Rockfish Recruitment and Ecosystem Assessment Survey and the Northwest Fisheries Science Center Pre-recruit Groundfish Survey, covering a geographic range from the US/Mexico border (32.5°N) to southern Washington (46.5°N). A modified midwater Cobb trawl (10–30 m headrope depth) was used to sample pelagic species along the CCE in the mixed layer where juvenile salmon are typically found. Methods were standardized between regions beginning in 2011 (Sakuma et al. 2016).

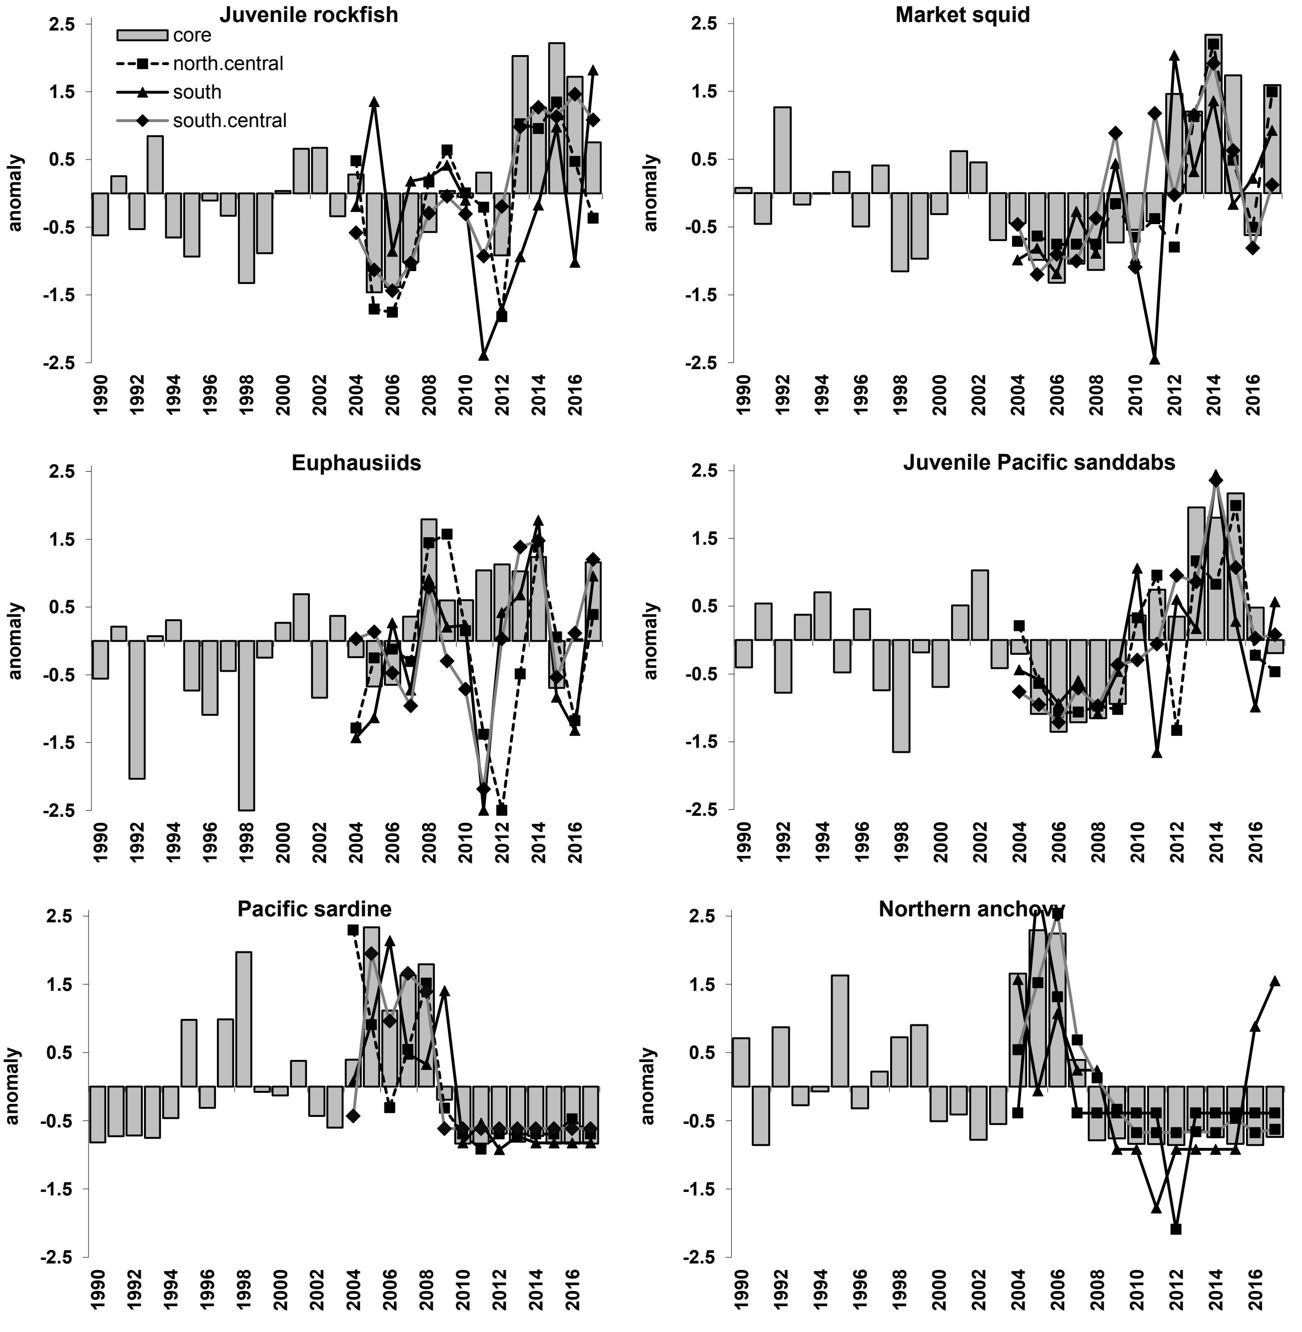

Figure 27. Long-term standardized anomalies of several of the most frequently encountered pelagic forage species from rockfish recruitment survey in the core (central California) region (1990–2017) and the southern, south-central and north-central survey areas (2004–17). Forage groups are YOY rockfish, market squid, krill (primarily *Euphausia pacifica* and *Thysanoessa spinifera*), YOY Pacific sanddab, Pacific sardine and northern anchovy.

extremely orthogonal to the low productivity years of 1998, 2005, and 2006. However, in 2017 the observed community switched to what might be considered a "normal" state, centrally located among the years 1990–2016. The switch in the forage base has important implications for seabirds, marine mammals, salmon and adult groundfish that forage primarily, or exclusively, on one or another component of the forage assemblage.

Southern California Current: CalCOFI region

The spring coastal pelagic fish survey in 2017 on NOAA ship *Reuben Lasker* was focused on northern anchovy rather than Pacific sardine and consequently the offshore extent of transects was reduced. No trawling was conducted offshore and unlike 2015 and 2016, no sampling was conducted north of San Francisco in 2017. The spring CalCOFI cruise on NOAA ship

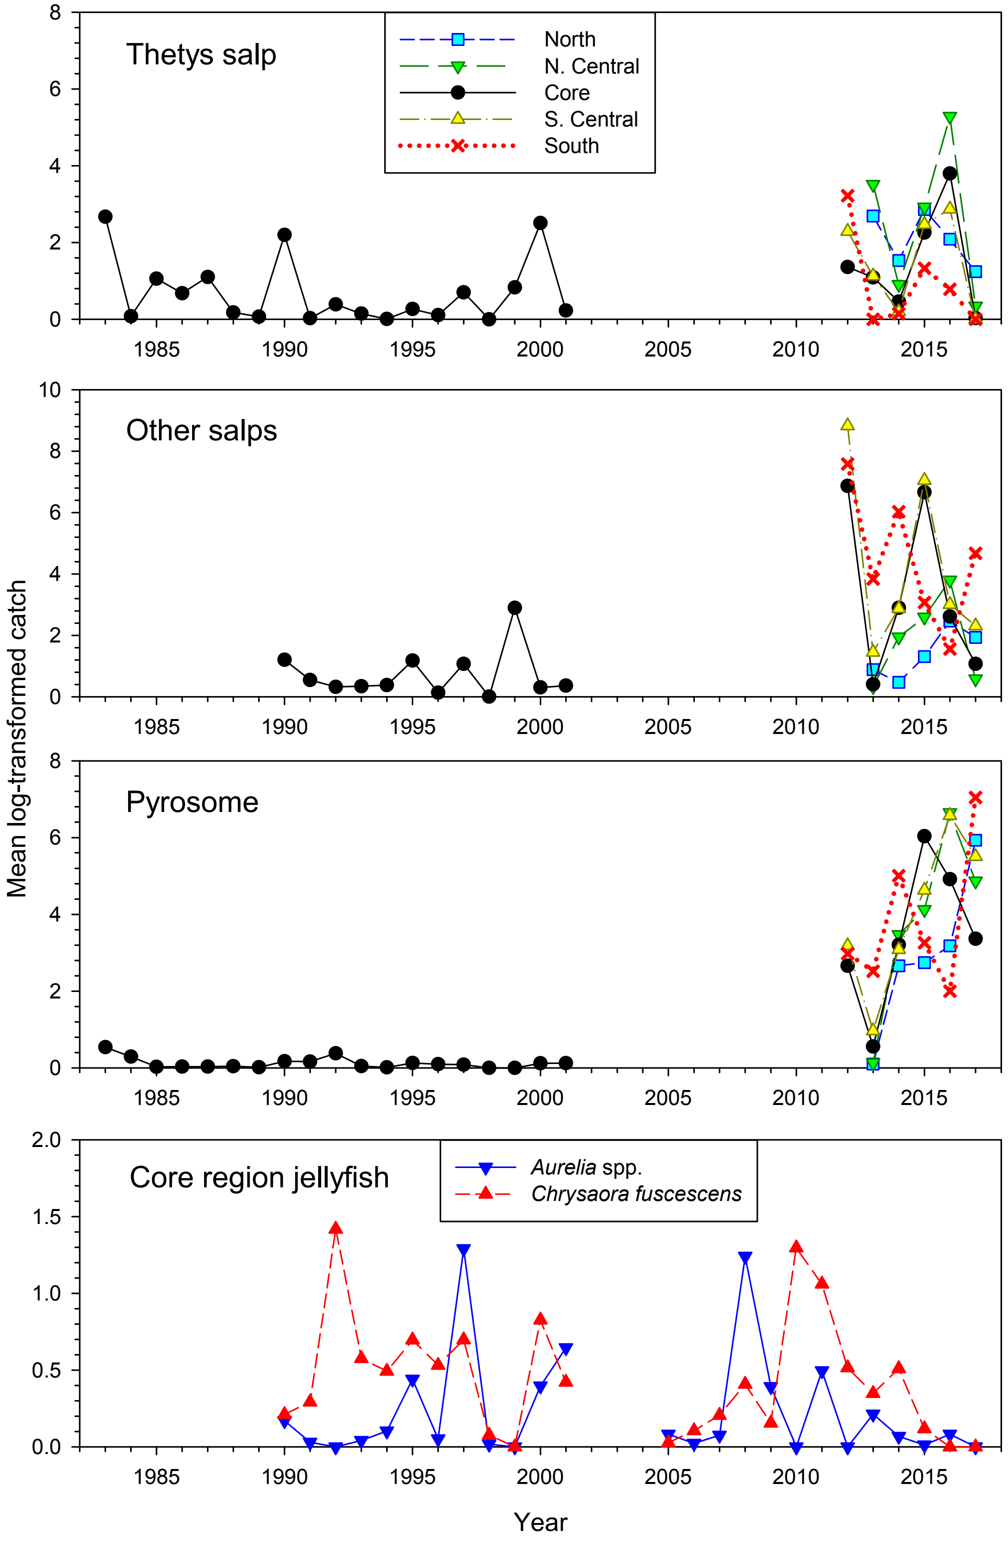

Figure 28. Standardized catches of jellyfish (*Aurelia* and *Chrysaora* spp.) and pelagic tunicates in the core and expanded survey areas.

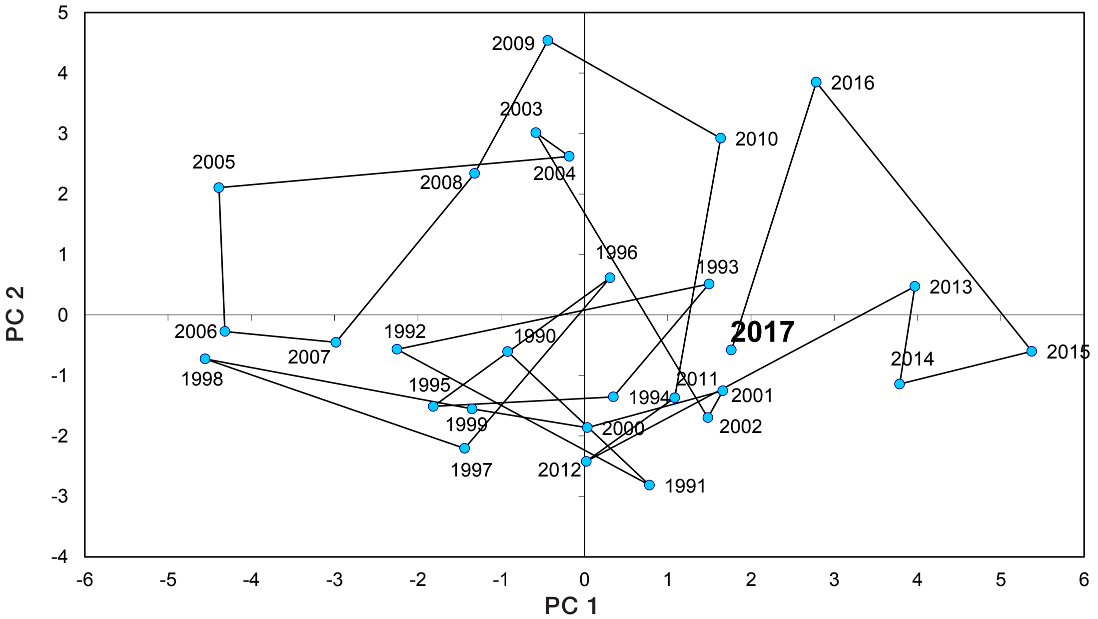

Figure 29. Principal component scores plotted in a phase graph for the nine key taxonomic groups of forage species sampled in the central California core area in the 1990–2017 period.

Bell M. Shimada sampled the usual 113-station winter and spring pattern (San Diego to San Francisco) (fig. 30).

Anchovy eggs in spring 2017 were notably more abundant than in 2016 (fig. 31). Anchovy eggs were also an order of magnitude more abundant in spring 2016 compared to 2015, but the increase was spatially restricted to small areas off Ventura, California and Newport, Oregon. By contrast, in spring 2017 anchovy eggs were widespread in the Southern California Bight, indicating that eggs were both more widely distributed and present at higher density than in 2016. It is notable that the highest egg count was very localized (again, off Ventura, California) and was associated with an extreme trawl catch of more than 600 kg of almost pure anchovy. This single catch was an order of magnitude larger than all of the other forage fish trawl catches on the entire cruise, and presumably represented a large school of northern anchovy.

In 2017, few anchovy eggs, and no adults, were collected north of Point Conception (fig. 30) although other continuous underway fish egg sampler surveys demonstrate concentrations of northern anchovy eggs off the Columbia River (fig. 21). Peak northern anchovy spawning off California generally occurs during March, so spawning patterns detected by the spring cruise may not be representative of the full northern anchovy spawning season.

Sardine and jack mackerel eggs were found at very low concentrations in the spring of 2017, consistent with the long-term trend. Sardine eggs were most abundant off the central California coast, south of Monterey, California (fig. 30). In 2016 the spawning distribution of sardine eggs was centered farther north (43˚–44.5˚N, off Oregon) than in spring 2015 (41˚–43˚N, California-Oregon border), but we are unsure if there was significant sardine spawning off Oregon in 2017 (fig. 31).

Whereas the ichthyoplankton assemblage (larval; an earlier stage than represented in fig. 27) in 2014–16 (based on spring samples from lines 80 and 90) was characterized by high abundances of southern, offshore mesopelagic fishes such as *Ceratoscopelus townsendi*, Gonostomatidae (mostly in the genus *Cyclothone*), *Triphoturus mexicanus*, and *Vinciguerria* spp. (mostly *V. lucetia*; these taxa are colored red on fig. 32), the 2017 assemblage was more "normal" (fig. 32). In multivariate space based on NMDS, NMDS 1 largely separated years when southern species (red font, fig. 32) were predominant (high NMDS 1) from years with primarily northern species (low NMDS 1; blue font on fig. 32), and NMDS 2 distinguished years with high Pacific sardine (high NMDS 2) and high northern anchovy (low NMDS 2). The 2017 assemblage fell in the middle of both NMDS axes 1 and 2, indicating that the assemblage was characterized by species with cosmopolitan distributions (colored green in fig. 32) and unexceptional abundances of both Pacific sardine and northern anchovy across the sampled region.

Evaluation of common mesopelagic taxa indicated that warm-water taxa generally declined between 2016 and 2017 while abundances of cool-water taxa were similar between these years. The southern warm-water taxa *Vinciguerria* spp. and *C. townsendi* fell to relatively low abundances in the spring of 2017 (fig. 33). The southern myctophid *T. mexicanus* declined dramatically from 2016

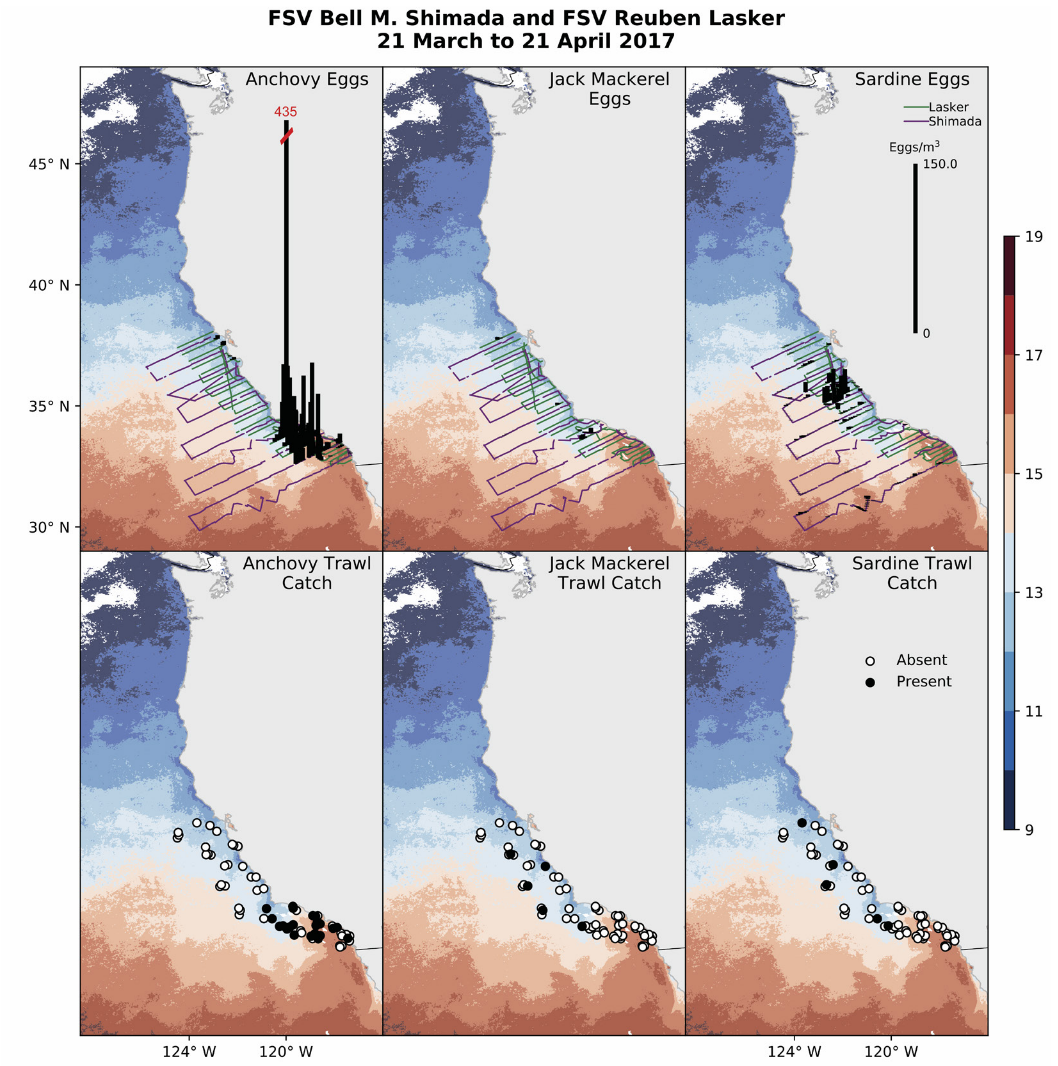

Figure 30. Density of eggs of northern anchovy, jack mackerel, and sardine collected with the continuous underway fish egg sampler (CUFES) during the spring 2017 CalCOFI and coastal pelagic fish cruises overlaid on satellite sea surface temperatures (˚C). Lower panels represent trawls in which anchovy, jack mackerel, and sardine where absent or present.

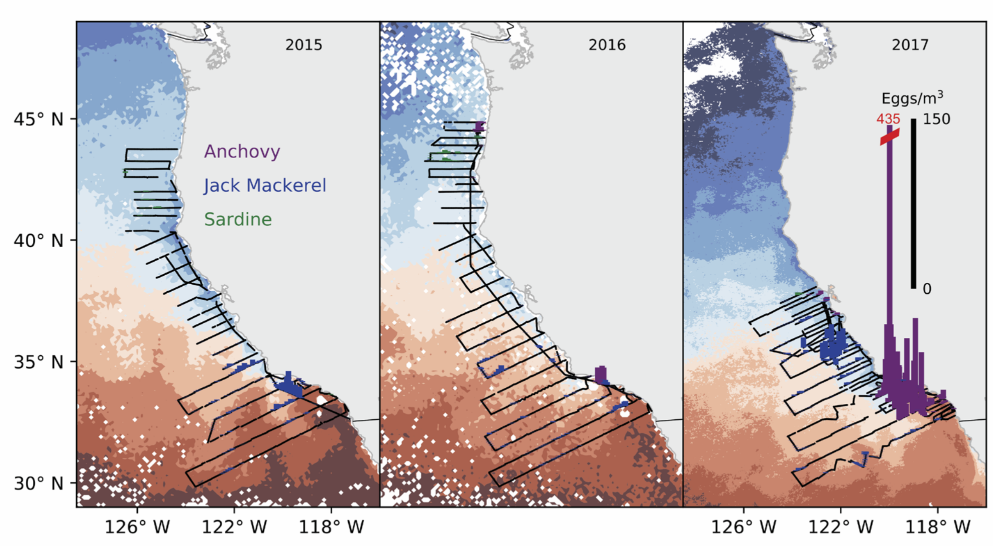

Figure 31. Density of eggs of northern anchovy, jack mackerel, and sardine collected with the continuous underway fish egg sampler (CUFES) during the spring 2015–17 CalCOFI and coastal pelagic fish cruises overlaid on satellite sea surface temperatures (˚C; scale bar is shown in Figure 30).

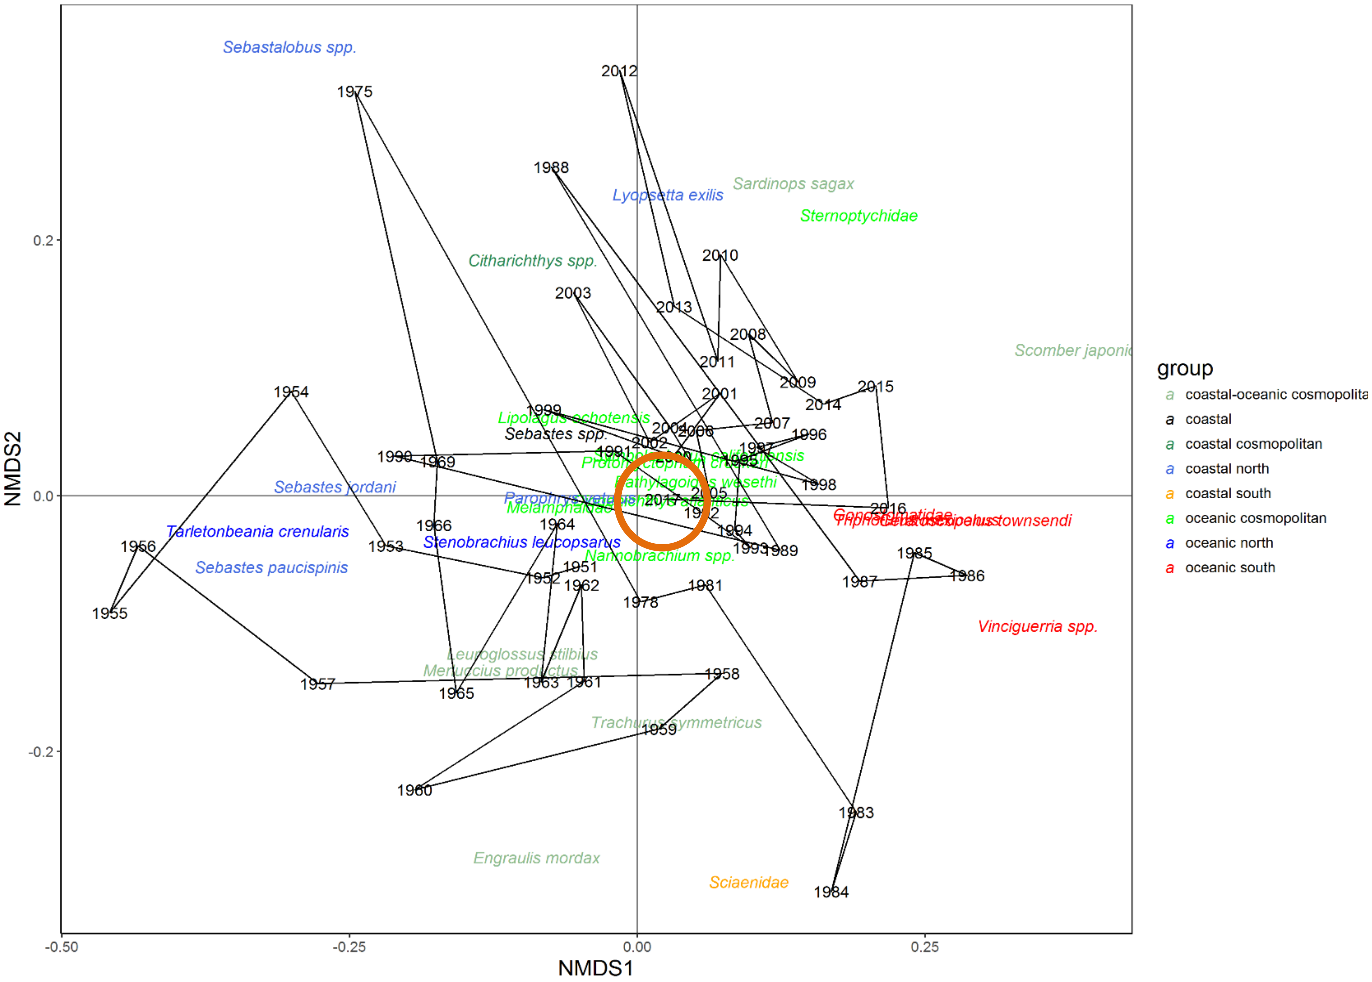

Figure 32. NMDS analysis depicting the composition of forage assemblage from lines 80 and 90 during the spring among years. The color of the species names characterizes their habitat affiliation and biogeographic range. Species in red or orange font are southern California Current, blue font are northern California Current, and green font are cosmopolitan. Open orange circle denotes the location of 2017.

but was still high relative to most years, while Gonostomatidae declined in 2017 to approximately average abundances (fig. 33). The northern cool-water myctophid *Stenobrachius leucopsarus* increased a bit relative to 2015–16 to near average levels (fig. 33), while another northern myctophid, *Tarletonbeania crenularis*, remained low (fig. 33).

For coastal pelagic species that are fished to varying degrees, northern anchovy abundance in spring was very similar to 2016 (fig. 34). Northern anchovy abundance from spring samples has been low since the early 1990s (with the exception of 2005), and 2017 had the third highest abundance of this species since 1994 (fig. 34). Abundance of northern anchovy in 2017, however, was still low relative to peaks between the 1950s and 1994. Pacific sardine, jack mackerel, and Pacific chub mackerel abundances were low in 2017 (fig. 34).

Shannon-Weaver diversity was almost exactly at a median level in spring of 2017 (fig. 35). This index tends to be low when coastal pelagic species are very abundant (e.g., correlation r = –.70 between Shannon-Weaver and northern anchovy) and high when southern mesopelagics are relatively abundant (e.g., r = .35 between Shannon-Weaver and *T. mexicanus*). The median diversity reflects results of the multivariate analysis on individual taxa suggesting that 2017 was characterized by having unexceptional abundances of both the southern mesopelagic taxa and northern anchovy. Overall species richness based on an estimated asymptote from bootstrap species accumulation curves was at the upper 75th quantile in 2017 and increased by approximately 8 species in comparison with 2016. Species richness also correlates positively with abundances of southern offshore species (e.g., r = .53 between Gonostomatidae and richness). Although the southern offshore species were down from 2015–16, some taxa (e.g., *T. mexicanus*, Gonostomatidae) were still relatively abundant (fig. 34). In addition, while a few commonly found taxa such as *Citharichthys* spp., shortbelly rockfish, and *Sebastes*

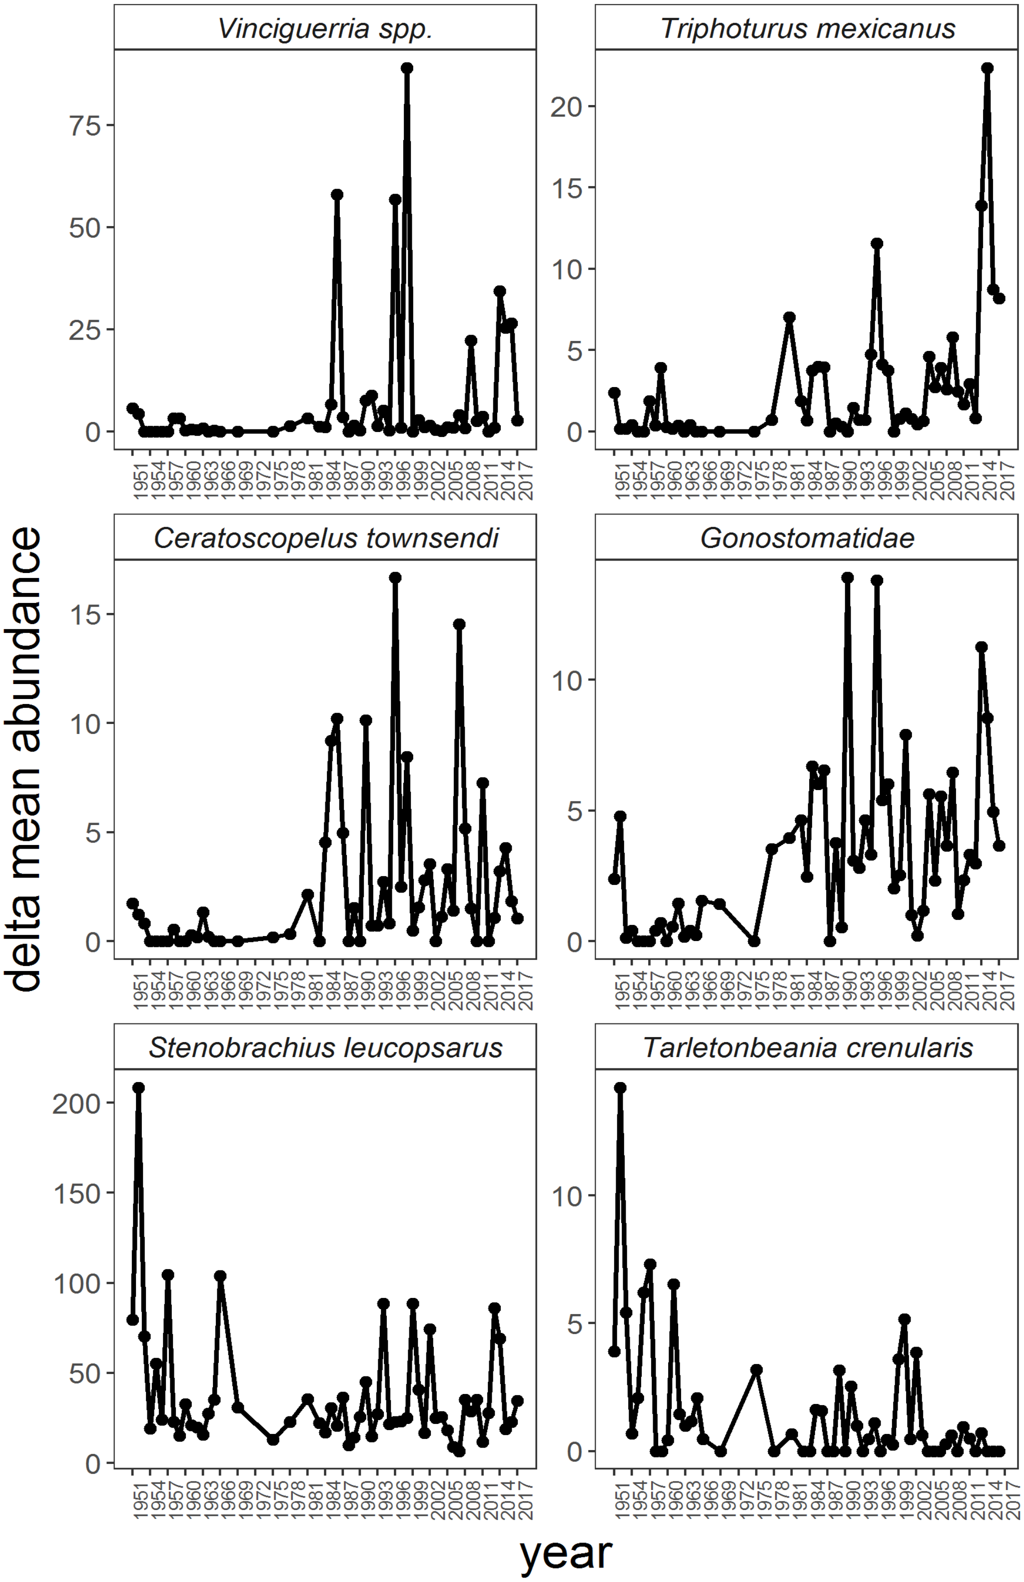

Figure 33. Delta-mean abundances of common mesopelagic taxa in spring between 1951 and 2017. Delta-mean calculations are used to estimate mean values from data with high numbers of samples that contain zero values (Pennington 1996). The four taxa in the top panels (*Vinciguerria* spp., *Triphoturus mexicanus*, *Ceratoscopelus townsendi*, and Gonostomatidae) have southern distributions relative to southern California and the two in the bottom panels (*Stenobrachius leucopsarus* and *Tarletonbeania crenularis*) are more broadly distributed to the north.

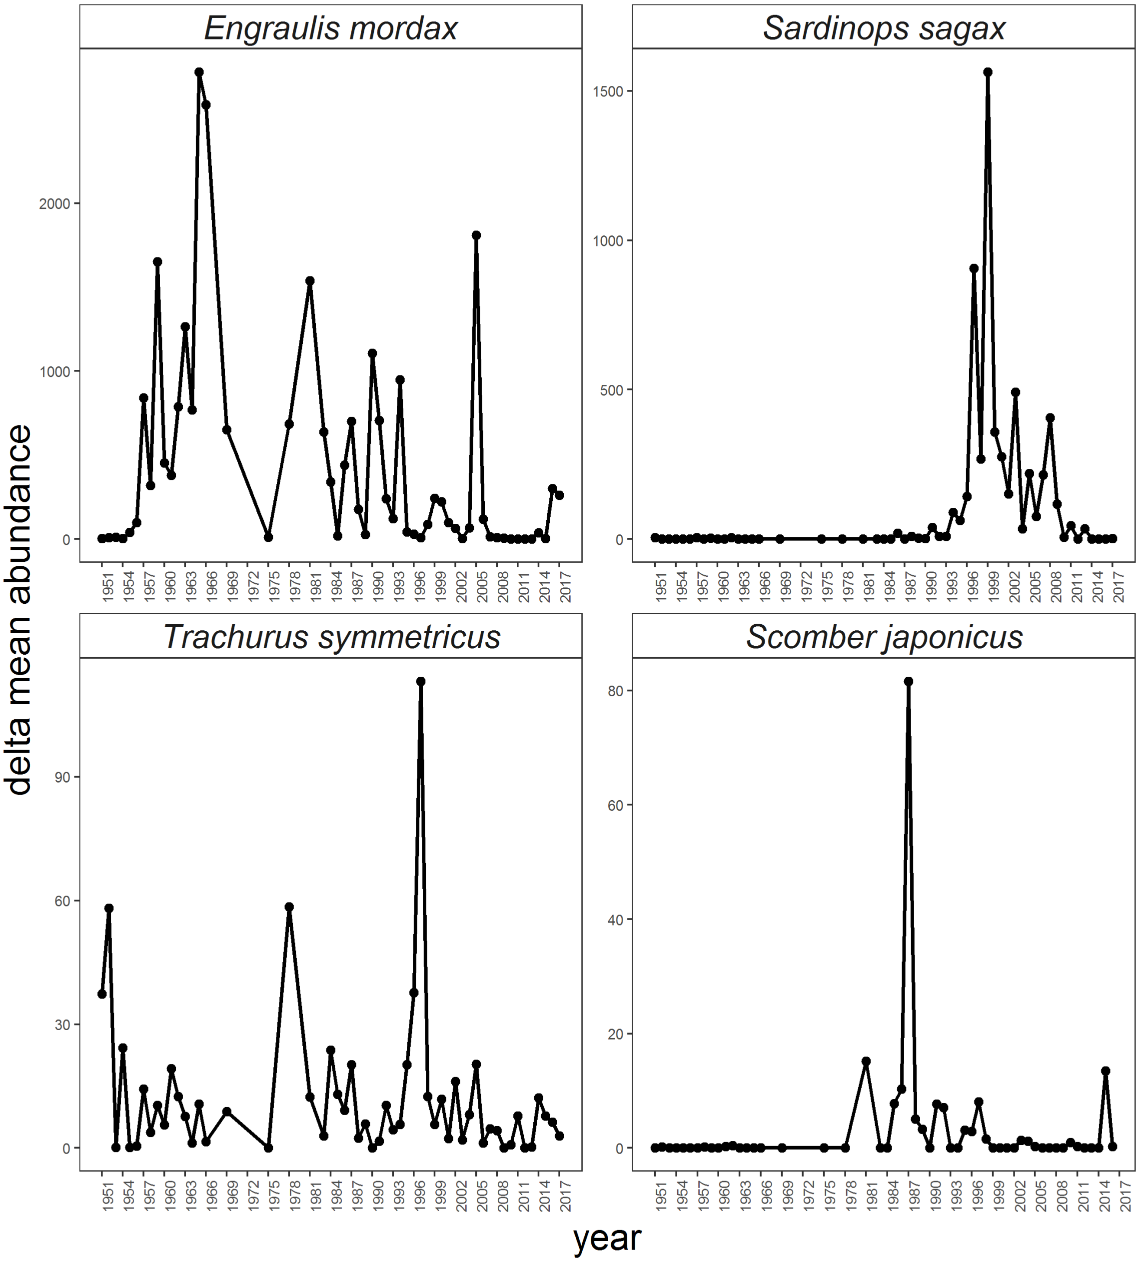

Figure 34. Delta-mean abundances of the most common coastal pelagic species that are to some extent commercially fished. Delta-mean calculations are used to estimate mean values from data with high numbers of samples that contain zero values.

paucispinis were completely absent in 2016, these taxa were again present in 2017.

REGIONAL PATTERNS IN BIRDS AND MARINE MAMMALS

Northern California Current: Yaquina Head, Oregon

Common murres (*Uria aalge*) at Yaquina Head experienced reproductive failure in 2016, as they had in 2015. Most (97%) murre eggs laid (n = 183) were not incubated long enough to hatch chicks. This was the second consecutive year of almost complete reproductive failure, and the only times this occurred during the 15 years of data collection. Murres at Yaquina Head exhibited a 6-year run (2011–16) of low reproductive success that is approximately a quarter the success of the first 9 years of our study (1998–2002, 2007–10, fig. 36). Murre reproductive success during the 2014–16 are the lowest on record. As in previous years, the reproductive failure is a combination of top-down predation and bottom-up food limitation. While the top-

down signal is most prominent, the bottom-up signal is evident. For example, the only location where a few murre chicks fledged in 2015 and 2016 was a small rock near sea level, not used for rearing chicks in previous years, and generally out of the way of predators. Even at this mostly predator-free site where a new study plot was added in 2016, the murre reproductive success was only 0.21 fledglings/pair, which is among the lowest recorded for the whole colony in our time series and similar to reproductive success during the 1998 El Niño (Gladics et al. 2015).

Since 2011 much of the reproductive loss for murres has been due to egg and chick predators (Horton 2014), however, 2016 had the highest rate of murre egg and adult loss, with 4.21 eggs destroyed and 0.28 adult murre fatalities per hour of observation (n = 243 hours). As in 2015, the disturbance by primarily bald eagles (95%; *Haliaeetus leucocephalus*) in 2016 was so intense early in the breeding season that most eggs were not incubated long enough to hatch chicks. Persistent eagle disturbance early season is also in part responsible for the later chick hatching dates of murres.

Brandt's (*Phalacrocorax penicillatus*) and pelagic (*P. pelagicus*) cormorant were both successful at rearing young. Brandt's cormorants reproductive success (0.87 fledglings/nest) was lower than 2015 (1.70 fledglings/nest), but greater than 2014 (0.72 fledglings/nest) and overall slightly above the long-term mean (fig. 37). Median hatch date (June 27th) was among the earliest recorded in our time series (fig. 37). Average brood size (1.65 chicks) was close to the long-term average (fig. 37).

Pelagic cormorants had their second highest reproductive success (1.37 fledglings/nest), only surpassed by 2013 (2.13 fledglings/nest; fig. 36). There were 30 nests visible from observation platforms, also second only to 2013 (34 nests) and more than double 2015 (11 nests). Pelagic cormorant reproductive success has been highly variable during our time series. Median hatch date (July 13th) was close to the long-term average (fig. 37).

The three main forage fish species fed to murre chicks in the Yaquina Head region have been smelt (Osmeridae), Pacific herring or sardine (Clupeidae), and Pacific sand lance (*Ammodytes hexapterus*). The relative proportion of the three species can be similar or one species may be numerically dominant in a given year. The failure of most of the colony prior to chick rearing provided an added challenge for diet data collection in 2015 and 2016. We were able to collect diet data, however, very few of these samples were likely fed to chicks, but instead simply adults flying into the colony with fish. Diets in 2016 were again dominated by smelt (82%), continuing a trend of smelt-dominated diets for six of the past seven years (since 2010; fig. 38). Murre diets in 2016 had the highest proportion of smelt (82%) recorded in a single year, with sand lance a distant second (16%). Pacific sand lance continues to be minimal in diets since 2010. The dominance of smelt, and lack of herring and sand lance is even notably different than diets during the 1998 El Niño (fig. 38). Sand lance are generally more prom-

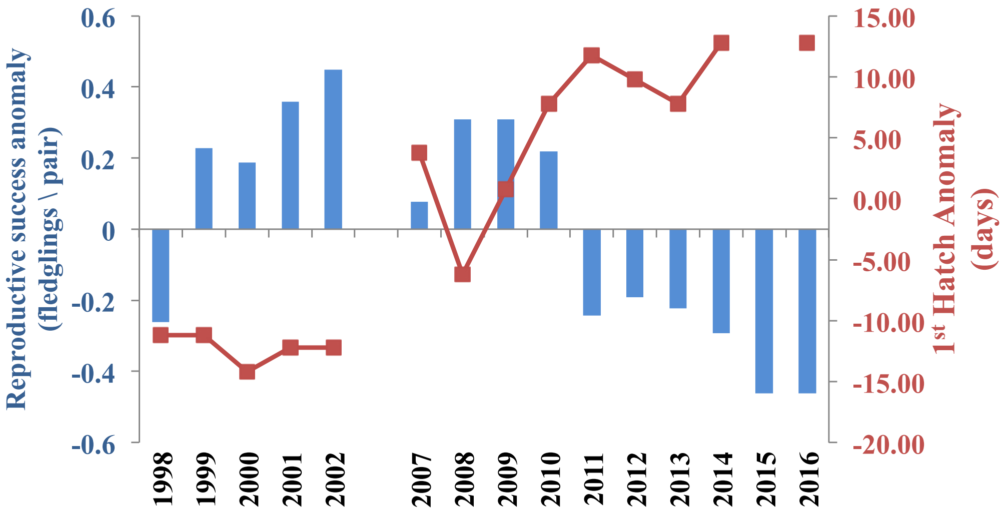

Figure 36. Anomalies of first chick hatch date and reproductive success for common murres nesting at Yaquina Head, Oregon, 1998–2016. 2016 was the second year that the colony failed to produce chicks from all but one small area where <10 chicks fledged each year.

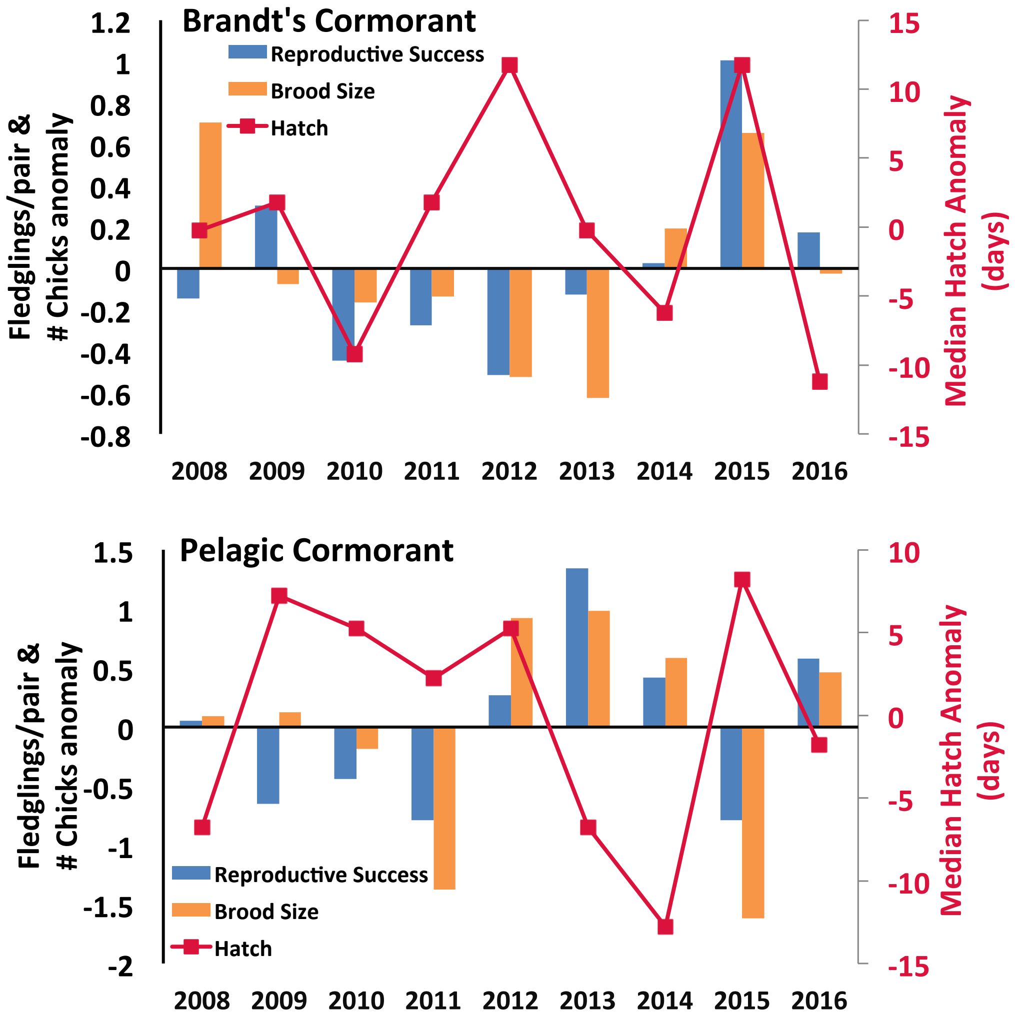

Figure 37. Anomalies of reproductive success and brood size for cormorants nesting at Yaquina Head, Oregon, 2008–16. Cormorants had average to above average reproductive success and brood size. Red lines indicate hatch date anomalies for cormorants.

inent in murre diets during cold water years (Gladics et al. 2014, 2015), as highlighted by their prevalence in 2008 (fig. 38). Clupeids (primarily Pacific herring, *Clupea pallasii*), are generally associated with warmer water and positive PDO (Gladics et al. 2015), although their occurrence in recent warm water years has been lower than expected.

Northern California Current: Cape Flattery, Washington to Newport, Oregon

Notably, mean bird densities at sea for the 2017 strip transect surveys between Cape Flattery and Newport were the lowest observed during the 13-year data set and may indicate continued poor reproductive performance of resident breeders in 2017 (i.e., common murre)[18]. There was an apparent downward trend in common murre abundance at sea since 2015, with the third lowest mean density value on the record (9.27 birds per km^2) occurring in 2017 (fig. 39). This species was also aggregated near the Columbia River mouth, with 70.5% of all individuals observed on the three transects closest to the Columbia River (Willapa Bay, WA and Columbia River/Cape Mears, OR). Common murres are usually the most numerous breeding species found in the California Current during the upwelling season. Murres may have been affected by low forage fish availability beyond the Columbia River plume. The region near the Columbia River mouth where common murres were observed was also the area where northern anchovy were collected in surveys, including the same survey as the bird observations, and where above-average egg densities were observed with continuous underway fish egg sampler (fig. 21).

Sooty shearwater (*Ardenna grisea*) abundance in 2017, although very similar to that in 2011, was the lowest value yet observed in all 2003–17 June surveys (8.96 birds per km2) (fig. 39). Sooty shearwaters were highly aggregated in their distribution, with almost all (85.8%) individuals observed during the survey found on two transect lines immediately north of the Columbia River mouth (Grays Harbor and Willapa Bay, WA) where adult northern anchovy were observed during the same period. Given that sooty shearwaters are the most numerous non-breeding piscivorous species found in the California Current during upwelling season (May–September), their absence may reflect a lack of available prey in the offshore oceanic and Oregon waters found on the shelf in 2017, an hypothesis supported by the unusual micronekton assemblage observed in the same survey (fig. 23).

---

[18] Seabird observations from an annual June survey encompassing 8 cross-shelf transects (extending ~30–50 km offshore) between Cape Flattery, WA and Newport, OR provide information on density patterns for the northern domain of the California Current.

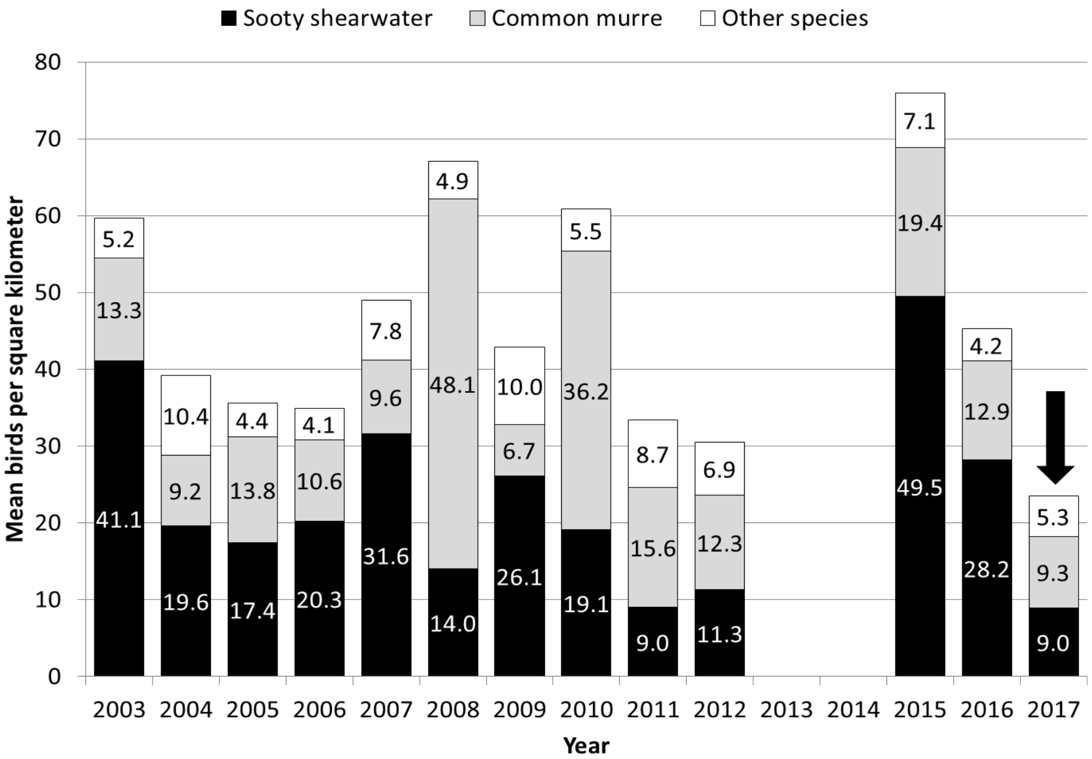

Figure 39. Seabird observations from an annual June survey encompassing 8 cross-shelf transects (extending ~30–50 km offshore) between Cape Flattery, WA and Newport, OR provide information on density patterns for the northern domain of the California Current.

Northern California Current: Castle Rock National Wildlife Refuge[19]

Common Murre are the most abundant surface-nesting seabird at Castle Rock and their reproductive success, nesting phenology, and chick diet have been studied since 2007. The percent of nesting pairs that successfully fledged young in 2016 was based on 93 breeding pairs monitored every other day for the duration of nesting. During 2016, murres only produced 0.16 fledglings per pair, which was 78% lower than the long-term average for this colony and the poorest year observed during the 10-year time-series (fig. 40). Although many murres hatched eggs (63%), chick starvation was frequent and 74% of chicks died prior to fledging. While the bottom-up food limitation was the primary cause of mortality, this food limitation caused murres to frequently leave chicks alone at the colony in search of prey, and these unprotected chicks were sometimes predated opportunistically by western gulls (*Larus occidentallis*) also nesting at the island. Reproductive failure of common murres at Castle Rock is consequential for the overall population of murres nesting in the California Current as this island is one of the most populous colonies south of Alaska (Carter et al. 2001).

In 2016, the average nest initiation date was 19 May, which was 10 days later than the long-term average at this colony (fig. 40) likely due to the later onset of upwelling-favorable winds (fig. 4) and weaker NPH and preconditioning (Schroeder et al. 2009, fig. 6). Although the timing of nesting by murres is not a direct response to the onset of upwelling, the increased availability of food associated with upwelling improves the body condition of egg-laying females and thereby influences the timing of nesting (Reed et al. 2006; Schroeder et al. 2009).

In 2016, the diversity of prey fed to chicks was lower than usual, (11 of 21 prey types observed), and no new prey types were observed[20]. Proportion of northern anchovy was 23x greater than the long-term average in 2016. Despite this increased prevalence of anchovy, smelt remained the predominant prey fed to chicks (fig. 40). Notably, the total number of prey observed at the colony was much less than usual because most chicks starved

---

[19] In recent times, Castle Rock National Wildlife Refuge (hereafter Castle Rock) has frequently been the most populous single-island seabird breeding colony in California (Carter et al. 2001). This island is located off the coast of Crescent City, just south of Point St. George, in the northern California Current System. To facilitate long-term monitoring of seabirds nesting at this colony, a remotely-controlled video monitoring system was installed at this island in 2006. For purposes of assessing the state of the California Current, the reproductive performance of common murre and Brandt's cormorants is provided. For common murre, nesting phenology and chick diet between 2007 and 2016 is also provided.

[20] To determine prey composition fed to common murre chicks, 2-hour diet surveys were conducted 6 days per week during the murre chick-rearing period (approximately 23 hours surveyed in 2016).

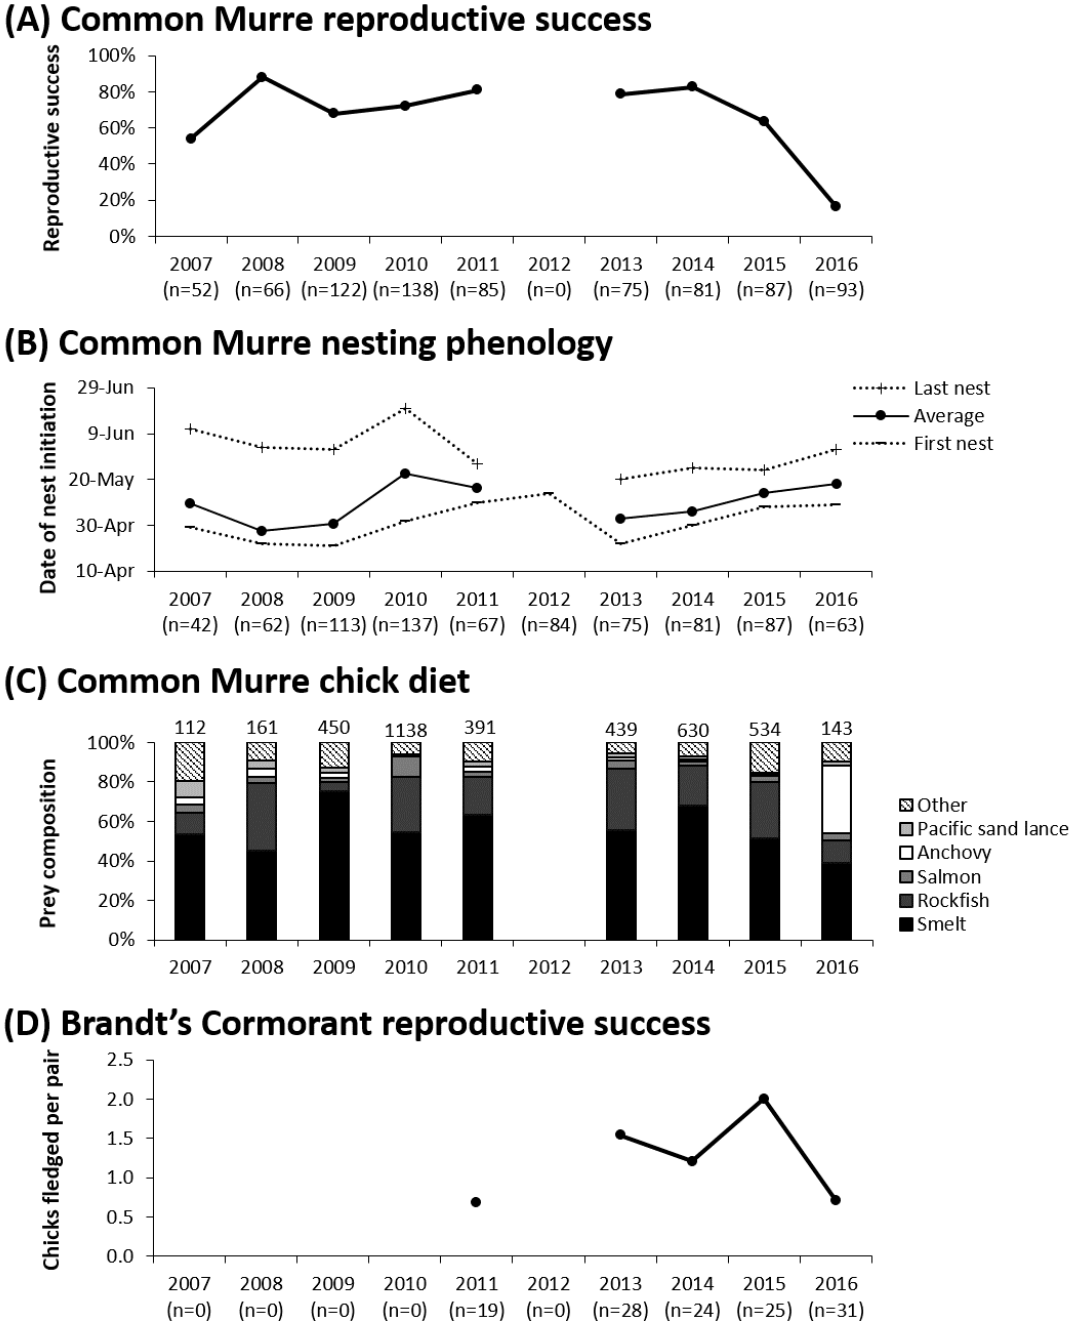

Figure 40. Reproductive data for seabirds nesting at Castle Rock National Wildlife Refuge (hereafter Castle Rock), Del Norte County, CA between 2007 and 2016; (A) Percent of common murre nesting pairs that successfully fledged young. The sample size (n) represents the total number of nesting pairs observed per year, and this figure does not include the success of replacement clutches. (B) First, average, and last dates for nests initiated by common murres. The date of nest initiation was the defined as the day that an egg was laid at a nest-site. The sample size (n) represents the total number of nests observed each year where nest initiation dates were accurate to ±3.5 days. (C) Composition of prey delivered to chicks by common murre. Numbers above each bar indicate the total number of prey identified each year. (D) Chicks fledged per nesting pair of Brandt's cormorant. The sample size (n) represents the total number of nesting pairs observed per year, and this figure does not include the success of replacement clutches. For each section, data from 2012 is lacking due to premature failure of the video monitoring system.

before they reached fledging age. Interestingly, murre diet data from Castle Rock and Yaquina Head continued to show northerly shifts in the forage fish community during 2016. Specifically, murres at Castle Rock had a dramatic increase in northern anchovy (more typical of central California colonies to the south) and Yaquina Head remain dominated by smelt (more typical of Castle Rock to the south).

Brandt's cormorant are the second-most abundant surface-nesting seabird at Castle Rock and their reproductive success has been studied since 2011. Based on 31 nests observed every three days throughout the 2016

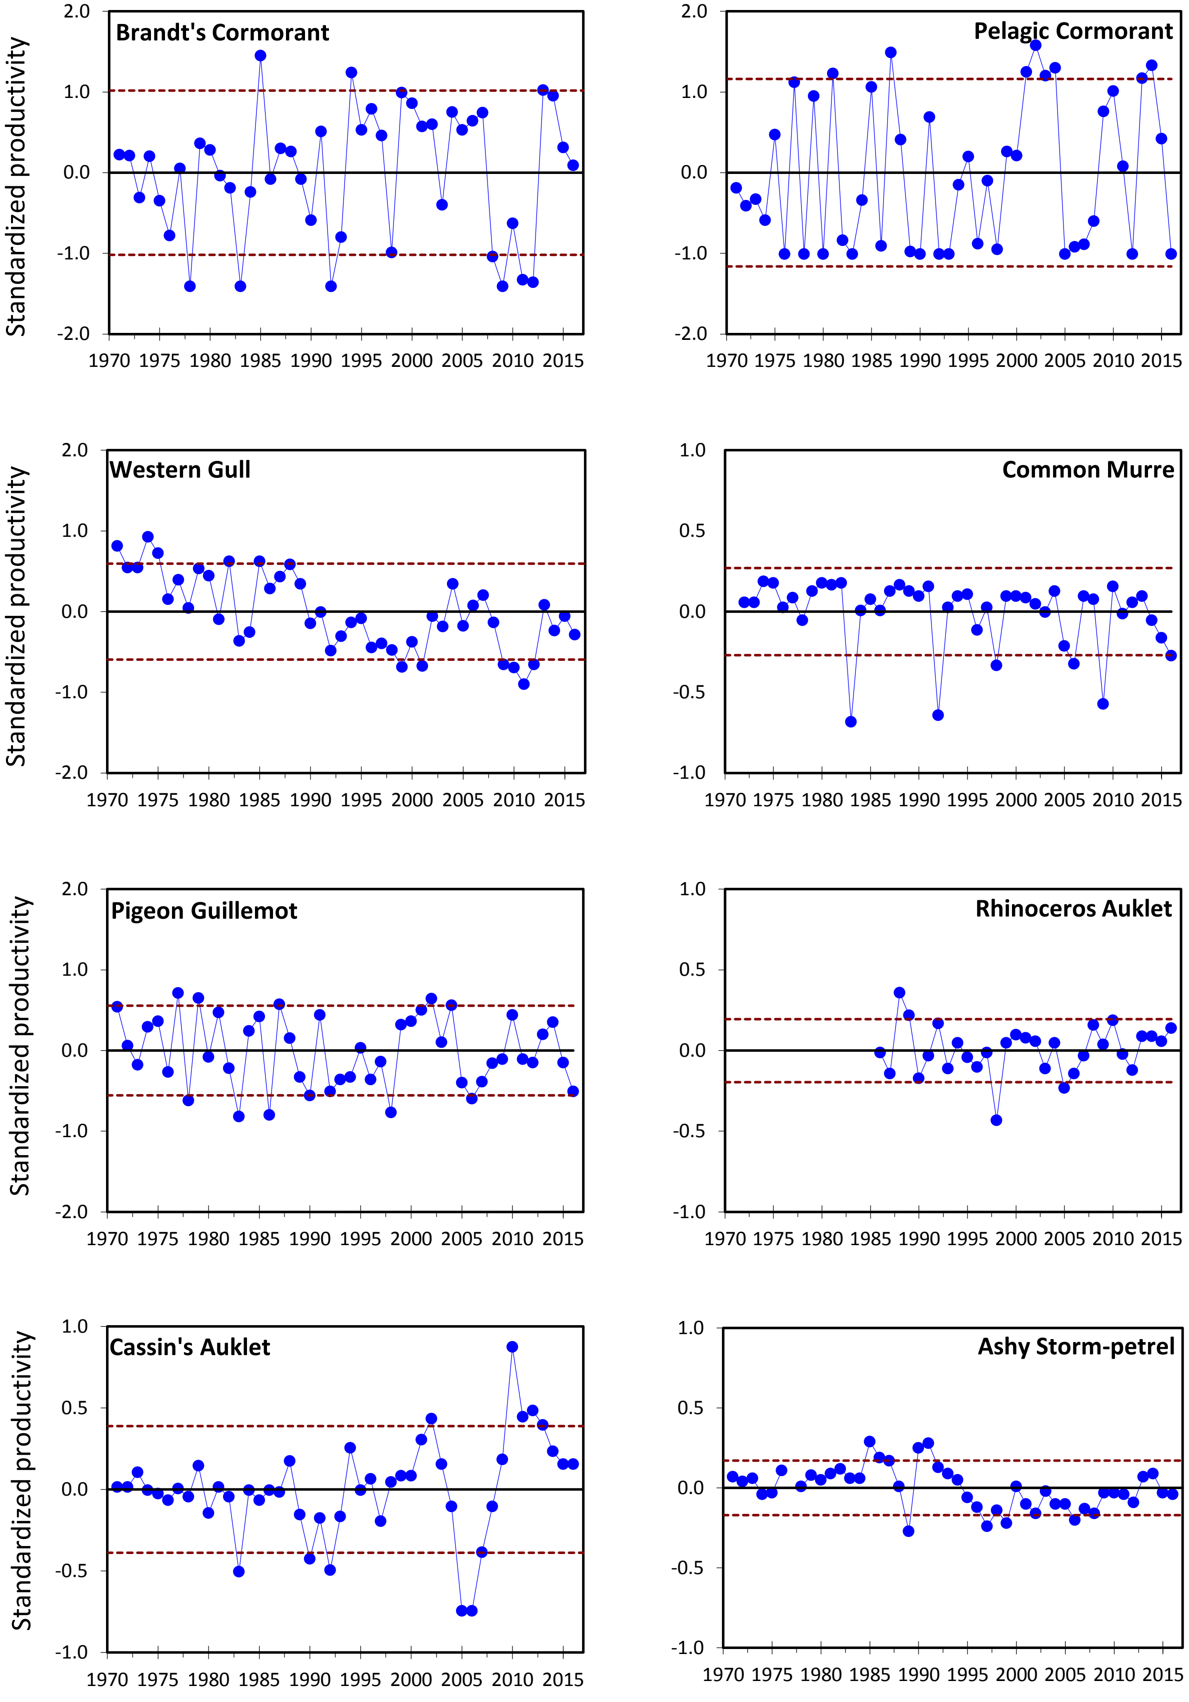

Figure 41. Standardized productivity anomalies (annual productivity minus 1971–2017 mean productivity) for 8 species of seabirds on Southeast Farallon Island.

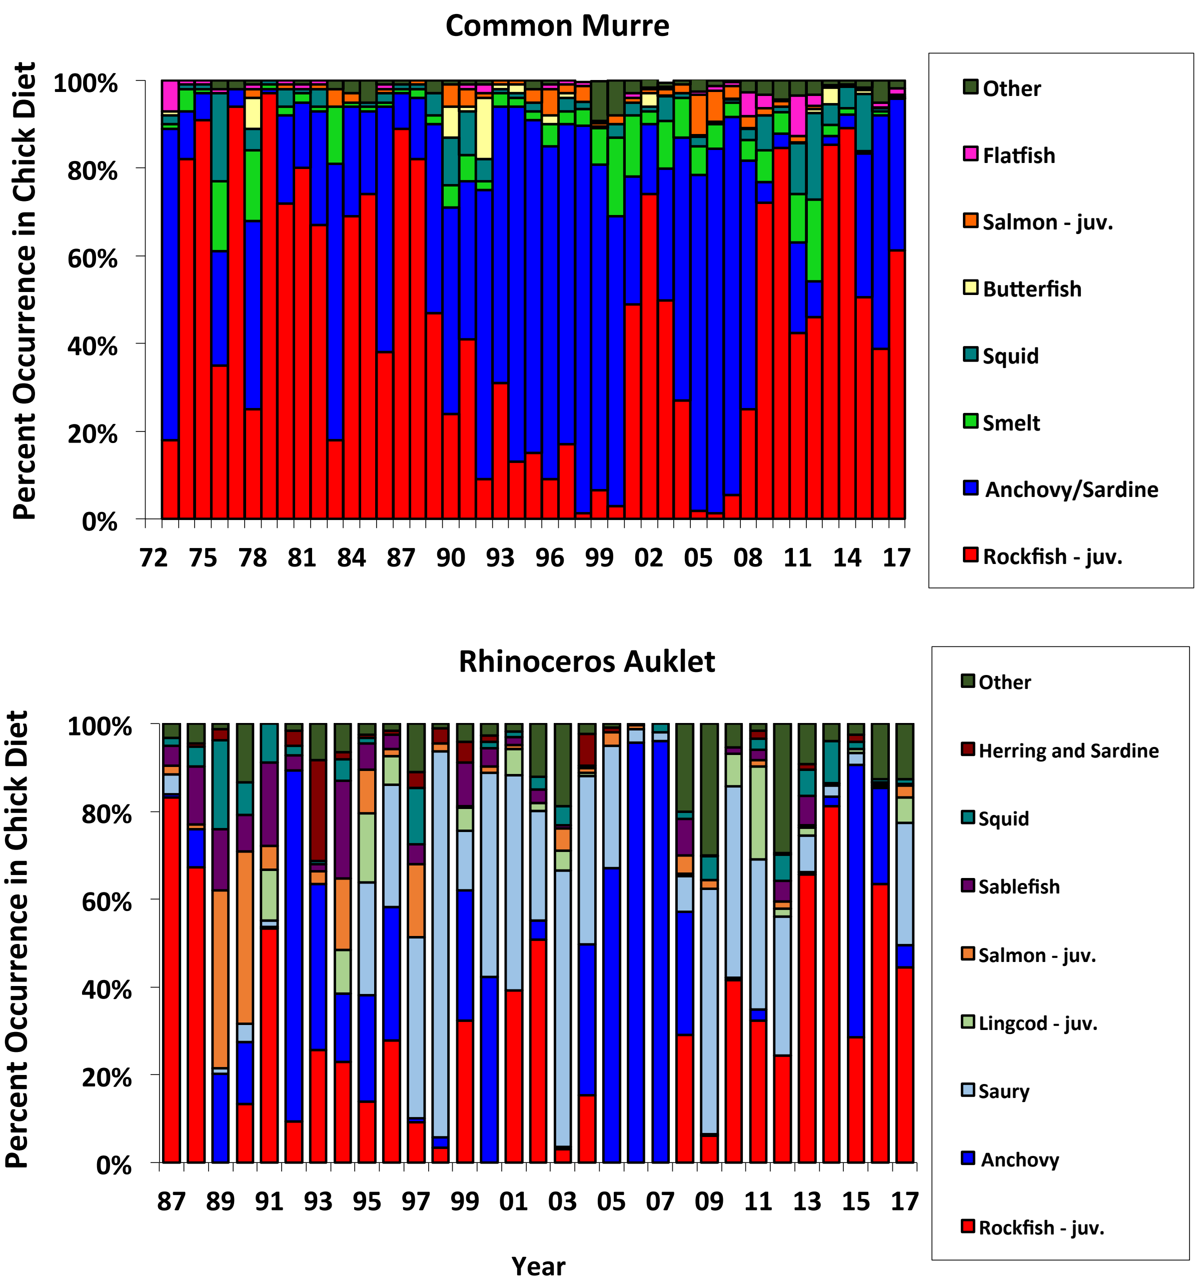

Figure 42. Diets of common murre and rhinoceros auklets returning to feed chicks 1987–2017. Note bar color differences between panels.

season, breeding pairs produced 0.71 chicks on average which was 1.9x lower than the long-term average at this colony and the second lowest observation since monitoring began (fig. 40). This reduction in success between 2015 and 2016 mirrored observations at Yaquina Head.

Central California: Southeast Farallon Island

Warm water conditions, such as those observed during the recent El Niño, typically lead to very low breeding success and even breeding failure for seabirds (fig. 41). This generally proved to be true in 2016 with reduced breeding populations and reproductive success for most species. However, the availability of common forage taxa such as rockfishes and krill muted the response relative to previous El Niño events such as 1998 during which these forage taxa were well below average (fig. 27). Overall breeding success of seabirds during the 2016 breeding season at Southeast Farallon Island can best be classified as a below average year for most species. Reproductive success was lower for most species when compared to 2015, including complete breeding failure for pelagic cormorants and the lowest success for pigeon guillemots (*Cepphus columba*) in 10 years. Common murres, Brandt's cormorant, and west-

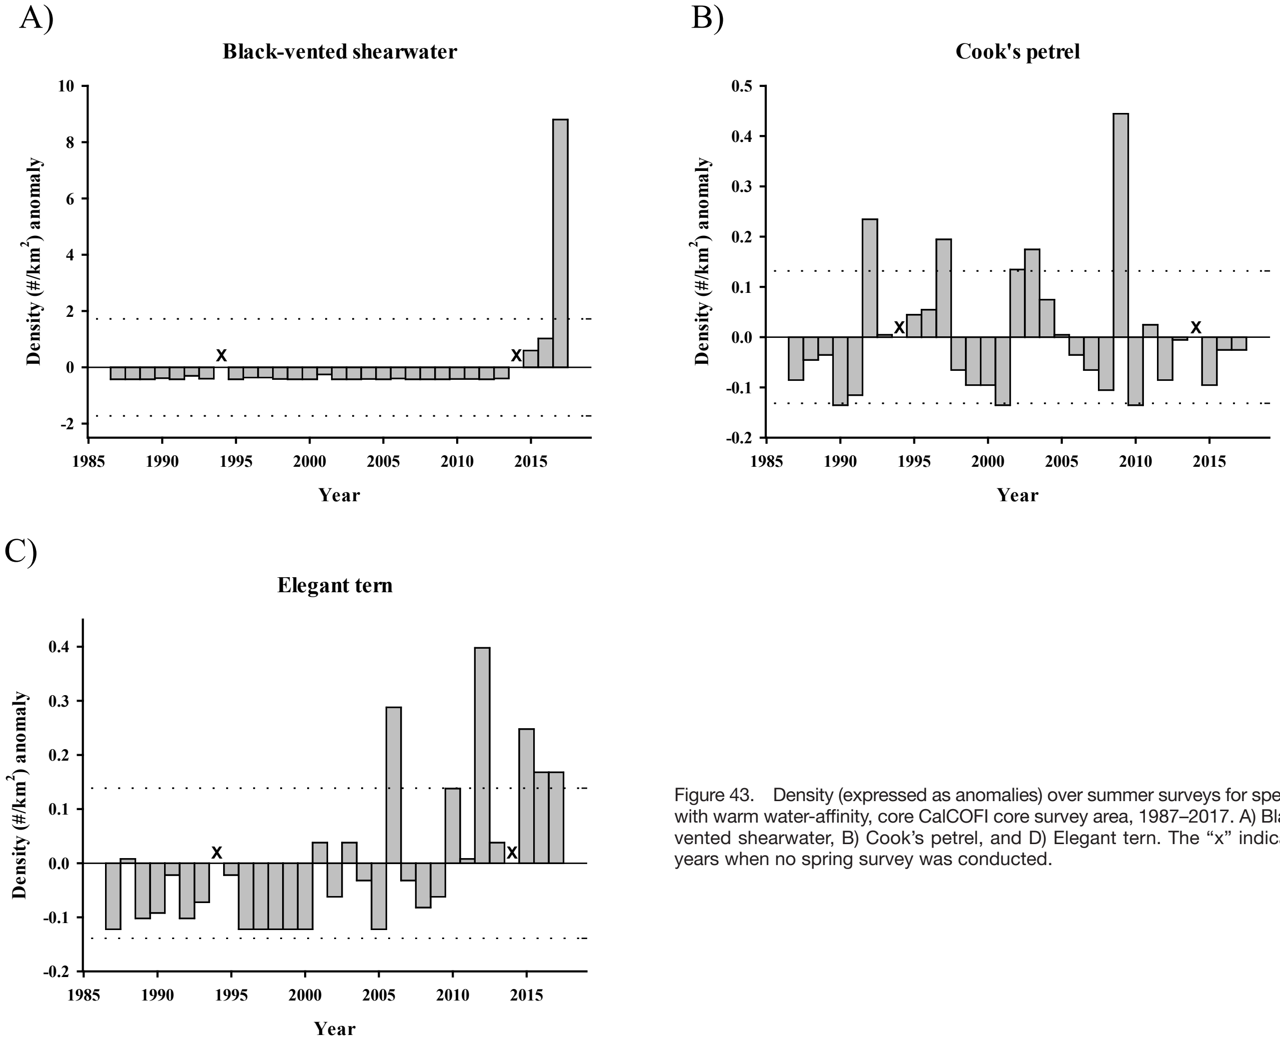

Figure 43. Density (expressed as anomalies) over summer surveys for species with warm water-affinity, core CalCOFI core survey area, 1987–2017. A) Black-vented shearwater, B) Cook's petrel, and D) Elegant tern. The "x" indicates years when no spring survey was conducted.

ern gull likewise suffered lower than average breeding success. Cassin's auklets (*Ptychoramphus aleuticus*) and rhinoceros auklets (*Cerorhinca monocerata*) were the only species to have higher than average breeding success. Cassin's auklets attempted few second broods but did manage to successfully fledge chicks from two of them, typically a sign of productive ocean conditions. Though the second broods did not significantly contribute to overall productivity this season, a high success rate for first broods resulted in an overall productive season.

Effects on breeding populations were mixed. Brandt's cormorants, Cassin's auklets, pigeon guillemots and western gulls all decreased whereas pelagic cormorants, double-crested cormorants (*Phalacrocorax auritus*) and tufted puffins (*Fratercula cirrhata*) increased. The western gull breeding population estimate was the lowest observed during our 46 years of monitoring while pigeon guillemots, Brandt's cormorants and Cassin's auklets were the lowest they have been in the last five years.

Following the strong upwelling periods in late March and April 2016 (fig. 4), zooplankton abundance (primarily krill) was average (fig. 27). Although diet analysis has not been completed, preliminary visual inspection of Cassin's diet samples indicated that krill remained the dominant item in auklet prey. This likely allowed for the higher than expected breeding in 2016 for Cassin's auklets. Similarly, the diets of common murre and rhinoceros auklet can be indicative of the current-year preyscape and resultant foraging behavior (Wells et al. 2017) and, ultimately, the reproductive success (Wells et al. 2008). Juvenile rockfish, a preferred prey, remained a significant portion of the diet fed to chicks in 2016 and 2017 (fig. 42) suggesting that significant reproductive failure is unlikely in 2017.

In general, although the 2015–16 El Niño may not have had as great an impact as previous events, the number of birds attempting to breed and their breeding success were both reduced during 2016. Chicks generally took longer to grow and fledged at lower weights

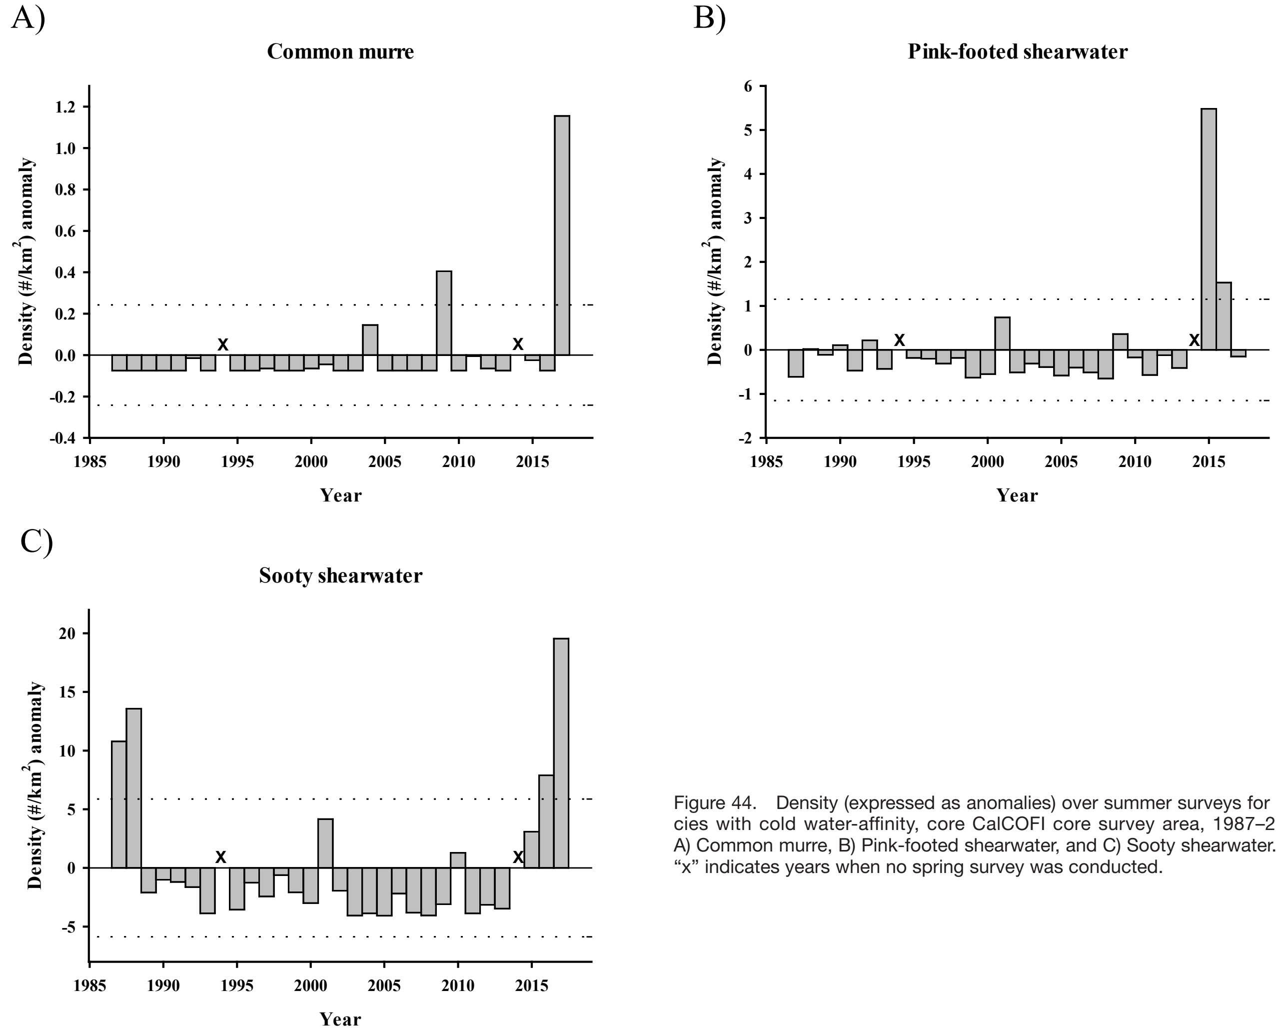

Figure 44. Density (expressed as anomalies) over summer surveys for species with cold water-affinity, core CalCOFI core survey area, 1987–2017. A) Common murre, B) Pink-footed shearwater, and C) Sooty shearwater. The "x" indicates years when no spring survey was conducted.

than in the past few seasons. Warm water continued to bring unusual species into the region. These included record numbers of brown boobies (*Sula leucogaster*), a few persistent blue-footed boobies (*Sula nebouxii*) and the first island record for least storm-petrel (*Oceanodroma microsoma*), all species that are normally found in more tropical regions.

Southern California Current: CalCOFI

Seabird distribution and abundance was surveyed during the 2017 summer CalCOFI cruise and seabird densities are presented here for the core survey area (defined here as the six CalCOFI lines, 77–93), 1987–2017. Anomalies of seabird species density in summer are indicative of species with affinities for warm and cold-water conditions (Hyrenbach and Veit 2003; Sydeman et al. 2009; Santora and Sydeman 2015). For summer, species with warm water-affinity include black-vented shearwater (*Puffinus opisthomelas*), Cook's petrel (*Pterodroma cookii*), and elegant tern (*Sterna elegans*) (fig. 43[21]). Cold water-affinity species include common murre, pink-footed shearwater (*Ardenna creatopus*), and sooty shearwater (fig. 44). Notable results from the 2017 summer survey indicate higher than average density of the warm-water species black-vented shearwater (highest density since 1992) and elegant tern. Interestingly, two of the three cool water-affinity species' (sooty shearwater and common murre) densities are well above any observed summer values since 1987. This is in stark contrast to results from northern California Current surveys that observed record low densities and may reflect superior foraging conditions within the core survey region during the 2017 spring CalCOFI cruise.

Sea Lions: San Miguel Island

California sea lions (*Zalophus californianus*) are permanent residents of the CCS, breeding in the California Channel Islands and feeding throughout the CCS

---

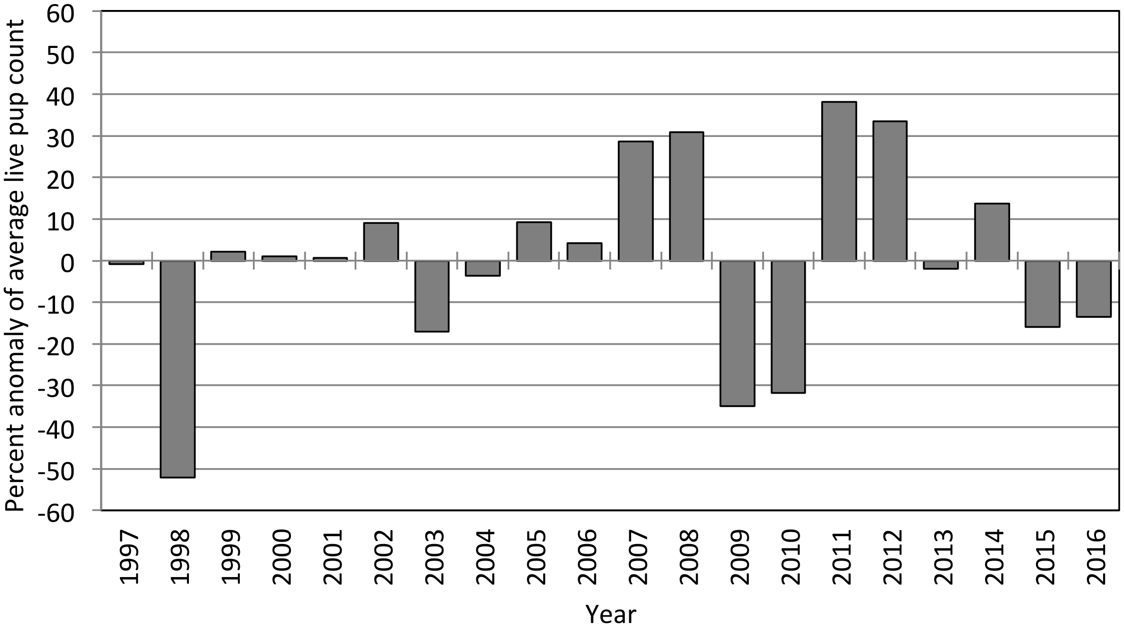

Figure 45. The percent anomaly of live California sea lion pup counts at San Miguel Island, California, based on a long-term average of live pup counts between 1997–2016 in late July when surviving pups were about 6 weeks old.

in coastal and offshore habitats[22]. They are also sensitive to changes in the CCS on different temporal and spatial scales and so provide a good indicator species for the status of the CCS at the upper trophic level (Melin et al. 2012). Two indices are particularly sensitive measures of prey availability to California sea lions: pup production and pup growth during the period of maternal nutritional dependence[23]. Pup production is a result of successful pregnancies and is an indicator of prey availability to and nutritional status of nursing females from October to the following June. Pup growth from birth to 7 months of age is an index of the transfer of energy from the mother to the pup through lactation between June and the following February which is related to prey availability to nursing females during that time[24].

In 2016, California sea lion pup births at San Miguel Island were 14% below the long-term average between 1997 and 2016 but showed a slight improvement from 2015 (16% below) (fig. 45)[25]. Pup condition and pup growth for the 2016 cohort increased from the record lows for the 2015 cohort. The average weights of three-month-old pups were 1.7 kg and 2.0 kg higher than the long-term average for female and male pups, respectively (fig. 46), representing a 10% increase in pup condition in 2016 compared to 2015. After two years of extremely low growth rates in 2014 and 2015, pup growth rates from three to seven months of age for female and male pups were similar to the 20-year average in 2016, marking a significant improvement in growth rates (fig. 47).

Since 2009, the California sea lion population has experienced low pup survival, low pup births, or both (Melin et al. 2012; McClatchie et al. 2016; DeLong et al. 2017). In March 2013, an unusual mortality event was declared for California sea lions in southern California in response to unusually high numbers of young pups from the 2012, 2014, and 2015 cohorts stranding along the coast and at San Miguel Island and other rookeries (Wells et al. 2013; Leising et al. 2014; Leising et al. 2015; McClatchie et al. 2016)[26]. The unusual mortality event was associated with poor foraging conditions for

---

[22] San Miguel Island, California (34.03°N, 120.4°W) is one of the largest colonies of California sea lions, representing about 45% of the US breeding population. As such, it is a useful colony to measure trends and population responses to changes in the marine environment.

[23] We used the number of pups alive at the time of the live pup census conducted in late July and the average weights of pups at 4 months and 7 months of age between 1997 and 2016 as indices of the population response to annual conditions in the CCS. The number of live pups in late July represents the number of pups that survived from birth to about 6 weeks of age. Live pups were counted after all pups were born (between 20–30 July) each year. A mean of the number of live pups was calculated from the total number of live pups counted by each observer. A long-term average live pup count based on counts between 1997 and 2016 was used to create annual anomaly percentages from the long-term average.

[24] Each year, between 200 and 500 pups were weighed when about 4 months old. Pups were sexed, weighed, tagged, branded, and released. Up to 60 pups were captured in February and weighed and measured at 7 months of age. Of the 60 pups captured in February, up to 30 pups were branded and provided a longitudinal dataset for estimating a daily growth rate between 4 months and 7 months old.

[25] We used a linear mixed-effects model fit by REML in R to predict average weights on 1 October and 1 February in each year because the weighing dates were not the same among years. The model contained random effects with a sex and days interaction (days = the number of days between weighing and 1 October and 1 February) which allowed the growth rate to vary by sex and year, and a full interaction fixed effects of sex and days. The average weights between 1997 and 2016 were compared to the long-term average for the average pup weights between 1975 and 2016.

[26]http://www.nmfs.noaa.gov/pr/health/mmume/californiasealions2013.htm

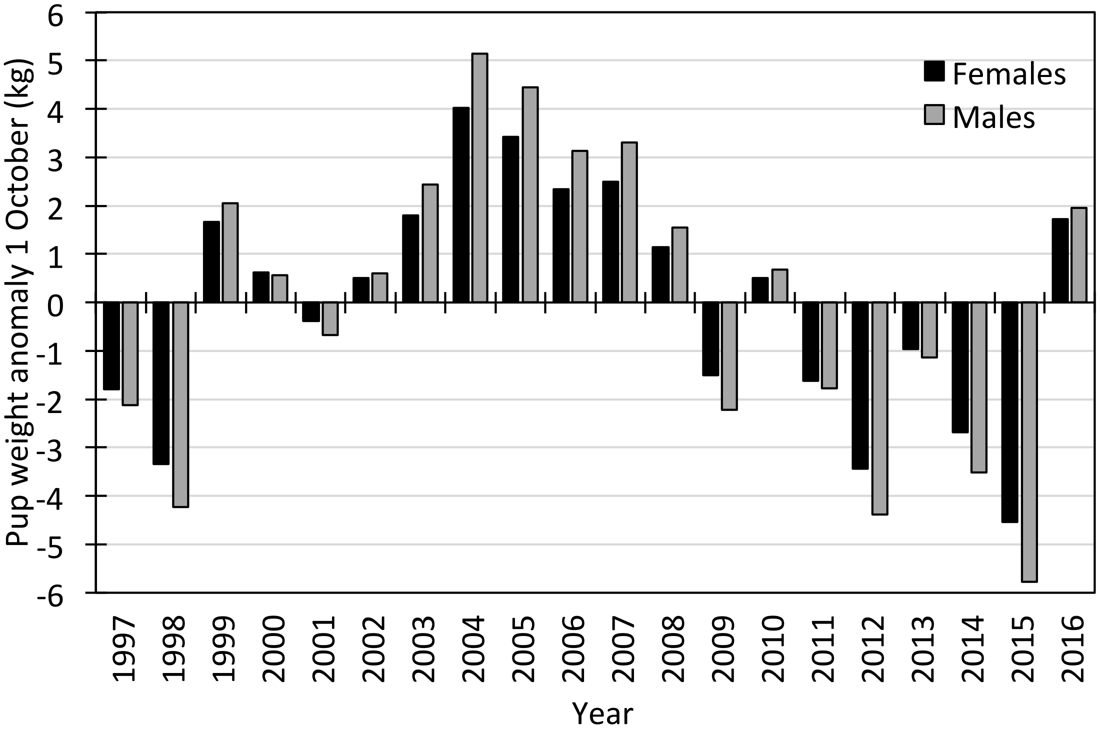

Figure 46. Average pup weight anomaly (kg) from predicted average weights of 3-month-old female and male California sea lion pups at San Miguel Island, California, from the long-term average between 1997 and 2016.

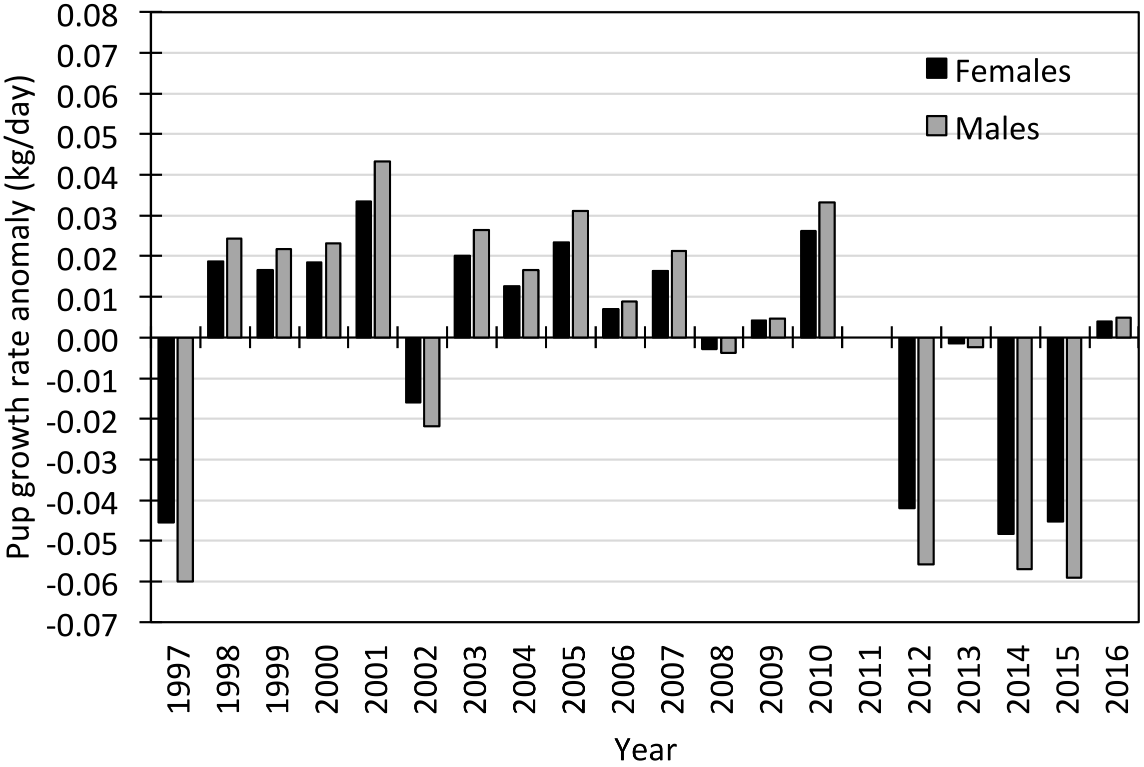

Figure 47. Average daily growth rate anomaly of female and male California sea lion pups between 3 and 7 months old at San Miguel Island, California, from the long-term average between 1997 and 2016.

nursing females due to shifts in the availability of prey and prey community composition in the central and southern CCS during the period of pup nutritional dependence. The low numbers of births in 2016 reflect the effects of low numbers of births and poor pup and juvenile survival since 2009 that have reduced the number of reproductive females in the population. However, the improved condition of pups in 2016 indicates that nursing females experienced better foraging conditions during the 2016–17 nursing period and were able to support the nutritional demands of their pups. The improved condition of pups in 2016 coincided with the return to a nursing female diet with high frequencies of northern anchovy (92%) and Pacific hake (63%) compared to a diet rich in juvenile rockfish and market squid that dominated the food habits during the unusual mortality event.

Marine Mammal Surveys: CalCOFI Surveys

On-effort visual detections of baleen whales for 2014–17 are shown in fig. 48[27]. During winter and spring cruises, most baleen whale sightings occurred within 200 nm of the shoreline. A nearshore shift in distribution of humpback whales (*Megaptera novaeangliae*) was seen during the spring in the 2016 and 2017 cruises. During summer, there were more baleen whale sightings along the continental slope and in offshore waters. During fall cruises in 2015 and 2016 baleen whale sighting were concentrated in the Channel Islands region.

Odontocete detections for 2014–17 are shown in Figure 49. In general, short-beaked common dolphins (*Delphinus delphis*) were detected offshore more frequently than inshore. In 2015, short-beaked common dolphins were not observed in the offshore areas, but they were present in the offshore areas during the summer and fall of 2016.

DISCUSSION

In this paper, we have not attempted to develop a quantitative model integrating all these data series. However, when we examine them in total, bolstered by current literature, we can make assertions about the temporal and spatial evolution of the California Current ecosystem encompassing the majority of links between environmental influences, population productivity, reproductive and foraging dynamics of top-predators, and the overall trophic structure. We finish with a comment regarding unanticipated ecosystem interactions resulting from recent anomalous ocean conditions and the realized and potential impact they have on coastal communities.

A weak La Niña in 2016, and stormy winter and sluggish upwelling in 2017

From spring 2016–spring 2017, the NPGO was at near-average values and the PDO remained positive, with values lower than the exceptionally high values of 2014–16. A weak tropical La Niña event was marked by modest negative ONI values from summer 2016–winter 2017. Together, these indices suggest that basin-scale patterns did not likely favor strong coast-wide productivity anomalies from spring 2016 to spring 2017. Above average upwelling north of 36˚N persisted from the spring to the fall of 2016 (March–September). By January and February 2017, stronger-than-average downwelling winds occurred in northern California Current (fig. 4) related to a continued weak NPH (fig. 6). As upwelling began in March and April 2017 it was weaker than typical north of 36˚N. Ultimately, chlorophyll during the March–May of 2017 was below average throughout much of the CCS with localized areas with positive chlorophyll anomalies in central California and the Channel Islands (fig. 9). The positive chlorophyll anomalies in central California may have been associated with strongly positive upwelling anomalies that began in May (fig. 4). As late-winter and spring conditions influence productivity of the forage base across the CCS (Logerwell et al. 2003; Schroeder et al. 2009, 2014) and structuring of the ecosystem (Wells et al. 2016, 2017), the observed weak upwelling conditions north of 36˚N during March–April 2017 could negatively affect the availability of forage to predators through 2017.

Dissimilar conditions emerged in the south and the north

Regional surveys during the 2016 El Niño found that surface waters were anomalously warm across the CCS and were also anomalously warm at depth south of Cape Mendocino (figs. 4, 7, 8). Through 2016, northern CCS copepod communities had an anomalously high abundance of subtropical species (fig. 10). Chlorophyll concentrations were low across the California Current in 2016. At Trinidad Head there was a *Pseudo-nitzschia* bloom in spring that abated by June. In the central and southern CCS domoic acid concentrations were negligible during 2016 (fig. 9).

Early in 2017 physical and biological conditions were dissimilar between the northern, central, and southern CCS. Surface conditions north of Cape Mendocino remained anomalously warm (fig. 4), chlorophyll was very low (fig. 9), and copepod species richness patterns

---

[27] Marine mammal surveys were initiated as part of the CalCOFI cruises in 2004. Visual monitoring incorporates standard line-transect survey protocol which includes two experienced observers scanning for marine mammals during transits between CalCOFI stations. Information on all cetacean sightings was logged systematically, including species, group size, reticle of cetacean position relative to the horizon, relative angle from the bow, latitude, longitude, ship's heading, behavior, environmental data and comments.

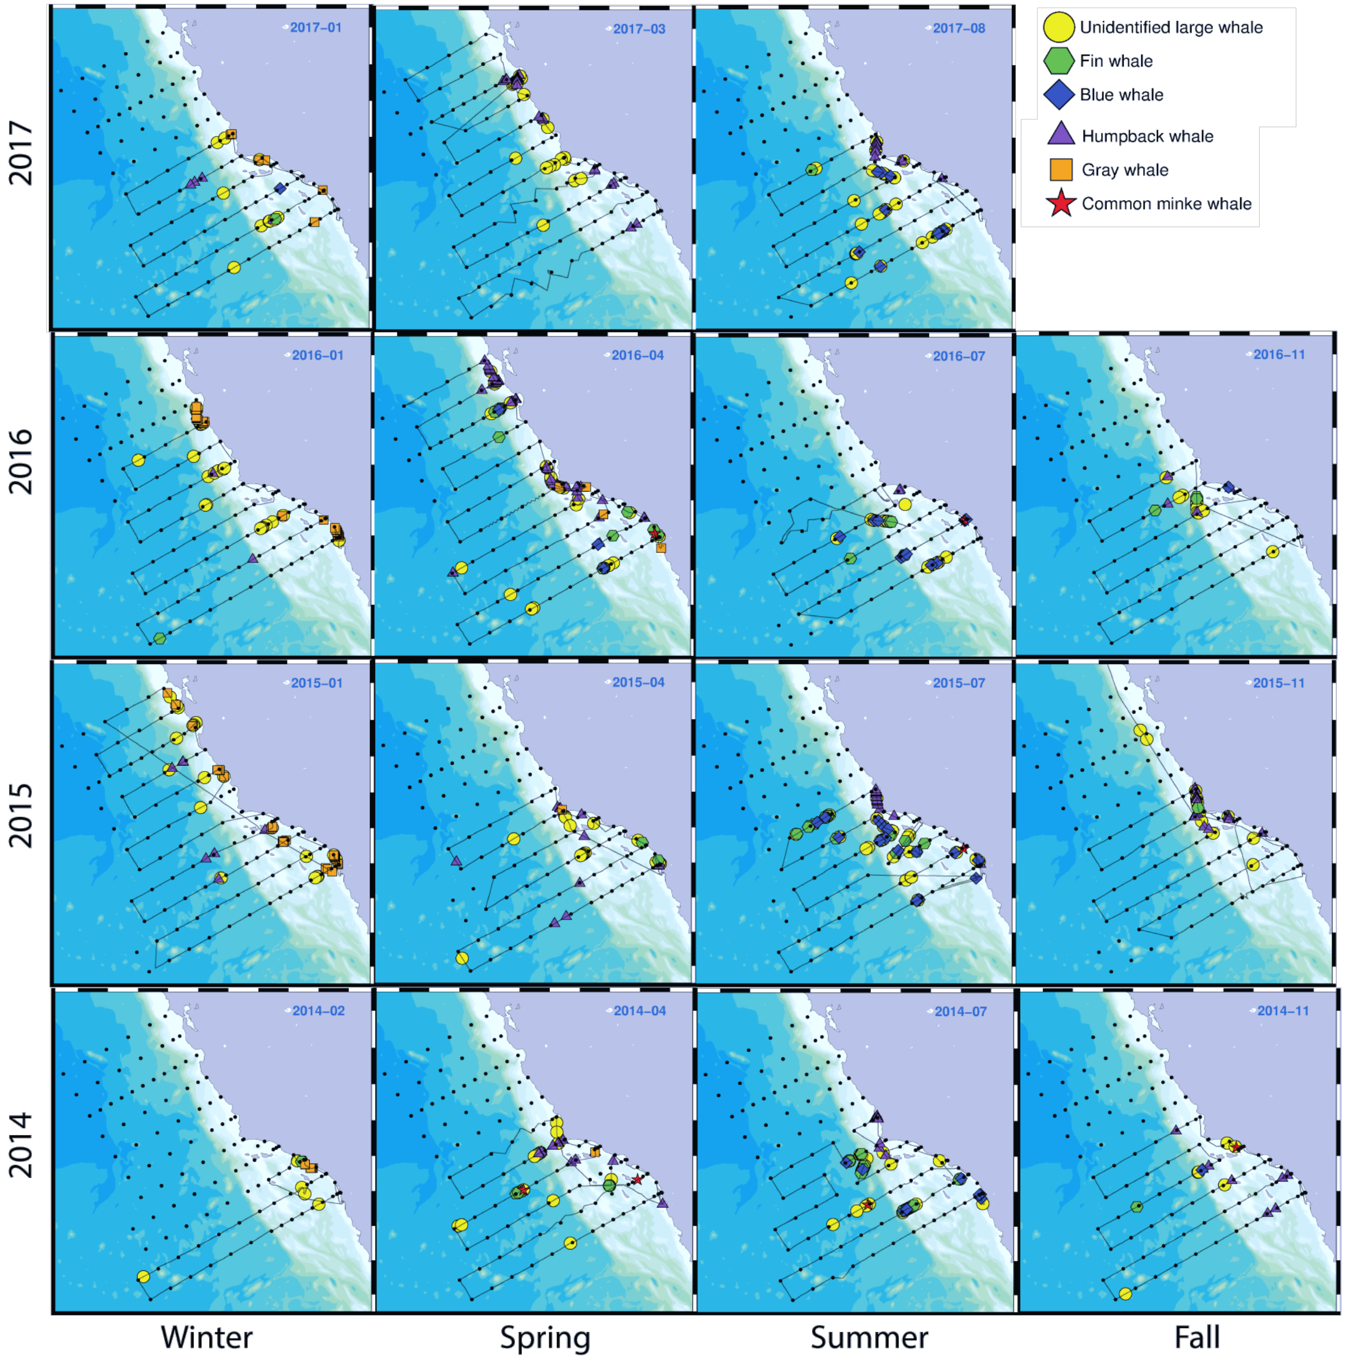

Figure 48. On-effort baleen whale sightings during CalCOFI cruises 2014–17. CalCOFI stations are represented by black dots and the ship's trackline is represented as a solid black line between stations. Symbol shapes and colors denote different species, as per legend.

were representative of southern assemblages in 2017 (table 1, fig. 10). Further, in January–April 2017 downwelling anomalies were evident along the West Coast from Monterey Bay to Vancouver Island, which were associated with increased storm events especially in California (figs. 3, 4). Southern and central regional surveys indicated that environmental conditions were typical for the longer time series, which suggests that central and southern regions may be returning to "normal." However, atypically, the increased chlorophyll in spring 2017 around the Channel Islands during April–May corresponded with a significant toxic event linked to increased estimates of *Pseudo-nitzschia* abundance (fig. 9). The event was responsible for an unusual mortality event for a number of seabirds and exceeded the regulatory limit for human consumption of fish and shellfish.

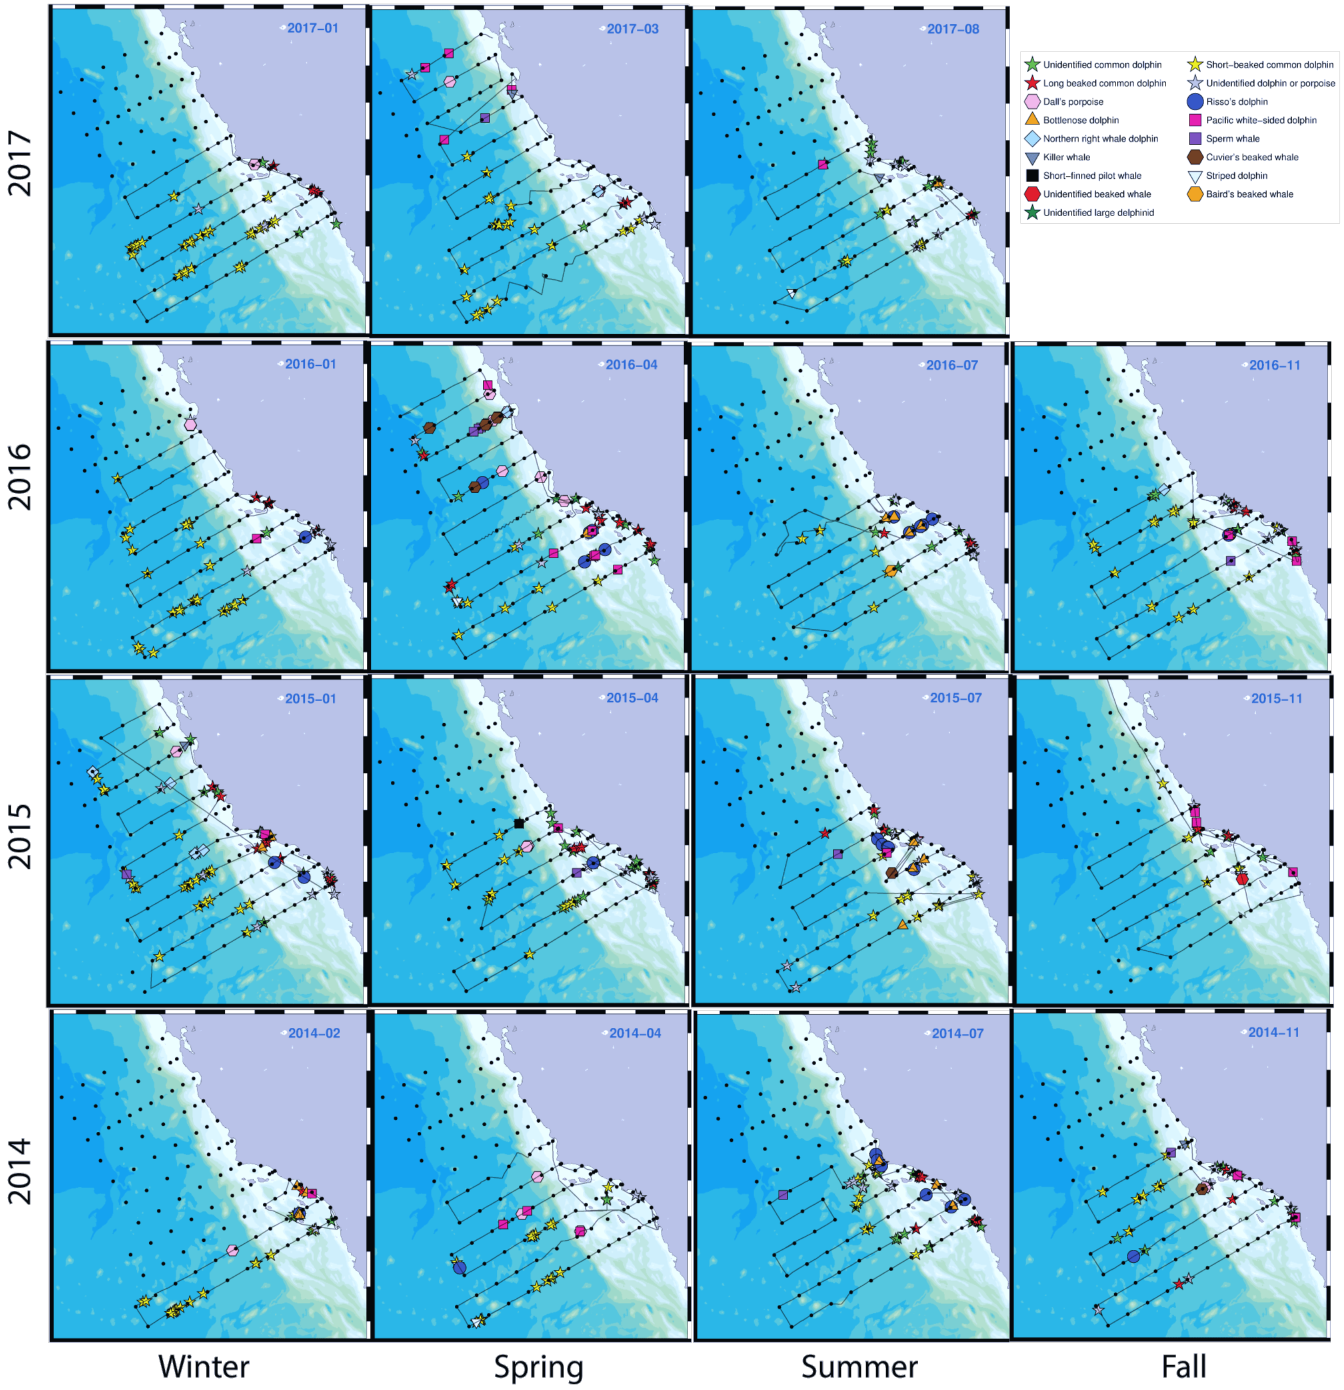

Figure 49. On-effort odontocete sightings during CalCOFI cruises 2014–17. CalCOFI stations are represented by black dots and the ship's trackline is represented as a solid black line between stations. Symbol shapes and colors denote different species, as per legend.

Micronekton communities responded to regional conditions and northern anchovy had notable spawning events

Micronekton abundance, distribution, and community structure reflect the larger patterns in environmental and zooplankton variability observed throughout the CCS. Namely, while conditions south of Cape Mendocino were typical of the longer times series, the northern regions did not return to a "normal" state following the end of the 2014–16 marine heatwave (Auth et al. 2017; Peterson et al. 2017). Specifically, the northern CCS was anomalously warm at the surface and the micronekton community was dominated by taxa originating from the south and off the shelf (e.g., pompano, myctophids, YOY Pacific hake, and YOY rockfishes) (Auth et al. 2017). In 2017 the dominant signal of warm-water taxa on the shelf included the extreme abundance of pyrosomes, which have been found with increasing frequency since 2014 in the northern California Current, but never in the extreme densities on the shelf region as observed this year (Brodeur, unpub.). The anomalously strong northward winds and the associated downwelling that occurred in the northern CCS in January–February 2017 (figs. 3, 4, 7) may have led to poor preconditioning of coastal waters (Hickey et al 2006; Logerwell et al. 2003) and directly contributed to the presence of offshore and southern taxa on the shelf in winter and spring. There may also be a biological reason for the reduction in typical fish taxa. Specifically, many of these fishes are short-lived and are regional residents. It is not unreasonable to expect that the preceding three years of poor productivity (due to the marine heat wave and El Niño) may have simply reduced their spawning stock biomass.

It is also notable that a greater than average abundance of northern anchovy has been observed in the northern CCS since 2014. As well, egg enumeration data indicates their spawning activity has been high (fig. 21). Interestingly, the most anomalous event in the southern CCS was the increased spawning activity of northern anchovy (fig. 31). While the greatest spawning activity was in the Southern California Bight and Columbia River shelf regions, greater than average spawning activity was also observed at a few isolated locations nearshore in central California (fig. 21). The mechanisms driving these dense spawning aggregations largely in the northern and southern parts of the CCS are to yet be determined, but they are consistent with the predictions of the Basin Model (MacCall 1990), which states that as the overall population abundance is reduced, as has been observed in recent years[28], dense spawning aggregations may be concentrated in areas of particularly suitable habitat. In the case of northern anchovy, they would be impinged along the remaining good habitats nearshore and expand to less optimal habitat as the population increases; such expansion may now be occurring in the core anchovy habitat within Southern California Bight.

Salmon habitat and observations

Recent climate extremes contributed to sharp downturns in the abundance (catch + escapement) of many West Coast Chinook and coho salmon populations. Historically poor freshwater conditions were caused by California's extreme "hot drought" from 2012–15. A broader "western snow drought" in 2015 related to a combination of precipitation and record high surface air temperatures contributed to extreme high freshwater temperature in many western rivers in 2015 that will impact catches and escapement during 2017–20. Record high coastal ocean temperature from 2014–16 and the associated ecosystem impacts that included shifts to more subtropical forage communities and shifting predator distributions likely contributed to sharp declines in survival rates for many US West Coast salmon populations. Fishery impacts included sharply reduced Chinook salmon landings in West Coast commercial fisheries and very low escapements in California's Klamath and Sacramento Rivers in 2016 (PFMC 2017a). The Klamath River fall Chinook ocean abundance forecast was the lowest on record (since 1985). This low abundance forecast and conservation concerns for other weak stocks led to heavily constrained or closed commercial, recreational, and tribal fisheries in California and Oregon (PFMC 2017b).

Results from northern surveys indicate that 2017 likely had anomalously high early-marine mortality for Columbia Basin origin coho and Chinook salmon. Specifically, 2017 had the lowest catch for juvenile Chinook and coho salmon in coastal surveys in the 20-year times series (1998–2017; fig. 24). The record-low catch is likely related to the forage composition (fig. 26) for out-migrants soon after they entered marine waters (Daly et al. 2017) rather than river conditions as the springtime stream flow was about average as the majority of smolts out-migrated in 2017. Early marine survival for 2017 out-migrants will influence the bulk of the adult coho salmon returns in 2018 and the bulk of the Columbia River Chinook salmon returns in 2019.

For the central CCS, environmental conditions in freshwater, estuaries and the coastal ocean from spring 2016 to summer 2017 were notably different than those during the 2012–15 hot drought and 2014–15 marine heat wave and 2016 El Niño. Out-migration flows in the Sacramento River were exceptionally low in spring 2014, 2015, and 2016. They were so low that emergency measures were taken that included trucking hatchery juveniles to the Bay-Delta for release[29,30]. By contrast, flows were high in spring 2017. Sacramento River stream temperature in 2014–15 was exceptionally high and contributed to record-low egg-to-fry survival for Central Valley winter-run Chinook salmon (Martin et al. 2016), while from spring 2016–summer 2017 stream temperatures were much more favorable for salmon. The improved freshwater conditions in 2016–17 likely resulted in improved salmon growth and condition at the time of out-migration to sea, thus improving their likelihood of survival (Woodson et al. 2013). Unfortunately,

[30] https://www.fws.gov/sfbaydelta/documents/2015_coleman_salmon_trucking_nr.pdf

at-sea observations of juvenile salmon from California are unavailable. However, ocean ecosystem indicators of early salmon survival have been developed for central California (Wells et al. 2016, 2017). For both spring 2016 and spring 2017 conditions in the Gulf of the Farallons were near normal. Likewise, the forage community supporting central California salmon in spring 2016 and 2017 was not significantly below average. Similarly, seabird diets on the Farallon Islands in springs 2016 and 2017, which have been linked to early salmon survival (fig. 42; Wells et al. 2017), were typical (i.e., largely rockfishes and northern anchovy) and did not demonstrate a significant increase in predation on juvenile salmon. Considering this suite of indicators based on ecosystem conditions related to key freshwater and marine salmon life stages, a Central Valley fall-run Chinook salmon fishery impact like that observed in 2007–08 (or 2016–17) appears to be unlikely for 2018–19.

Seabird reproductive success and foraging behavior reflect forage communities regionally

The reproductive success of seabirds in 2016 (the most current year available) was negatively related to latitude. In addition, there existed a northward shift in the prey field. In the northern California Current, at Yaquina Head and Castle Rock breeding colonies, some of the lowest reproductive success rates on record were observed. Nest failures were attributed to a combination of bottom-up and top-down forces. At Castle Rock, most chicks died of starvation, whereas at Yaquina Head, most nests failed due to predation by bald eagles seeking alternate prey. At-sea surveys of distribution and abundance of seabirds in northern California Current indicate that the reproductive success in 2017 may also be catastrophic. Namely, extremely low abundances were observed for migrant and central-place feeders. The few occurrences of common murre and sooty shearwaters observed at sea in 2017 in the north were at the locations where rare concentrations of forage (i.e., northern anchovy) were also observed, indicating close coupling of available forage patches and seabird aggregations. Preliminary observations at Castle Rock and Yaquina Head in 2017 also corroborate this speculation of catastrophic reproductive failure; fledging success of murres was 0%, with most chicks starving in the first few days, and it is likely Brandt's cormorants at Castle Rock also failed to produce young.

South of Cape Mendocino seabird reproductive success was generally below average. However, the significant decreases noted in the north were unapparent. Examination of the prey field (fig. 27) and the diets (fig. 42) indicate that the availability of primary forage taxa to seabirds remained average although the overall community was diverse (Santora et al. 2017a) and, in 2016, atypical (fig. 29) likely resulting from the inclusion of offshore forage taxa on the shelf during the El Niño event.

In 2017 the divergent characteristics of the environment, forage assemblages, and seabird abundances were apparent. For example, in southern California where forage communities were typical and the surface waters only slightly warmer than typical, the abundance of sooty shearwater was far above average. Yet, in the northern CCS abundance of sooty shearwater was the lowest in the observed record; observations also confirm lower abundance in central California (but within 1 SD of mean)[31]. As sooty shearwater migrate northward along the California Current, it is possible that they stopped their migration in southern California to benefit from persistent trophic hot spots there (Santora et al. 2017b) rather than continue to the northern California Current to lower quality forage assemblages. In addition, forage may have been reduced on their main foraging grounds in the Alaskan Bering-Sea Aleutian Islands ecosystem. Although unconfirmed, the seabirds in the south may be responding to the increased abundance of northern anchovy in the Southern California Bight (figs. 21, 27, 31); in the northern surveys the increased density of anchovy was isolated to the region of Columbia River mouth where the few seabirds were observed (fig. 21).

California sea lions show signs of recovery since the unusual mortality event

Increases in the abundance of northern anchovy coincided with improved condition of pups in 2016. Namely, lipid-rich northern anchovy and Pacific hake occurred in greater frequencies in the nursing female diet compared to the diet during the unusual mortality event that was dominated by juvenile rockfishes and market squid, which have low caloric value. The superior diet of nursing females translated into better condition of their dependent pups. If foraging conditions continue to improve, pup condition and survival should also improve. However, pup production will likely remain suppressed for several more years because the smaller cohorts produced from the unusual mortality event will comprise a greater proportion of the breeding population.

Whales shifting to nearshore habitats

There was a shoreward shift in the distribution of baleen whales. This distributional shift is quite apparent in central and southern California where there has been a recent, dramatic increase in whale entanglements with fixed fishing gears[32]. Humpback whales likely forag-

[32] http://www.westcoast.fisheries.noaa.gov/mediacenter/WCR%202016%20Whale%20Entanglements_3-26-17_Final.pdf

ing on the increased nearshore abundances of northern anchovy are the most at risk[33]. However, gray (*Eschrichtius robustus*) and blue (*Balaenoptera musculus*) whales have also been increasingly encountering gear. While yet to be determined, there are several potential causes for the increased interactions such as increased population abundance and increased predation on anchovy as an alternative prey. For example, humpback whales shift their foraging patterns between nearshore and offshore prey communities (Ainley and Hyrenbach 2010), focusing their foraging effort on krill during cool, productive years and on northern anchovy more inshore during years of delayed upwelling or lower productivity (Fleming et al. 2016).

Human dimensions

The ecosystem conditions observed during the last few years demonstrate the impacts that ocean variability and unanticipated environmental-food web-fishery interactions can have on coastal communities. For example, the marine heat wave was associated with coast-wide blooms of *Pseudo-nitzschia australis* that resulted in fishery season delays and closures (e.g., Dungeness crab, razor clams, rock crab) (Leising et al. 2015, McClatchie et al. 2016, McCabe et al. 2016). Further, due to increased SST, adult northern anchovy and associated spawning aggregations nearshore became more common in the northern CCS. Presumably, while foraging on the nearshore schools of northern anchovy, a dramatic increase of human-predator interactions occurred, including whale entanglements with fixed fishing gears that were deployed in greater density during the condensed and delayed Dungeness crab season of 2016. The risk for these interactions may increase if northern anchovy, a nearshore resident, continues to increase in abundance, or if there are further delays (or increased late-season effort) in Dungeness crab and other fixed-gear fisheries. Beyond fishery impacts, there could also be a need for alteration of coastal shipping lanes in trophic hot spots to reduce ship strikes on whales (Redfern et al. 2013, Santora et al 2017b).

The low catches of juvenile salmon in the northern CCS survey may indicate a significant impact on the fisheries and dependent communities. Salmon represent an example of how unanticipated, negative synergistic interactions can emerge. Salmon recruitment is reliant on ocean and river conditions the salmon experience early in life. In 2007–08, Central Valley Chinook salmon fishery collapsed requiring a Congressional appropriation of $170,000,000 from disaster relief (Lindley et al. 2009). The proximate cause of that collapse was poor ocean conditions in central California during 2005–06 (Lindley et al. 2009). Specifically, the anomalous ocean conditions and low productivity reduced forage availability that motivated a switch by predators, such as common murre, from preferred prey to adult northern anchovy nearshore. This switch in foraging behavior led to increased incidental predation on juvenile salmon as they outmigrated to sea. This interaction between ocean environment whereby bottom-up influences in the ocean environment led to top-down impacts on salmon was largely responsible for the extreme mortality of juvenile salmon and the subsequent collapse of the fishery (Wells et al. 2017). Similar mechanisms have been argued for salmon in the northern California Current (Pearcy 1992; Emmett et al. 2006; Phillips et al. 2017) and could be a contributor to the low juvenile salmon numbers observed in the northern survey during 2017. As predator populations increase, especially for potential salmon predators such as common murre (Wells et al. 2017) and humpback whales (Chenoweth et al. 2017), the impacts of poor ocean conditions on salmon may be magnified. One potential mitigation effort is to improve freshwater conditions such that more, larger, and an increased portfolio of salmon life histories contribute to increased diversity in the smolt out-migration to sea (e.g., more diversity in ocean-entry timing, smolt size, or migration routes) (Carlson and Satterthwaite 2011; Woodson et al. 2013). However, improvements to inland habitat would not be disconnected from interactions with agriculture, hydropower, and flood control. Regardless, the ocean is not always the primary determinant of recruitment. The "hot drought" affecting California from 2012–15 is considered a dominant driver of the lowest escapement to Central Valley since the collapse of the fishery a decade ago (PFMC 2017a). In such cases, recruitment of salmon to the fishery may rely on mitigation of mortality in freshwater by exceptional ocean ecosystem productivity where smaller (Woodson et al. 2013) and ill-timed (Satterthwaite et al. 2014) out-migrants have a better opportunity of survival.

Ultimately, given the highly variable CCS ecosystem and its variety of interacting components, management actions aimed at sustainability in living marine resources and resource systems will require an ecosystem-based fishery management approach. Efforts to better understand ecosystem interactions and the cascading consequences of anomalous ocean conditions will be critical to the ability of managers to respond effectively to variable ocean conditions while avoiding undesirable impacts to fisheries, protected resources and coastal communities.

Extending the empirical results of these and similar integrative programs to quantitative models capable of evaluating competing management scenarios may be a key aspect of affective management in a variable environment.
