	)	

DECLARATION OF DR. DAVID WELLER

I, Dr. David Weller, declare as follows:

1. I am a wildlife research biologist with the Marine Mammal and Turtle Division of the National Marine Fisheries Service (NMFS) Southwest Fisheries Science Center (SWFSC), within the National Oceanic and Atmospheric Administration. Within the Division, I conduct research as part of the Cetacean Health and Life History Program. The Marine Mammal and Turtle Division of the NMFS SWFSC, located in La Jolla, California, is the agency's lead for gray whale science, responsible for developing, collecting, and analyzing the best available scientific information to inform NMFS's management decisions. As a member of the Division, I am familiar with the policies and requirements of and NMFS's responsibilities under the Marine Mammal Protection Act (MMPA).

2. My professional training is in animal behavior, marine science, and wildlife and fisheries sciences. I am recognized as an expert on gray whales and have written extensively on and contributed to the scientific understanding of gray whales since 1997. I have authored or co-authored over 60 papers or reports on gray whales. These works include information on: gray whale abundance, occurrence, distribution, migration, reproduction, survival, behavior, genetics,

population structure, and interactions with human activities such as fishing gear and offshore oil and gas development. The geographic range of the topics covered in this scholarship encompasses the eastern and western North Pacific, including areas off the U.S., Mexico, Canada, Russia, Korea, Japan, and China. My major writings on gray whales within the past 10 years (2008-2018) are listed in my Curriculum Vitae, attached. NMFS Ex. 3-1.[1] I have been and continue to be engaged in research on gray whales including aspects of their distribution, abundance, movements, population structure, and calf production.

3. In addition to my written works on gray whales, during the past several decades I have studied gray whales in the field from boats, ships, shore stations, unmanned drones, and autonomous acoustic recorders. This work has included used of a number of methods, including: photography (boat, ship, shore, and aerial), satellite tagging, biopsying, underwater acoustic recording, infrared camera imaging, theodolite tracking, scat sampling, and visual observations. Also, as NMFS's lead for gray whale science, I review, evaluate, and contribute to the agency's official stock assessment reports (SARs) for gray whales, prepared in accordance with section 117 of the MMPA (16 U.S.C. § 1386). The MMPA's requirements pertaining to SARs and NMFS's procedures for preparing them are explained in the Declaration of Dr. Shannon Bettridge, filed herewith.

4. I am a member of the Society for Marine Mammalogy and the International Union for Conservation of Nature (IUCN) Western Gray Whale Advisory panel (*http://www.iucn.org/western-gray-whale-advisory-panel*). I also participate as a member of the U.S. delegation to the International Whaling Commission (IWC). The IWC is an inter-

---

[1] NMFS's exhibits are labeled as follows: "NMFS Ex. 1-XX" for exhibits attached to the Declaration of Chris Yates; "NMFS Ex. 2-XX" for exhibits attached to the Declaration of Dr. Shannon Bettridge; "NMFS Ex. 3-XX" for exhibits attached to the Declaration of Dr. David Weller; and, "NMFS Ex. 4-XX" for exhibits attached to the Declaration of Dr. Jeffrey Moore.

governmental organization whose purpose is the conservation of whales and the management of whaling. The IWC implements the International Convention for the Regulation of Whaling (Convention), established in 1946. All signatories to the Convention are members of the IWC. Currently, the IWC membership comprises about 87 countries, including the United States. *See generally https://iwc.int/home.*

5. Since 2002, I have been a member, on behalf of the United States, of the IWC's Scientific Committee (SC) (*see https://iwc.int/scmain*). The IWC SC is composed of leading experts on cetaceans, including all baleen whales, and is charged with providing the best scientific advice to the IWC. I participate on several IWC SC working groups to address, among other things, the range-wide status of gray whales. As a member of the U.S. delegation to the IWC and from my experience participating in the IWC SC and various scientific working groups, I am familiar with and have developed expertise in the provisions of the Convention, the United States' positions with respect to implementation of the Convention, and the scientific underpinnings of the IWC's work.

6. Pursuant to the Convention, commercial whaling by member states has been banned since 1986. The IWC provides a framework for the take of whales by aborigines of member states for subsistence purposes. To obtain an IWC allocation for aboriginal subsistence whaling, a member state must identify a subsistence need and request a quota of whales from the relevant stock. The IWC SC has a standing working group tasked with providing scientific advice on the sustainability of catch limits for aboriginal subsistence whaling operations that takes into account scientific uncertainty and meets the IWC's management and conservation objectives. These conservation objectives focus on ensuring that requests for aboriginal subsistent hunts are sustainable and do not seriously increase the risk of extinction (highest

priority); enable hunts in perpetuity; and maintain stocks at the highest net recruitment level (or if they are below that level, ensure that they move toward it). The objective of the working group's assessment and evaluation process is to determine sustainable catch limits, by way of simulation modeling over a 100-year period. These simulations account for plausible levels of uncertainty regarding a large number of factors including knowledge of population structure, abundance and trends, historic and future catch levels, reproduction, survivorship, and environmental conditions. The computer simulations used by the working group are called strike limit algorithms (SLAs). Although SLAs are intended for long-term use, regular reviews (usually every five to six years) are undertaken to ensure that no new information has been obtained that suggests new testing is required. Together, these methods are referred to as aboriginal whaling management procedures. After consulting with the IWC SC, the IWC decides whether or not to endorse a requested catch limit. Catch limits that meet the IWC's conservation objectives are included in a legally binding "Schedule" to the Convention.

7. As explained in the Bettridge Declaration, NMFS currently recognizes two stocks of gray whales under the MMPA, the eastern North Pacific (ENP) stock and the western North Pacific (WNP) stock. Bettridge Decl. ¶¶ 16-18. The agency's determination to classify these two populations as separate stocks was informed, in part, by the findings of a 2012 NMFS task force composed of agency marine mammal experts convened to provide an objective scientific evaluation of gray whale stock structure as defined under the MMPA. I was asked to chair that task force and was lead author of a report documenting its deliberations and conclusions. *See* NMFS Ex. 3-2 (Weller *et al.* 2013). The task force report was internally peer reviewed and published as part of the NMFS technical memorandum series. The task force found that levels of genetic differentiation between WNP and ENP gray whales provided convincing evidence that

WNP gray whales and ENP gray whales should be recognized as separate stocks under the MMPA.

8. The IWC also recognizes ENP and WNP gray whales as separate stocks for evaluating catch limits, although the IWC's criteria for identifying and managing stocks are not the same as those used by NMFS under the MMPA. Generally, the IWC uses data regarding range, distribution, movements, genetic structure, mixing rates, and morphology to identify stocks. For management purposes, the IWC may identify a management stock or a management unit that may or may not be equivalent to a single biological stock; for example, a management unit may include animals that happen to be present in a defined region and defined season where management is taking place or is contemplated.

9. Since 1997, the United States has routinely requested an aboriginal subsistence whaling quota for ENP gray whales from the IWC on behalf of the Makah Indian Tribe. These requests have been made through a joint proposal with the Russian Federation. The IWC recently approved a 2018 joint request that became effective December 29, 2018. Article 13(b)(2) of the IWC Schedule establishes a seven-year catch limit of 980 ENP gray whales with an annual cap of 140 ENP gray whales. The catch limit runs for a seven year period from 2019 through 2025, when a status quo or modified request may be made for a new six-year term. NMFS Ex. 3-3 (IWC 2018a). A United States and Russian Federation bilateral agreement allocates the catch limit between the two countries and provides annual limits of up to five ENP gray whales for the Makah Tribe and 135 ENP gray whales for the Russian Federation. NMFS Ex. 3-4 (Fominykh and Wulff 2018). As provided for in the bilateral agreement, either country may initiate discussions on the transfer of unused strikes. *Id.* In the past, the United States has assigned all of its unused catch limit to Russia for use by Chukotka hunters. *See, e.g.*, NMFS Ex.

3-5 (Fominykh and Wulff 2017); NMFS Ex. 3-6 (Fominykh and Smith 2016); NMFS Ex. 3-7 (Ilyashenko and DeMaster 2012); NMFS Ex. 3-8 (Ilyashenko and Hogarth 2007).

10. I am familiar with the proposed waiver and regulations that are the subject of this proceeding and with the scientific evidence submitted by NMFS in support of the proposed waiver and regulations. Based on my experience as a gray whale scientist and a member of the IWC SC, it is my professional opinion that the scientific evidence submitted by NMFS in support of the proposed waiver and regulations represents the best available scientific information regarding gray whales.

OVERVIEW OF GRAY WHALE BIOLOGY AND SCIENCE

11. Given my expertise on gray whales, I participated in the development and drafting of the gray whale sections of the February 2015 Draft Environmental Impact Statement on the Makah Tribe Request to Hunt Gray Whales (2015 DEIS). The 2015 DEIS, Chapter 3, provides a thorough discussion of gray whale biology and ecology. The following paragraphs summarize the best available scientific information on gray whales.

ENP GRAY WHALE STOCK

12. The range of the ENP gray whale stock is vast and crosses many large marine ecosystems, including the Pacific Central American Coast, California Current, Gulf of Alaska, and Bering and Chukchi Seas. NMFS Ex. 3-9 (Longhurst 1998); NMFS Ex. 3-10 (Sherman and Alexander 1998). Most ENP gray whales spend the winter months off the Baja California Peninsula then migrate north along the coast of North America to their summer/fall feeding range, which extends as far north as the Chukchi, Beaufort, and northwestern Bering Seas for most of the population. *See* NMFS Ex. 1-7, at 3 Fig. 2 (NMFS 2019a).

13. The ENP gray whale stock's southward migration generally begins in late November, and most whales reach the wintering grounds in northern Mexico and southern California starting in late December through February. Whales begin migrating north to the summer feeding areas in February, with the final phase of the migration, composed primarily of females whales with their calves, winding down by late May. Migrating gray whales are steady swimmers during migration (estimated to travel between 3-6 miles (5-10 km) per hour) and often exhibit directed travel and predictable breathing and dive patterns. NMFS Ex. 3-11 (Jones and Swartz 2002). During migration, gray whales generally remain close to shore (especially where the continental shelf is narrow) and the best available information indicates that most northbound and southbound whales migrate within 27 miles (43 km) of shore. NMFS Ex. 3-12 (Green *et al.* 1995); NMFS Ex. 3-13 (Green *et al.* 1992); NMFS Ex. 3-14 (Pike 1962).

14. Mating can occur throughout the southward migration, with a mean conception date of December 5. NMFS Ex. 3-15, at 74 (Rice and Wolman 1971). Females that have not successfully bred may enter a second estrous cycle within 40 days, *id.* at 90, such that a few females may breed as late as the end of January while present on the winter grounds. NMFS Ex. 3-16 (Jones and Swartz 1984). Some ENP gray whales calve in the shallow, protected lagoons of Baja Mexico starting around late December and ending by approximately the beginning of March, although around one-quarter to one-half of calves are born north of Carmel, California during the southward migration. NMFS Ex. 3-17 (Swartz and Jones 1983); NMFS Ex. 3-18 (Sanchez-Pacheco 1998); NMFS Ex. 3-19, at 10-14 (Sheldon *et al.* 2004).

15. Gray whales feed on a wide variety of prey throughout their range using various feeding techniques, including suction feeding, also called benthic or bottom feeding, and engulfing or skimming prey in the water column and on the sea surface. Researchers have

observed gray whales aggregating in particular areas to feed where prey densities are high, especially in portions of the northern seas. *See, e.g.*, NMFS Ex. 3-20, at 11 (Berzin 1984); NMFS Ex. 3-21, at 5 (Yablokov and Bogoslovskaya, 1984); NMFS Ex. 3-22, at 4 (Clarke and Moore 2002); NMFS Ex. 3-23, at 1 (Moore *et al.*, 2000); NMFS Ex. 3-24, at 2 (Moore *et al.* 2003); NMFS Ex. 3-25, at 3 (Highsmith *et al.* 2007). Areas where whales congregate to feed on a regular basis have been referred to as "feeding grounds" or "feeding areas" *See, e.g.*, NMFS Ex. 3-20, at 7 (Berzin, 1984); NMFS Ex. 3-26, at 1 (Calambokidis *et al.* 2002); NMFS Ex. 3-24, at 1 (Moore *et al.* 2003); NMFS Ex. 3-27, at 3 (Calambokidis *et al.* 2004). Gray whales change location and habitat to exploit the optimum prey species at any one time, based on abundance, density, size, caloric content, and predation pressure. Such factors may vary by season and year, depending on environmental variability and the population dynamics of prey. NMFS Ex. 3-28, at 19-24 (Darling *et al.* 1998); NMFS Ex. 3-22 (Clarke and Moore 2002); NMFS Ex. 3-29 (Moore *et al.* 2007).

16. Not all ENP gray whales make the full migration every year to the northern feeding grounds in the Chukchi, Bering, and Beaufort Seas. Beginning in the 1970s, researchers observed that some gray whales spend summer/autumn months feeding off the coasts of Oregon, Washington, and Vancouver Island. *See, e.g.*, NMFS Ex. 3-30 (Hatler and Darling 1974); NMFS Ex. 3-31 (Darling 1984). Based on photo-identification studies, which NMFS has participated in and helped fund, researchers have identified individual whales that use these areas each year or most years, rather than continuing to the more northern feeding grounds. *See* NMFS Ex. 3-32 (Calambokidis *et al.* 2000); NMFS Ex. 3-26 (Calambokidis *et al.* 2002); NMFS Ex. 3-33, at 2-3 (Calambokidis *et al.* 2017). These whales have been referred to as the Pacific Coast Feeding Group, or PCFG. The IWC defines the PCFG as gray whales observed between

June 1 and November 30 within the region between northern California and northern Vancouver Island (from 41° N lat. to 52° N lat.) and photo-identified within this area during two or more years. *See* NMFS Ex. 3-34, at 18 (IWC 2011a); NMFS Ex. 3-35, at 7 (IWC 2011c). NMFS has adopted this definition. *See* NMFS Ex. 2-7, at 8 (Caretta *et al.* 2017). A majority of PCFG whales make the southern migration to the wintering grounds off Baja California along with the rest of the ENP stock.

17. One of the purposes of the 2012 NMFS task force described in paragraph 7 above was to consider whether the PCFG should be designated as a separate stock under the MMPA. The task force examined several lines of evidence, including genetics, photo-identification, tagging, and other studies, representing the best scientific evidence available regarding gray whale stock structure.

18. With respect to genetics, the task force found small but significant differences in patterns of mitochondrial DNA (*i.e.*, diversity in a form of DNA inherited only from the mother), between samples collected from whales meeting the PCFG definition and whales sampled in northern feeding areas, including Chukotka, Russia. NMFS Ex. 3-36, at 7 (Lang *et al.* 2011a). Similar results were found in an independent study comparing mtDNA diversity between whales sampled during summer on the PCFG feeding ground and samples collected from whales, most of which had stranded, between southern California and the Chukotka Peninsula. NMFS Ex. 3-37 (Frasier *et al.* 2011). However, when analyzing microsatellites of nuclear DNA, which is inherited from both parents, no significant differences were identified between whales from the different feeding areas or between whales sampled during summer on the PCFG feeding ground and whales sampled in one of the Mexican wintering lagoons. *See* NMFS Ex. 3-38, at 6 (D'Intino *et al.* 2013). Lang *et al.* (2011) concluded that these results indicate that: (1) structure

is present among gray whales using different feeding areas, (2) matrilineal fidelity plays a role in creating such structure, and (3) individuals from different feeding areas may interbreed. In other words, calves likely follow their mothers to feeding areas and to some extent they return to those feeding areas in subsequent years. There was no evidence, however, that whales that frequent one feeding area are reproductively isolated from whales that frequent other feeding areas. NMFS Ex. 3-36, at 7-9 (Lang *et al.* 2011a).

19. Based on the MMPA's requirements, NMFS's guidance, and the best available scientific information, the task force concluded that there is substantial uncertainty in the strength of the lines of evidence supporting demographic independence of the PCFG and that the status of the PCFG as a population stock remains unresolved. The task force recommended that research should continue. NMFS Ex. 3-2, at 47-48 (Weller *et al.* 2013). Key areas of research identified by the task force included expanding photo-identification and tagging efforts, assessing interactions with fishing gear, and exploring genetic relatedness to better understand recruitment to the PCFG. NMFS continues to fund photo-identification surveys and is leading analyses regarding the recruitment of PCFG whales and assessing human-caused injury and mortality affecting gray whales in the PCFG range. *See e.g.*, NMFS Ex. 3-33 Table 1 (Calambokidis *et al.* 2017); NMFS Ex. 2-10 (Carretta *et al.* 2018a).

20. Because the task force was unable to provide definitive advice as to whether the PCFG qualifies as a population stock, NMFS continues to recognize the PCFG as part of the larger ENP stock. *See* NMFS Ex. 3-2 (Weller *et al.* 2013); Bettridge Decl. ¶ 18.

21. Because the ENP gray whale migration corridor is close to shore, the ENP stock has been routinely studied and monitored for many years by scientists from the U.S., Mexico, Canada, Russia, and elsewhere. Consequently, more is known about this stock than about most

other large cetacean stocks. NMFS estimates the ENP gray whale population size based on systematic shore-based surveys conducted during the whales' southbound migration. NMFS has conducted these surveys since 1967. I have been a project leader of these abundance surveys since 2009. The survey methods and data have been reviewed and accepted by the IWC SC and have been published in peer-reviewed literature. *See* NMFS Ex. 3-39, at 31 (IWC 2018d); NMFS Ex. 3-40 (Durban *et al.* 2015).

22. An Unusual Mortality Event (UME) during the 1999/2000 season reduced the ENP stock by as much as one fourth. The stock recovered from that decline and has been increasing since then, and the current abundance estimate of about 27,000 is the highest that has been recorded in the 1967-2016 time series. Several factors following the die-off, including the aforementioned increasing trend in abundance, suggest that the event was short-term and acute and not a chronic situation. *See* NMFS Ex. 2-7, at 10 (Carretta *et al.* 2017).

23. As explained in the Bettridge Declaration and the Declaration of Dr. Jeffrey Moore, filed herewith, NMFS annually publishes stock assessment reports (SARs) for each marine mammal stock in U.S. waters. A SAR includes, among other data, an estimate of the stock's abundance, minimum abundance (Nmin), and potential biological removal (PBR) level. The most recent SARs for the ENP and WNP stocks are designated as the 2016 SARs. Bettridge Decl. ¶ 11. NMFS recently released draft 2017 SARs, which include updated information for the WNP and ENP stocks. NMFS Ex. 2-10 (Caretta *et al.* 2018).

24. The 2016 SAR for the ENP gray whale stock estimates abundance at 20,990 and concludes that the stock is within its optimum sustainable population level (OSP). The SAR estimates an annual PBR of 624 and average annual human-caused mortality for the period 2008-2012 of 133. Bettridge Decl. ¶ 19. The average annual human-caused mortality is due to:

Russian harvest (127); mortality and serious injury from commercial fisheries (4.45); and ship strikes (2.0). Concerns identified in the SAR include injuries due to fisheries interactions, ship strikes, and marine debris, as well as a number of habitat concerns such as industrialization, pollution, and shipping congestion throughout the nearshore migratory corridors. Climate change is likely to affect the availability of habitat and prey species, but species such as the gray whale (which feed on both benthic and pelagic prey) have been predicted in some studies, *see, e.g.*, NMFS Ex. 3-41, at 17 (Bluhm and Gradinger 2008), to adapt better than trophic specialists. Shipping and natural resource exploration and development activities (*e.g.*, for oil and gas deposits) are also expected to increase in the Arctic and elsewhere, which in turn could increase risks to whales from spills, ship strikes, and anthropogenic noise. The SAR does not indicate that these factors are a threat to the status of the ENP stock at this time.

25. The draft 2017 ENP gray whale SAR includes NMFS's current abundance estimate for the ENP stock, which is 26,960, based on data through the 2015/2016 migration season. NMFS Ex. 2-10, at 5 (Caretta *et al.* 2018); NMFS Ex. 3-42, at 4 (Durban *et al.* 2017). Based on our statistical methods of estimating abundance, there is 95 percent confidence that the true abundance is between 24,420 and 29,830. *Id.* In 2017 and 2018, the IWC SC reviewed the abundance estimate of 26,960 (from Durban *et al.* (2017)) and adopted it for use in the IWC SC assessment of aboriginal subsistence whaling for gray whales. *See* NMFS Ex. 3-39, at 31 Table 6b (IWC 2018d); NMFS Ex. 3-43, at 15, 99 (IWC 2018b). Durban *et al.* (2017) noted that a recent 22 percent increase in ENP gray whale abundance over 2010/2011 levels is consistent with high observed and estimated calf production between 2012 and 2016. NMFS Ex. 3-42, at 4 (Durban *et al*. 2017); *see also* NMFS Ex. 3-44, at 3 (Perryman *et al.* 2017). Recent increases in abundance also support hypotheses that gray whales may experience more favorable feeding

conditions in arctic waters due to an increase in ice-free habitat that might result in increased primary productivity in the region. NMFS Ex. 3-45 (Perryman *et al.* 2002); NMFS Ex. 3-46 (Moore 2016).

26. The ENP gray whale SARs have included abundance estimates for the PCFG as well as informational estimates of PBR for the group and other information. *See* Bettridge Decl. ¶ 21. The most recent abundance estimate of PCFG whales, which is reflected in the draft 2017 ENP gray whale SAR, is 243 whales with a minimum abundance (Nmin) of 228. NMFS Ex. 3-33, at 2, 11 (Calambokidis *et al.* 2017); NMFS Ex. 2-10, at 5 (Caretta *et al.* 2018). Calambokidis *et al.* (2017) also note that PCFG abundance estimates showed a high rate of increase in the late 1990s and early 2000s and "have been fairly stable since 2002 and recently increasing." NMFS Ex. 3-33, at 11 (Calambokidis *et al.* 2017). During this period of stability, the lowest abundance of 192 (Nmin of 171) occurred in 2007. *Id.* at 32.

27. The 2012 NMFS task force noted that the levels of internal versus external recruitment to the PCFG appear to be comparable, but these are not quantified well enough to determine if the population dynamics of the PCFG are more a consequence of births and deaths within the group (internal dynamics) rather than related to immigration and/or emigration (external dynamics). Data from photo-identification surveys between 1999 and 2014 indicate that an average of 14.9 whales per year were recruited (seen in a subsequent year) into the PCFG. NMFS Ex. 3-33, at 9 (Calambokidis *et al.* 2017). In addition to internal recruitment (*i.e.*, calves born to PCFG mothers), the annual coastal migration of the vast majority of ENP gray whales brings most individuals into contact with the habitat used by the PCFG, thereby serving as a substantial and continuous source of external recruitment into the PCFG. NMFS Ex. 3-2, at 46 (Weller *et al.* 2013). It has been estimated that about four new ENP gray whales immigrate to

the PCFG each year. NMFS Ex. 1-7, at 29 (NMFS 2019a); NMFS Ex. 3-47, at 7 (Lang and Martien 2012). From 2002 through 2015, the PCFG increased from 197 to 243 animals, which is an annual average increase of 3.5 whales over 13 years. NMFS Ex. 3-33, at 32 (Calambokidis *et al.* 2017).

28. Based on surveys during the past 20 years, about 48 percent of the 750 ENP gray whales identified in the proposed hunt area during the summer/fall feeding period (June 1 through November 30) are PCFG whales. NMFS Ex. 3-33, at 9 (Calambokidis *et al.* 2017). The other 52 percent are ENP gray whales that are seen once and not re-sighted. During the migration period (December 1 through May 31), 28 percent of ENP gray whales present in the proposed hunt area are currently estimated to be PCFG whales. NMFS Ex. 3-39, at 8 (IWC 2018d). Currently, we estimate that approximately 50 percent of PCFG whales are female. A. Lang, NMFS, personal communication, Oct. 17, 2017.

29. The photo-identification methods used to identify PCFG whales are well-developed and widely used in the management of large cetaceans. *See* NMFS Ex. 3-33 (Calambokidis *et al.* 2017); NMFS Ex. 3-39 (IWC 2018d). Photo-identification involves matching photographs of an individual whale based on the whale’s unique features and markings. Unique features used for individual identification of gray whales include the shape of the dorsal hump, spacing between ‘knuckles’ on the tail stock, and the mottled color patterns and scarring on the flukes and lateral flanks, which are visible when gray whales surface to breathe and arch to dive. Through photo-identification, researchers can track an individual whale’s location across years based on photographic evidence.

30. I have used photo-identification methods as part of my research on whales and dolphins since 1988. I have helped to create numerous photo-identification catalogs, including

catalogs for bottlenose dolphins, gray whales, humpback whales, and sperm whales, as well as related databases. I am personally familiar with the methods and procedures used to identify individual gray whales through photographs and genetic samples.

31. There are several photo-identification catalogs currently in use for identifying gray whales. For PCFG whales, the primary catalog is the Pacific Northwest Catalog, curated by the Cascadia Research Collective (Cascadia), located in Olympia, Washington. Cascadia is a non-profit scientific organization that has conducted research and education in the fields of marine mammal and bird biology, animal behavior, ecology, and toxicology for the past 39 years. The Pacific Northwest Catalog contains an extensive photographic database of gray whales (including PCFG and ENP whales) and other large cetaceans, and has on staff qualified individuals who can match new photos to photos in the database, if they exist. Several researcher groups collaborate on Cascadia's photo-identification program and provide photographs to Cascadia. Photographs taken by researchers under NMFS funding are also provided to the NMFS Marine Mammal Lab in Seattle, Washington. Cascadia has informed NMFS that matches can usually be made within 24 hours. J. Calambokidis, Cascadia Research Collective, personal communication, Jan. 23, 2017. Although there are no quantitative assessments regarding the error rate for either false positives or false negatives, a recent IWC workshop on North Pacific gray whales reviewed the Cascadia catalog data and estimated a combined error rate of 20 percent, resulting in 80 percent photo-matching accuracy. NMFS Ex. 3-39, at 9 (IWC 2018d).

32. In some cases, genetic data can also be used to identify PCFG and WNP whales by way of genotype matching. However, such cases require that the sample obtained (*e.g.*, tissue

residue obtained during aboriginal subsistence hunting or research) be an identical match to the genetic signature of an animal that has previously been sampled and its genotype cataloged.

WNP GRAY WHALE STOCK

33. The main feeding ground for the WNP gray whale stock is in the Okhotsk Sea off the northeastern coast of Sakhalin Island, Russia, but some animals occur off eastern Kamchatka and in other coastal waters of the northern Okhotsk Sea. NMFS Ex. 3-48 (Weller *et al.* 2002); NMFS Ex. 3-49 (Vertyankin *et al.* 2004); NMFS Ex. 3-50 (Tyurneva *et al.* 2010). Some WNP whales are thought to migrate south along the coast of Asia in the fall, but the migration route(s) and winter breeding ground(s) are poorly known. Information collected over the past century indicates that the range of the WNP stock is much more restricted at present than it was historically (NMFS Ex. 3-51 (Reeves *et al.* 2008)), and that whales migrated along the coasts of Japan and South Korea (NMFS Ex. 3-52 (Andrews 1914); NMFS Ex. 3-53 (Mizue 1951); NMFS Ex.3-54 (Omura 1984)), to wintering areas somewhere in the South China Sea, possibly near Hainan Island (NMFS Ex. 3-55 (Wang 1984).

34. Until recently, scientists believed that the WNP stock was geographically isolated from the ENP stock. In the past decade, however, photo-identification studies (NMFS Ex. 3-56 (Urbán *et al.* 2012); NMFS Ex. 3-57 (Weller *et al.* 2012)), genetic research (NMFS Ex. 3-58 (Lang *et al.* 2010); NMFS Ex. 3-59 (Lang *et al.* 2011b)), and telemetry studies (NMFS Ex. 3-60 (Mate *et al.* 2011); NMFS Ex. 3-61 (Mate *et al.* 2015)), have documented that some gray whales observed on the feeding grounds in the western North Pacific migrate to and from the eastern North Pacific Ocean. Such documentation includes: (1) six whales photographically matched between Sakhalin Island and southern Vancouver Island (during April and May); (2) two whales genetically matched from samples off of Sakhalin and off of Santa Barbara, California (March);

(3) thirteen whales photographically matched between Sakhalin Island and San Ignacio Lagoon, Mexico; and (4) three satellite-tagged whales that migrated east from Sakhalin Island to the west coast of North America. NMFS Ex. 3-61, at 2 Fig. 1 (Mate *et al.* 2015). Additional matching analyses are ongoing, and this work brings the total number of gray whales that have been recorded both at Sakhalin Island and in the eastern North Pacific to at least 30. Telemetry studies in 2010 to 2012 provide evidence of three whales migrating during the winter from the western North Pacific to the eastern North Pacific, with one whale tracked from the western North Pacific to Baja Mexico and back to the western North Pacific over the course of 408 days (August 2011 to October 2012). NMFS Ex. 3-60 (Mate *et al.* 2011); NMFS Ex. 3-62 (Marine Mammal Institute 2012).

35. Based on data showing that significant mtDNA and nuclear DNA differences exist between samples of whales summering in the western North Pacific and samples of those summering in the eastern North Pacific (NMFS Ex. 3-59 (Lang *et al.* 2011b)), and the fact that gray whales in the western and eastern North Pacific have exhibited different rates of recovery and levels of abundance following over-exploitation as a result of commercial harvest (NMFS Ex. 3-63 (Rugh *et al.* 1999); NMFS Ex. 3-64 (Swartz *et al.* 2000); NMFS Ex. 3-65 (Swartz *et al.* 2006)), NMFS has concluded that the gray whales identified the western North Pacific are members of the WNP gray whale stock that migrate to areas previously thought to have been occupied only by ENP gray whales.

36. The 2016 WNP gray whale SAR provides an abundance estimate of 140 non-calf animals in 2012. Bettridge Decl. ¶ 22. A more recent population assessment for the WNP stock estimates the population at 200 non-calf animals, with a 95 percent confidence interval of 187 to 212 individuals. NMFS Ex. 3-66, at 7 (Cooke 2018). The stock is estimated to have increased

from 1995 through 2015 at a rate of about five percent annually. *Id.* The 2016 SAR for the WNP stock calculates a PBR for U.S. waters of 0.06 whales per year or one whale every 17 years. Bettridge Decl. ¶ 22.

37. As with PCFG whales, WNP whales can be individually identified based on photographs. The primary catalogs for identifying WNP whales are the Western North Pacific Catalog I, often referred to as the U.S.-Russia Catalog, and the Western North Pacific Catalog II. Catalog I is curated by the Kamchatka Branch of the Pacific Institute of Geography, Russian Academy of Sciences, and Catalog II is curated by the National Scientific Centre for Marine Biology (formerly Institute of Marine Biology), Vladivostok, Russia. The Institute of Marine Biology also curates a Kamchatka Catalog, which contains additional WNP whale photographs. The International Whaling Commission is currently facilitating the development of a unified WNP catalog and related database to be held under the auspices of the IWC. *See* NMFS Ex. 3-67, at 5 (IWC 2017). In addition to these curators, researchers at Cascadia are capable of performing identifications of WNP whales with these catalogs. J. Calambokidis, Cascadia Research Collective, personal communication, Jan 23, 2017.

EFFECTS OF THE PROPOSED WAIVER AND REGULATIONS TO THE ENP GRAY WHALE STOCK

ABUNDANCE

38. I have reviewed and am familiar with NMFS's proposed waiver and regulations that would authorize the Makah Tribe to conduct a limited hunt for ENP gray whales. Under the proposed regulations, the maximum potential mortality of ENP gray whales would be three whales in even-year hunts and two whales in odd-year hunts or 2.5 whales per year on average, based on the strike limits. Over the 10-year duration of the proposed regulations, the maximum mortality of ENP gray whales would be 25.

39. Loss of 2.5 whales per year from the ENP stock would represent an average annual reduction of 0.009 percent. A total mortality of up to 25 whales over 10 years represents about one-tenth of one percent of the ENP stock, or 0.09 percent of the population of approximately 27,000 animals. The PBR level for the ENP stock from the 2016 SAR is 624, and based on the updated ENP stock abundance data, is estimated as 801 in the draft 2017 SAR. Bettridge Decl. ¶ 23. The 2016 SAR estimates average annual human-caused mortality and serious injury, including from the Chukotkan hunt, of 133 whales, and the draft 2017 SAR provides an estimate of 138 whales. *Id.* The level of mortality that could occur under the proposed hunt is a small fraction of the annual variability of the stock's abundance (between around 16,000 – 27,000 animals since the mid-1990s) and well below PBR estimates.

40. In my professional judgment, based on the best available scientific information, the level of mortality that could occur under the proposed waiver and regulations would have no discernable effect on the ENP stock's abundance or rate of growth and no effect on the ENP gray whale stock's abundance relative to OSP.

41. The proposed removal of an average of 2.5 ENP gray whales per year and maximum of five strikes in any calendar year is within the catch limits allocated by the IWC and defined in the bilateral agreement between the United States and Russia.

42. In 2018, the IWC Standing Work Group on Aboriginal Subsistence Whaling Management Procedures (AWMP) completed testing of the strike limit algorithm for ENP gray whales and concluded that harvest levels, including the U.S. proposal for a Makah tribal hunt, meet the IWC's conservation objectives for aboriginal subsistence whaling. NMFS Ex. 3-43, at 17-23 (IWC 2018b). After modelling the best available data, the AWMP agreed that the proposed hunt management plan for a Makah tribal hunt meets the IWC conservation objectives

for ENP gray whales as well as for PCFG and WNP whales. NMFS Ex. 3-43, at 17-23 (IWC 2018b). The IWC SC supported this conclusion. *Id.*

43. Further, as described in paragraph 9 above, the United States has a long-standing practice of transferring any unused IWC quota for ENP gray whales to the Russian Federation for use by Chukotkan native hunters, under the bilateral agreement between the two countries. As there is no reason to expect the United States to alter this practice in the future, the net effect on the ENP gray whale stock likely would be the same with or without the proposed waiver and regulations.

DISTRIBUTION AND MIGRATORY MOVEMENTS

44. Under the proposed regulations, some whales would be approached by hunt vessels, and some would be subjected to unsuccessful strike attempts or training harpoon throws, but would not be struck or killed. Hunt vessels proposed for use by the Tribe include a canoe and a motorized chase vessel.

45. The proposed regulations would allow a maximum of 353 approaches of ENP gray whales per calendar year by tribal training or hunting vessels, resulting in a maximum of 3,530 approaches over the 10 years of the regulations. Of the 353 annual approaches, not more than 142 per year could be approaches of PCFG whales. The regulations define an “approach” as causing a hunting or training vessel to be within 100 yards (91 meters) of a gray whale.

46. Based on my personal experience and research, I am familiar with how gray and other baleen whales react to vessel approaches. For example, I have spent nearly 30 years approaching whales and dolphins from small boats and ships for research purposes. Much of this work has been on baleen whales, particularly gray whales, and I have witnessed reactions or the lack thereof firsthand. Individual vessel approaches are likely to elicit a range of reactions from whales, from showing no response to whales diving, exhaling underwater and exposing only

their blowholes, fluke slapping, or changing direction and speed. Based on the literature (see, for example, the 2015 DEIS Sections 3.4 and 4.4) and my firsthand experience, these changes in whale behavior are generally short-term, meaning they do not have a lasting effect on the whale's health or behavior.

47. As an example, according to Calambokidis *et al.* (2017), between 1996 and 2015, researchers photographed 21,235 gray whales representing 1,638 unique individuals between southern California and Kodiak Island, an area that overlaps the PCFG range. NMFS Ex. 3-33. Obtaining a photograph of sufficient quality to make an identification requires a close approach. Notwithstanding these close approaches, ENP gray whales, including PCFG whales, continue to use these areas. Similarly, despite over a hundred gray whales being pursued and killed in native hunts off Chukotka each year (many of which are killed during the summer feeding months), there has not been a discernible change in the availability and location of hunted whales in that region. *See* NMFS Ex. 3-68, 3 (Zagrebelnyy 2018); NMFS Ex. 1-7, at 28 (NMFS 2019a). Based on the foregoing information and my firsthand observations, in my professional judgement 353 approaches of ENP gray whales per year, including up to 142 approaches per year of PCFG gray whales, would not have a lasting effect on the health or behavior of the affected whales.

48. The proposed regulations would also limit unsuccessful strike attempts and training harpoon throws, combined, to 18 during an even-year hunt and 12 during an odd-year hunt. Over the course of the 10 years of the regulations, there could be 90 unsuccessful strike attempts and training harpoon throws during even-year hunts and 60 during odd-year hunts (for a total of 150). An unsuccessful strike attempt, as defined in the regulations is an attempted strike that does not penetrate the skin of the whale. A training harpoon throw is defined as an attempt

to contact a gray whale with a blunted spear-like device that is not capable of penetrating the whale's skin.

49. Because an unsuccessful strike attempt or training harpoon throw would not penetrate a whale's skin, it would not result in death of the affected animal. It would likely result in temporary disturbance, but would not be expected to have a lasting effect on the whale's health or behavior, because of the whale's thick skin and blubber layer and the requirement to pad or blunt the tip of the training harpoon. It is uncertain how whales would react to unsuccessful strike attempts and training harpoon throws, but their reactions could be similar to those of whales that are tagged or biopsied for research purposes. In these instances, tags and biopsy darts are projected at whales using air-powered rifles or crossbows. With the exception of suction-cup tags, tracking devices are attached with cutting blades. In the case of biopsy sampling, a small coring device is used. In my experience and based on the available literature, tagging or biopsying whales elicits a range of responses from subtle to overt, including a brief startle or flinch, fluke slapping, quick submergence, rapid swimming, and breaching. *See, e.g.*, NMFS Ex. 3-69 (Harvey and Mate 1984); NMFS Ex. 3-70 (Clapham and Mattila 1993); NMFS Ex. 3-71 (Gauthier and Sears 1999).

50. Based on the best available scientific information, it is my professional opinion that any changes in gray whale behavior due to an unsuccessful strike attempt or training harpoon throw would likely be short-term and not have more than temporary effect on the affected whale's health or behavior. Given these considerations, and the relatively small number of training harpoon throws and unsuccessful strike attempts allowed under the proposed regulations, it is reasonable to expect that whales exposed to these hunt-related activities would experience them as temporary and localized events.

51. Even-year hunts and training exercises conducted from December through May would encounter mostly migrating whales that pass through the ocean portion of the Makah U&A. Migrating whales would be able to transit the widest portion of the Makah U&A (approximately 32 miles or 51 km north-south) in several hours. *See* NMFS Ex. 3-11 (Jones and Swartz 2002). As explained in the Declaration of Chris Yates, filed herewith, during even-year hunts, adverse weather conditions in the Makah U&A in winter and early spring coupled with shorter periods of daylight would keep most hunts and training exercises close to shore and of shorter duration than during the summer. It is reasonable to expect that the relatively small number of migrating whales subjected to non-lethal hunt encounters, including hunting or training approaches, unsuccessful strike attempts, or training harpoon throws, during the migration season would experience the encounter as temporary and localized near-shore events that would otherwise not affect their migration.

52. Odd-year hunts during July through October would likely encounter whales exhibiting feeding behavior, including milling in small, localized areas close to shore and typically within three miles (five km) of shore. NMFS Ex. 3-13 (Green *et al* 1992); NMFS Ex. 3-31 (Darling 1984); NMFS Ex. 3-72 (Sumich 1984); NMFS Ex. 3-73 (Mallonée 1991); NMFS Ex. 3-74 (Dunham and Duffus 2001); NMFS Ex. 3-75 (Scordino *et al.* 2011). Some animals have been seen clustering relatively far offshore (12-16 miles or 19-26 km) but these sightings are considered unusual. *See* NMFS Ex. 3-76 (Calambokidis *et al.* 2009). During summer hunts and training exercises, most gray whales would be found within the PCFG range from northern California to northern Vancouver Island, of which the hunt area is a small proportion (less than five percent of the coastline in the PCFG range). Whales are known to focus on specific areas within this range but also move extensively in search of food. NMFS Ex. 3-77 (Calambokidis *et*

al. 1999); NMFS Ex. 3-27 (Calambokidis *et al.* 2004);NMFS Ex. 3-78 (Calambokidis *et al.* 2014). The effects of hunt activities on feeding whales are likely to be temporary and limited to relatively small areas, resulting in negligible impacts on overall feeding opportunities and the nutritional state of the whales.

53. I am familiar with the provisions in the proposed regulations intended to limit the impacts of a tribal hunt on PCFG whales. The regulations limit the number of overall strikes of PCFG whales to 16 over the 10-year duration of the proposed waiver, and only 8 of those strikes may be of females. The strike limit on PCFG females is a precautionary measure given recent evidence that PCFG whales may be recruited through maternally-directed site fidelity (see paragraph 18 above), and based on the latest genetic data indicating a 1:1 sex ratio for PCFG whales. *See* NMFS Ex. 1-7, at 47 (NMFS 2019a).

54. Although the proposed waiver and regulations allow up to 16 strikes on PCFG whales over 10 years (average 1.6 whales per year), the actual number of PCFG whales killed is likely to be lower. As explained in the Yates Declaration, the proposed regulations would count all whales struck during odd-year hunts as PCFG whales, which is a conservative assumption. Currently, the best available estimate is that PCFG whales comprise approximately 48 percent of whales present in the hunt area during the months of odd-year hunts, so assuming that all strikes (10) were used, a total of 4.8 PCFG whales would be struck during odd-year hunts over 10 years. During even-year hunts, we estimate that PCFG whales comprise approximately 28 percent of whales in the hunt area. If all strikes (15) were used during even year hunts, a total of 4.2 PCFG whales would be struck over 10 years. Combining these totals provides an estimate of nine PCFG whales struck over the waiver period.

55. As explained in paragraph 27 above, PCFG abundance has increased by an average of 3.5 whales per year based on data from 2002 through 2015. This level of recruitment would exceed the level of removals authorized under the proposed regulations, meaning we would expect PCFG abundance to remain relatively stable or increase slightly, assuming that no broader environmental or ecological perturbations occur, over the duration of the proposed waiver.

56. In addition to the seasonal strike limits and the 10-year PCFG strike limits, the proposed regulations would not allow hunting in a given season if the estimated PCFG abundance for that season is below 192 whales, or if the minimum abundance estimate is below 171 whales. Published population estimates typically lag one or more years behind the most currently available survey data, so for purposes of the regulations, estimates for an upcoming hunting season would be projected using a population forecast model fit to the time series of data. The forecast model is explained in the Moore Declaration. The threshold values of 192 (and 171) represent the point estimate of PCFG abundance (and associated minimum 20th percentile estimate) in 2007. These thresholds represent the lowest values estimated for the population during the recent period of stability in abundance that started in 2002. Exhibit 3-33 (Calambokidis *et al.* 2017).

57. As explained in paragraphs 29 through 32 above, I am familiar with photo and genetic identification techniques for whales and with the PCFG catalogs and photo-matching expertise available through the Cascadia Research Collective. I have also reviewed the *NMFS Protocol for Identifying Gray Whales Encountered in Makah Hunts* proposed for use in managing the Makah hunt. NMFS Ex. 1-9 (NMFS 2019b). Based on my expertise, I conclude

that the photo-identification measures in the proposed regulations and the NMFS protocol are reasonable, feasible, and reliable methods for managing the strike limits for PCFG whales.

58. Under the proposed regulations, up to 142 PCFG whales annually could be approached by hunt vessels, and some PCFG whales would be subjected to unsuccessful strike attempts or training harpoon throws. There is the possibility that some of these encounters would be repeat encounters with the same whale. For the reasons described in paragraphs 44-50 above, I would not expect these approaches, unsuccessful strike attempts, and training harpoon throws to result in more than minor, temporary disturbance to the affected animals or to cause the affected whales to abandon the PCFG feeding area.

59. Based on the information above and my conclusions in paragraphs 40, 47, 50-52, and 58, it is my professional opinion that the proposed waiver and regulations would not have a meaningful effect on the distribution or migratory movements of the ENP gray whale stock, including distribution within the PCFG range.

BREEDING HABITS

60. As explained in paragraph 14 above, gray whale mating can occur throughout the southward migration. Under the proposed waiver and regulations, the expected time that hunting or hunt training would likely overlap with gray whale breeding would be in December-January. As explained in the Yates Declaration, NMFS expects that few if any hunt activities would occur in December-January due to inclement weather. While it is possible that hunt activities could occur in December-January and could encounter mating whales, I would not expect any adverse effects to the ENP stock due to the small portion of the migration corridor where hunt activities could occur, the limited level of hunt activity likely to occur, and given that any whales disturbed

but not struck would likely have additional opportunities to mate throughout the remainder of the southbound migration season.

EFFECTS OF THE PROPOSED WAIVER AND REGULATIONS TO WNP GRAY WHALES

61. As explained in paragraph 34 above, researchers have documented the presence of some WNP whales in the eastern North Pacific Ocean during the winter/spring migration season, including near the area where hunting would occur under the proposed waiver and regulations. I am familiar with the provisions in the proposed regulations intended to limit risks to WNP whales.

62. To assist NMFS in evaluating the risk to WNP whales from the proposed regulations and also at the request of the IWC SC, Dr. Jeffrey Moore and I conducted an analysis of the likelihood of Makah hunters encountering a WNP whale during an authorized hunt. We conducted this analysis first in 2013, and again in 2018 based on revisions made by NMFS to the initial hunt proposal. We published our most recent results in a NOAA Technical Memorandum. NMFS Ex. 4-8 (Moore and Weller 2018). Dr. Moore's Declaration explains in detail the results of our analysis.

63. The analysis in Moore and Weller (2018) addresses the risk of Makah hunters encountering a WNP gray whale during the December-May migration season. There is no evidence that WNP gray whales would be present in the hunt area during the summer/fall feeding season, when we expect that WNP gray whales would be feeding in the western North Pacific. Although we do not expect a WNP gray whale to be encountered by hunters during summer/fall odd-year hunt season, the proposed regulations establish photo-identification requirements, so that NMFS would look for matches between the WNP catalogs and any whales struck during odd-year hunts, and hunting would cease if NMFS determined that a WNP gray whale had been struck. Genetic data would also be used if available. For the reasons described

in paragraphs 29-32 above, it is my professional opinion that the proposed photo-identification measures are a reasonable and reliable method for determining whether a WNP gray whale has been struck.

64. As explained in the Declaration of Dr. Moore, our modelling indicated that Makah tribal hunters would approach about 14 WNP gray whales over the 10 years of the regulations, assuming that the full number of approaches were made each year, and all of them, including training approaches, occurred between December 1 and May 31, when WNP gray whales could be present in the hunt area. NMFS Ex. 4-8, at 5 note 3 (Moore and Weller 2018). This is an unlikely scenario. Realistically, we would expect a substantial number of approaches to occur during the summer and fall, when hunting conditions are more favorable *Id.*; *see* Yates Decl. ¶ 66. However, even if 1.4 WNP gray whales per year were approached by tribal hunters, I would not expect these approaches to have a lasting effect on the approached whale's health or behavior for the reasons explained in paragraphs 44-47 above.

65. In addition to being approached, there is about a 30 percent probability that one WNP whale would be subjected to an attempted strike or training harpoon throw over the 10 years of the regulations. If this were to occur, for the reasons explained above (see paragraphs 48-50), I would not expect it to lead to mortality injury, or more than temporary disturbance to the affected animal.

66. The IWC has not established a catch limit for WNP gray whales. The IWC recently reviewed the potential impact of the proposed waiver and regulations on WNP gray whales and, as described in paragraph 42 above, concluded the proposal meets the IWC conservation objectives for this group. NMFS Ex. 3-43 (IWC 2018b).

EFFECTS OF THE PROPOSED WAIVER AND REGULATIONS ON THE MARINE ECOSYSTEM

67. As stated in paragraph 1 above, I am familiar with the policies and requirements of the MMPA, including the policy that marine mammals should not be permitted to diminish beyond the point at which they cease to be a significant functioning element of their ecosystems and that the health and stability of marine ecosystems should be maintained.

68. As explained in paragraph 12 above, the range of the ENP gray whale stock is vast (*see* NMFS Ex. 1-7, at 3 Fig. 3 (NMFS 2019a)), and crosses many large marine ecosystems, including the Pacific Central American Coastal, California Current, Gulf of Alaska, and Bering and Chukchi Seas. The hunt area is within what oceanographers call the California Current System or Province (NMFS Ex. 3-10 (Sherman and Alexander 1989); NMFS Ex. 3-9 (Longhurst 1998)), a part of the North Pacific Gyre that moves cool ocean waters south along the western coast of North America, beginning off British Columbia, flowing southward past Washington, Oregon, and California, and ending off Baja California. Within that province, scientists regularly study and predict physical and biological features and processes in the northern California Current ecosystem, which is generally described as extending from northern California to Vancouver Island (*e.g.*, NMFS Ex. 3-79 (Field *et al.* 2001); NMFS Ex. 3-80 (Field *et al.* 2006); NMFS Ex. 3-81 (Hickey and Banas 2008); NMFS Ex. 3-82 (Sydeman and Elliott 2008); NMFS Ex. 3-83 (Harvey *et al.* 2017); NMFS Ex. 3-84 (Wells *et al.* 2017)), though some studies extend only to the U.S. Canada border in the north because of differing management regimes between the two countries (NMFS Ex. 3-79 (Field *et al.* 2001); NMFS Ex. 3-80 (Field *et al.* 2006)). The northern California Current ecosystem corresponds with the seasonal range of the PCFG and is the smallest recognized marine ecosystem that encompasses the area of the proposed hunt.

69. The ENP gray whale stock numbers between about 24,420 and 29,830, with a point estimate of 26,960. The potential impact of the proposed regulations on the ENP stock would thus be the annual removal of less than one tenth of one percent of the population. This level of removal, which is an order of magnitude less than the natural variability of the population, would be too small to have a perceptible effect on the functioning of ENP gray whales as an element of the large Pacific Central American Coastal, California Current, Gulf of Alaska, or Bering and Chukchi Seas ecosystems, or on the health of the ecosystems themselves.

70. For similar reasons, the proposed regulations will not result in gray whales ceasing to be a significant functioning element of the smaller northern California Current ecosystem. This ecosystem is shaped by dynamic, highly energetic, large-scale processes, including currents, upwelling, freshwater runoff, seasonal wind/storm patterns, and variable climate patterns such as El Niño, and the role of ENP gray whales in structuring these habitats is limited. *See* 2015 DEIS at 3-33 to 3-50. A hunt carried out under the proposed regulations is likely to result in a negligible decrease in the numbers of whales present in the northern California Current ecosystem or the northern Washington coastal environment. *Id.* at 4-51 to 4-61.

71. For the same reasons, although the northern Washington coast is not considered a separate ecosystem, even at the scale of the hunt area, the proposed hunt would not have a significant effect on the health or functioning of the marine environment. Also, the protections for PCFG whales in the proposed regulations would ensure that the hunt does not reduce PCFG abundance below recent stable levels, which would prevent any detectable changes in the marine habitat associated with the PCFG range.

72. As explained in the Yates Declaration, hunt-related activities associated with the proposed waiver and regulations could include operating motorized vessels and towing a carcass onto the shore, which would potentially disturb the pelagic, benthic, and nearshore environments. I would expect any such disturbance to be short-term and localized. The biological composition and productivity of these areas is diverse, variable, and generally patchily distributed owing to the dynamic physical processes, which differ across a spectrum of temporal and spatial scales. The dynamic nature of these processes results in variable biological productivity of both benthic and pelagic organisms. The magnitude of any hunt-related disturbance would also be extremely small in the northern California Current ecosystem or the northern Washington coastal environment, which are large areas characterized by constant, highly energetic, and large-scale physical disturbances as described above.

73. For these reasons, I conclude that hunt-related activities under the proposed waiver and regulations are unlikely to affect the health or stability of the marine ecosystem or the functioning of gray whales in their ecosystem at any relevant scale.

I declare under penalty of perjury under the laws of the United States that the foregoing is true and correct to the best of my knowledge, information, and belief.

David W. Weller

EDUCATION, AFFILIATION AND RELEVANT EXPERIENCE

Education

1998
Ph.D. Wildlife & Fisheries Sciences, Texas A&M University

1991
M.A. San Diego State University

1986
B.A. University of Hawaii

Institutional Affiliation

1998-2019
Southwest Fisheries Science Center, NOAA, NMFS - *Research Wildlife Biologist (Marine Mammals)*

Professional Experience

2017-2019
International Whaling Commission - *Science Advisor to U.S. Commissioner*

2018-2019
International Whaling Commission – *Chairman, Ship Strike Working Group*

2006-2019
International Union for Conservation of Nature (IUCN) - *Member, IUCN Western Gray Whale Advisory Panel*

2002-2019
International Whaling Commission - *Member, U.S. Delegation to the IWC Scientific Committee*

1998-2019
San Diego State University - *Adjunct Professor*

2012-2013
NOAA Task Force on Gray Whale Stock Identification - *Chairman*

2007-2008
Cuyamaca College - *Instructor of Oceanography*

2003-2004
Journal of Mammalogy - *Associate Editor*

NOAA Technical Memorandum NMFS

The National Oceanic and Atmospheric Administration (NOAA), organized in 1970, has evolved into an agency that establishes national policies and manages and conserves our oceanic, coastal, and atmospheric resources. An organizational element within NOAA, the Office of Fisheries is responsible for fisheries policy and the direction of the National Marine Fisheries Service (NMFS).

In addition to its formal publications, the NMFS uses the NOAA Technical Memorandum series to issue informal scientific and technical publications when complete formal review and editorial processing are not appropriate or feasible. Documents within this series, however, reflect sound professional work and may be referenced in the formal scientific and technical literature.

SWFSC Technical Memorandums

SWFSC Technical Memorandums are available online at the SWFSC web site (http://swfsc.noaa.gov). Copies are also available from the National Technical Information Service, 5285 Port Royal Road, Springfield, VA 22161 (http://www.ntis.gov).

This **NOAA Technical Memorandum NMFS** issued by the Southwest Fisheries Science Center may be cited in following manner:

Weller, D.W., Bettridge, S., Brownell, R.L., Jr., Laake, J.L., Moore, J.E., Rosel, P.E., Taylor, B.L and Wade, P.R. 2013. Report of the National Marine Fisheries Service gray whale stock identification workshop. U.S. Dep. Commer., NOAA Tech. Memo. NMFS-SWFSC-507

Executive Summary

The Marine Mammal Protection Act of 1972 (MMPA) requires that the National Marine Fisheries Service (NMFS) and the Fish and Wildlife Service develop stock assessment reports for all marine mammal stocks in waters under U.S. jurisdiction. NMFS considers stock structure as part of these assessments and has developed guidance for delineating separate population stocks under the MMPA. A single population stock of gray whales (*Eschrichtius robustus*), referred to as the eastern North Pacific (ENP) stock, is presently recognized in U.S. waters (Carretta *et al*. 2013). New information, however, suggests the possibility of recognizing two additional stocks of gray whales in U.S. waters: the Pacific Coast Feeding Group (PCFG) and the western North Pacific (WNP) stock. To evaluate the currently recognized and potentially emerging characterization of gray whale stock structure, NMFS established a scientific Task Force (TF). The overarching objective of this TF was to provide an objective scientific evaluation of gray whale stock structure as defined under the MMPA and implemented through the NMFS Guidelines for Assessing Marine Mammal Stocks (GAMMS; NMFS 2005). More specifically, the TF was convened to provide advice on the primary question – "*Is the PCFG a "population stock" under the MMPA and GAMMS guidelines"?* In addition, the TF was asked to provide advice on a question of developing importance – "*Is the WNP stock a "population stock" under the MMPA and GAMMS guidelines"?*

Both of these questions have immediate management implications, including: (1) how future NMFS stock assessment reports will address gray whale stock structure in the North Pacific, and (2) how to interpret any new information in the context of the Makah Indian Tribe's MMPA waiver request to resume hunting gray whales off Washington State, USA.

As the agency lead for gray whale science, the Southwest Fisheries Science Center convened a meeting of the aforementioned TF from 31 July to 2 August 2012. Using the best scientific information available at the time of the workshop, the TF worked to: (1) review new information relevant to gray whale stock structure, and (2) provide advice on revisions to stock structure so as to be available for management consideration. The TF conducted its work as an advisory rather than prescriptive body and therefore its conclusions should viewed as scientific advice based on review and discussion of the available science.

The implications of new data pertinent to stock structure, including considerable information related to the PCFG and WNP gray whales, were thoroughly reviewed during the workshop. Evaluating the new findings relevant to the status of the PCFG proved particularly complex. After review of results from photo-identification, genetics, tagging, and other studies within the context of the GAMMS guidelines (NMFS 2005) there remains a substantial level of uncertainty in the strength of the lines of evidence supporting demographic independence of the PCFG. Consequently, the TF was unable to provide definitive advice as to whether the PCFG is a population stock under the MMPA and the GAMMS guidelines. Members of the TF ranged in their opinions from strongly agreeing to strongly disagreeing about whether the PCFG should be recognized as a separate stock.

In the case of WNP gray whales, the work of the TF was more straightforward. The mitochondrial DNA and nuclear DNA genetic differentiation found between the WNP and ENP stocks provided convincing evidence that resulted in the TF providing unambiguous advice that the WNP stock should be recognized as a population stock pursuant to the GAMMS guidelines and the MMPA.

Additional research may narrow the uncertainty associated with the question of whether the PCFG should be recognized as a population stock. To work towards this objective, the TF recommended further investigation of recruitment into the PCFG. Presently, both the photo-identification and genetics data indicate that the levels of internal versus external recruitment are comparable, but these are not quantified well enough to determine if the population dynamics of the PCFG are more a consequence of births and deaths within the group (internal dynamics) rather than related to immigration and/or emigration (external dynamics). The TF offered a number of research recommendations, using the existing photo-identification and genetics datasets, that could provide increased resolution on the issue of recruitment and, in turn, the question of stock identification.

While the need for additional data collection was apparent, especially with regard to recruitment into the PCFG, the purpose of the workshop was for the TF to determine whether the *existing* best available science was sufficient to advise that the PCFG be recognized as a population stock under the language of the MMPA and GAMMS guidelines. Therefore, the advice of the TF offered in this report should be viewed as a contemporary "snapshot" taken from an emerging and ever-changing body of knowledge regarding the PCFG.

The TF emphasizes that the PCFG is relatively small in number and utilizes a largely different ecosystem from that of the main ENP stock. While the status of the PCFG as a population stock has yet to be resolved, continued research on these whales should be undertaken with particular attention dedicated to collecting data relevant to the question of stock identification.

1. Introductory Remarks

Dr. Lisa Ballance, Director of the Marine Mammal and Turtle Division at Southwest Fisheries Science Center (SWFSC), welcomed the workshop participants. She noted that this workshop represented a significant event, in that it: (1) brings agency scientists together to review research that continues to evolve and reveal unexpected patterns, (2) provides results that will be relevant to management activities for the National Marine Fisheries Service (NMFS), and (3) typifies the ideal model for how NMFS works, illustrating science addressing management actions and highlighting the collaboration between NMFS scientists, regional offices, and headquarters.

The technical and scientific expertise required on the Task Force (TF) was determined by SWFSC in consultation with the NMFS Northwest Regional Office (NWR) and the NMFS Office of Protected Resources (OPR). TF members were experts in their respective fields with ample experience and ability to bridge scientific and policy issues related to marine mammal stock structure. Members of the TF included the following eight NMFS scientists:

Dr. Shannon Bettridge	NMFS – Office of Protected Resources
Dr. Robert L. Brownell, Jr.	NMFS – Southwest Fisheries Science Center
Dr. Jeffrey L. Laake	NMFS – Alaska Fisheries Science Center
Dr. Jeffrey E. Moore	NMFS – Southwest Fisheries Science Center
Dr. Patricia E. Rosel	NMFS – Southeast Fisheries Science Center
Dr. Barbara L. Taylor	NMFS – Southwest Fisheries Science Center
Dr. Paul R. Wade	NMFS – Alaska Fisheries Science Center
Dr. David W. Weller (Chairman)	NMFS – Southwest Fisheries Science Center

In addition to the TF, a number of agency scientists and NMFS affiliates (e.g., post-docs, contractors, etc.) attended the workshop to observe and provide information. These participants included: Eric Archer (SWFSC), Lisa Ballance (SWFSC), Laurie Beale (NOAA General Counsel), Jim Carretta (SWFSC), Donna Darm (NWR), Kirsten Erickson (NOAA General Counsel - by phone), Jason Foreman (NOAA General Counsel), Annette Henry (SWFSC), Aimee Lang (SWFSC), Karen Martien (SWFSC), Sarah Mesnick (SWFSC), Phil Morin (SWFSC), Vicki Pease (SWFSC), Bill Perrin (SWFSC), Wayne Perryman (SWFSC) and Steve Stone (NWR). At the request of the TF, several of these participants provided valuable information to the workshop in the form of expert knowledge, presentations and/or written documents. Aimee Lang and Annette Henry generously agreed to serve as workshop rapporteurs.

The agenda for the workshop was circulated amongst the TF for input in advance of the meeting (Appendix 1). It was agreed, however, that the agenda would serve to guide the workshop proceedings but be viewed as flexible so as not to constrain discussion. Documents for the workshop were made available on a file sharing website. Appendix 2 provides a list of the workshop documents available for review and consideration by the TF in preparation for the workshop.

1.1 Workshop objectives

NMFS presently recognizes a single stock of gray whales (*Eschrichtius robustus*) in U.S. waters that is referred to as the eastern North Pacific (ENP) stock (Carretta *et al*. 2013). New information, however, suggests the possibility of recognizing two additional stocks of gray whales in U.S. waters, including: (1) the Pacific Coast Feeding Group (PCFG) - defined as whales observed between 1 June to 30 November within the region between northern California and northern Vancouver Island (from 41°N to 52°N) and photo-identified within this area during two or more years (see section 3.3), and (2) western North Pacific (WNP) gray whales - defined as whales observed feeding during summer and fall off Sakhalin Island, Russia, and other areas in the WNP (see section 3.2). The main objective of the TF was to provide scientific advice regarding gray whale stock structure using the definitions given in the GAMMS guidelines (NMFS 2005; see also Moore and Merrick 2011). More specifically, the TF was convened to provide advice on two questions: (1) *Is the PCFG a "population stock" under the MMPA and GAMMS guidelines?*, and (2) *Is the WNP stock a "population stock" under the MMPA and GAMMS guidelines?* Both of these questions have immediate management implications, including: (1) how future NMFS stock assessment reports (SAR) will address gray whale stock structure in the North Pacific, and (2) how to interpret any new information in the context of the Makah Indian Tribe's MMPA waiver request to resume hunting gray whales off Washington State, USA.

1.2 Workshop relationship to stock assessment reports

At the request of the TF, Carretta (SWFSC) summarized the relationship of the workshop to future gray whale stock assessment reports (SARs). The current eastern North Pacific gray whale SAR (Carretta *et al*. 2013) provides a summary of present knowledge but is expected to evolve based on the input received at this workshop as well as from input from the scientific review groups (SRG)[1], NWR and OPR. The TF expected that the outcome of the workshop would influence how the SAR is structured in the future, including how various data sources (i.e., genetics, movements, distribution) are evaluated for future stock designation. The workshop report will also serve as a useful SRG background document on gray whale stock structure.

1.3 Workshop relationship to Makah waiver request

Newly available information from genetic, photo-identification and tagging studies suggests that more than one stock of gray whales may occur in U.S. waters (Lang *et al*. 2010; Frasier *et al.* 2011; Lang *et al.* 2011a; Lang *et al*. 2011b; Mate *et al*. 2011; Calambokidis *et al.* 2012; Weller *et al*. 2012). With that in mind, the TF requested that Darm (NWR) present a summary of the Makah Indian Tribe's request to hunt gray whales off northwest Washington State, USA.

The Makah's right to hunt whales is secured by the 1855 Treaty of Neah Bay, where the Makah ceded lands to the U.S. government but reserved the right to hunt, fish, seal and whale. The Ninth Circuit Court of Appeals decision in 2004 (Anderson v. Evans) held that for the Makah to exercise their right to hunt whales they must comply with the requirements of the MMPA. In 2005, the Makah requested authorization from NOAA/NMFS, under the MMPA and the Whaling Convention Act, to resume limited hunting of gray whales for ceremonial and subsistence purposes in the coastal portion of their usual and accustomed (U&A) fishing grounds off the coast of Washington State (NMFS 2008). The spatial overlap of the Makah U&A with the summer distribution of PCFG whales has management implications. The proposal by the Makah Tribe includes time/area restrictions designed to reduce the probability of killing a PCFG whale and to focus the hunt on whales migrating to/from feeding areas to the north.

The NWR was assigned responsibility for evaluating the Tribe's request under the MMPA and National Environmental Policy Act (NEPA) process. Section 101(a) of the MMPA imposes a

---

[1] Pursuant to Sec. 117 of the MMPA, independent scientific review groups, representing Alaska, and the Pacific and Atlantic coasts, were established in 1994. These groups consist of individuals with expertise in marine mammal biology and ecology, population dynamics and modeling, commercial fishing technology and practices, and stocks taken under section 101(b).

moratorium on the take of all marine mammals, although the statute provides for certain exemptions allowing the take of marine mammals. Section 101(a)(3)(A) allows for a waiver of the take prohibition; this exemption applies to a specific stock and is only authorized to the extent provided for in the waiver. Determination of whether the waiver will be granted must be made based on the best scientific information, in consultation with the Marine Mammal Commission, and with due regard to the distribution, abundance, breeding habits, and movements of the stock in question. For the waiver to be granted there must also be a finding that the requested take is in accord with sound principles of resources protection and conservation as provided for in the MMPA.

Unlike most rulemaking by the agency, this determination will entail a formal rulemaking process in which the agency presents evidence before an administrative law judge (ALJ) to support the rule. This process may involve presenting evidence on the status of relevant stocks, including their optimum sustainable population level (OSP)[2], and whether the stocks are at or below that level (i.e., depleted).

Although the NWR made substantial progress in evaluating the waiver request during the past few years, this progress had been slowed by: (1) new information pertinent to the question of whether the PCFG is a separate stock, and (2) the potential implications of movements of whales between the WNP and ENP. Therefore, the advice of the TF will provide a collective “best professional judgment” useful to the ongoing evaluation of the waiver by the NWR.

In discussion, the TF asked Darm if there would be a potential need to get more than one waiver to the MMPA if it was determined that three stocks of gray whales occur in U.S. waters (i.e., ENP, PCFG and WNP stocks). In that case, Darm replied that there would be some possibility of needing to request multiple exemptions (waivers). However, the need for a waiver would be informed by the likelihood of take and obtaining a waiver for WNP gray whales (if the group is recognized as a stock) is highly unlikely given that they are listed as endangered under the Endangered Species Act (ESA) and as such, would be considered depleted under the MMPA.

2. Overview of MMPA Language, GAMMS Guidelines and Related Key Concepts

From the outset of the workshop, the TF concurred that it was important to review the existing language of the MMPA and GAMMS with regard to the definition of “population stock”. In addition, it was also agreed important to discuss three key concepts inherent to defining a population stock, including: (1) “demographic independence”, (2) “interbreed when mature”, and (3) “functioning element of the ecosystem”.

Under the MMPA, population stock (used interchangeably with “stock” and “population” hereafter) is the fundamental conservation unit. The MMPA (Sec. 3) defines population stock as: “*a group of marine mammals of the same species or smaller taxa in a common spatial arrangement, that interbreed when mature.*” The purposes and polices underlying the stated definition, as follows, are found in Sec. 2(2) and Sec. 2(6) of the MMPA:

---

[2] The maximum net productivity level is described in the National Marine Fisheries Service's definition of "optimum sustainable population" (OSP) (50 CFR 216.3) as the abundance level that results in the greatest net annual increment in population numbers or biomass resulting from additions to the population due to reproduction and/or growth less losses due to natural mortality. Under the U.S. Marine Mammal Protection Act, populations above MNPL are considered to be at OSP; populations below MNPL can be designated as ‘depleted’ and are afforded a greater level of protection.

(1) *"[marine mammal] species and population stocks should not be permitted to diminish beyond the point at which they cease to be a significant functioning element in the ecosystem of which they are a part, and, consistent with this major objective, they should not be permitted to diminish below their optimum sustainable population."*

(2) *"… the primary objective of their management should be to maintain the health and stability of the marine ecosystem."*

Acknowledging the above definitions and objectives of the MMPA, the TF then considered the related guidelines contained in the "Definition of Stock" section of the GAMMS guidelines (NMFS 2005):

(1) *"For the purposes of management under the MMPA, a stock is recognized as being a management unit that identifies a demographically isolated biological population."*

(2) *"Demographic isolation means that the population dynamics of the affected group is more a consequence of births and deaths within the group (internal dynamics) rather than immigration or emigration (external dynamics). Thus, the exchange of individuals between population stocks is not great enough to prevent the depletion of one of the populations as a result of increased mortality or lower birth rates."*

The TF noted that within the broader field of population biology, the term "isolation" generally implies little or no exchange (emigration or immigration of individuals) between stocks and is a criterion commonly used to distinguish taxonomic units higher than that of a population (e.g., species, subspecies). In contrast, the GAMMS guidelines and definition of stock clearly allow for the "*exchange of individuals between population stocks"* (NMFS 2005), a distinction more in line with use of the term "demographic independence" rather than "demographic isolation". The use of the term "independence" as opposed to "isolation" is potentially confusing and has been noted by a number of NMFS reviewers and workshops (Eagle *et al*. 2008). To avoid this confusion, Eagle *et al*. (2008) suggested that the term "demographic isolation" be replaced by "demographic independence".

Moore (SWFSC) provided the TF with an overview of the GAMMS III workshop, convened by NMFS in February 2011, which also noted the potential confusion over the use of "isolation" as opposed to "independence". The GAMMS III workshop recommended revising the SAR guidelines to reflect that the intent of the GAMMS II guidelines (NMFS 2005) was to base stock identification on demographic independence as noted in Eagle *et al.* (2008) and proposed that the term demographic isolation be replaced with "demographic independence" as follows:

(1) *"For the purposes of management under the MMPA, a stock is recognized as being a management unit that identifies a demographically independent biological population."*

(2) *"Demographic independence means that the population dynamics of the affected group is more a consequence of births and deaths within the group (internal dynamics) rather than immigration or emigration (external dynamics). Thus, the exchange of individuals between population stocks is not great enough to prevent the depletion of one of the populations as a result of increased mortality or lower birth rates."*

In other words, the participants at the GAMMS III workshop viewed this as a semantic issue where the term demographic independence is a better description for the current GAMMS guidelines definition than is the term demographic isolation.

2.1 Discussion of "demographic independence"

This interpretation of "isolation" differs substantively from how it is used within the GAMMS guidelines definition above, wherein allowance is made for some level of exchange of individuals between stocks. The TF concurred that in spite of using the term "isolation", the actual definitions under the current GAMMS guidelines (see above) are more consistent with MMPA objectives to protect population stocks than with the objective of protecting just subspecies and species.

Given that the draft GAMMS guideline revisions from the GAMMS III workshop have not yet been formally approved, the TF agreed to use the current GAMMS guidelines definition (NMFS 2005) for the purposes of their discussions and deliberations but noted that the actual definition used in the two versions (for demographic isolation and demographic independence) is essentially the same in that neither implies true "isolation" within the context of the MMPA.

2.2 Discussion of "interbreed when mature"

Bettridge (OPR) presented a brief overview of relevant language under the MMPA and GAMMS guidelines pertaining to NMFS interpretation of "interbreed when mature". She explained that the draft second revision to the SAR guidelines (from the GAMMS II workshop held in Seattle in 2003) included a definition of interbreed when mature. This term was interpreted to mean cases in which either:

(1) "*mating occurs primarily among members of the same demographically isolated group*"

or

(2) "*the group migrates seasonally to a breeding ground where its members breed with members of the same group as well as with members of other demographically distinct groups which have migrated to the same breeding ground from a different feeding ground.*"

When comments were solicited on the draft GAMMS II guidelines (69 FR 67541, 18 November 2004), the Marine Mammal Commission (MMC) supported the aforementioned interpretations, but suggested that a more rigorous analysis was needed of how the revisions fit with the language of the MMPA. Additionally, the MMC stated that NMFS should develop criteria for applying the modified guidelines to determine when a population is demographically isolated to an extent that it is a discrete group that warrants recognition as a separate stock.

In its response to comments on this issue (70 FR 35397, 20 June 2005), NMFS stated that public comments were sufficient to raise questions about the proposed interpretation, and the agency removed the proposed text pertaining to "interbreed when mature" from the final GAMMS II guidelines.

Subsequent NMFS review and consultation with MMC staff and NOAA General Counsel suggest that the GAMMS II workshop definition of "interbreed when mature" is consistent with NMFS GAMMS guidelines and the review undertaken in Eagle *et al.* (2008, see below). In those forums NMFS has consistently interpreted a population stock not as one that is completely reproductively isolated but rather as something less restrictive.

Regarding the MMC request for scientific criteria for how much interbreeding would be consistent with the proposed GAMMS II guidelines definition, the TF noted that specific quantitative criteria would be impractical to apply consistently across all contexts of uncertain stock definition and that determining whether a population is demographically independent or an isolated unit would likely have to be conducted on a case-specific basis. Some TF members felt that the “interbreed when mature” component of the MMPA definition of stock should merely be viewed as a necessary but not sufficient criterion for defining a stock. In other words, individuals “in a common spatial arrangement” would not constitute a stock unless there is some interbreeding (satisfying the need criterion), but this would not preclude individuals of a stock from also breeding with members of other stocks.

For the purposes of the workshop, the TF agreed they would continue to interpret “interbreed when mature” consistent with “demographic independence” as suggested by Eagle *et al*. (2008) and GAMMS II (NMFS 2005), with the minor change of “isolation” being replaced with “independence”.

2.3 Discussion of “functioning element of the ecosystem”

Sec. 2 of the MMPA states that marine mammals are “resources of great international significance, esthetic and recreational as well as economic” and “that the primary objective of their management should be to maintain the health and stability of the marine ecosystem”. The TF therefore considered whether the functioning element of the ecosystem criteria is aesthetically or ecologically based (or both) but no clear resolution on how to best define functioning element of the ecosystem was reached by the TF.

The TF then focused its discussion on defining the ecosystem and appropriate scale of management with respect to gray whales. The TF agreed the matter was complex given the species’ seasonal use of different ecosystems. In general, the TF agreed that the Chukotka Peninsula/Bering Strait feeding areas were not part of the same ecosystem as that found off the Pacific Northwest and used by the PCFG. In discussion of this concept, it was noted by some TF members that even for the largest-scale classification system for marine ecosystems (Longhurst 1998, discussed in Moore and Merrick 2011), it could be argued that the PCFG is in a different ecosystem than other gray whales. Other TF members pointed out, however, that this was only true for part of the year, and that the interpretation was complicated because non-PCFG animals migrate through the area defined for PCFG whales and, in some cases, may feed there in a given year but not return in a subsequent year.

2.4 Additional information on the definition of “population” for marine mammals

In addition to applying the MMPA language and GAMMS guidelines definitions, the TF considered two documents relevant to the question of stock definition under the MMPA. In the first (Taylor 1997), simulation analyses were used to explore the potential consequences, in terms of the risk of violating MMPA ecosystem function objectives, of defining a population stock as a unit akin to an evolutionarily significant unit or reproductively isolated group. Briefly, this analysis considered scenarios in which a single reproductively isolated population was distributed as a network of discrete groups occupying distinct habitat areas throughout its range, with some level of dispersal between discrete groups. The major analytical finding was that, if allowable human caused mortality (HCM) for the entire population (i.e., sum of all discrete groups) were to act disproportionately on certain groups, those groups could be extirpated, depending on whether the amount of immigration from other groups was below a certain dispersal rate threshold (which varied with simulation conditions). In conclusion, to achieve MMPA objectives of maintaining marine mammals as “functioning elements of their ecosystem”, distinct groups should be managed as separate stocks if their connectivity to other groups via dispersal is low, although how low is context specific.

Taylor (1997) provides several examples (Figure 1) where localized removals lead to local extirpation which arguably violates the ecosystem goals of the MMPA. For all of the models tested, when dispersal fell below a few percentage of the population per year, recruitment into the population with HCM was insufficient to compensate for removal, and population levels declined below those sought by management objectives. Therefore, populations should be managed separately if dispersal between them is less than several percent per year.

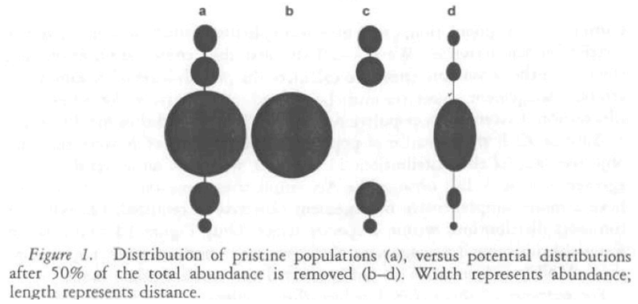

Figure 1. Distribution of pristine populations (a), versus potential distributions after 50% of the total abundance is removed (b–d). Width represents abundance; length represents distance.

Figure 1. Original figure from Taylor (1997).

Taylor (SWFSC) cautioned the TF, however, that it is impossible to have a "one number fits all" criterion and that a better approach would be to have an objective that states what is important in terms of maintaining the extent and connectivity of the range. There are some cases where it is obvious that a stock is no longer a functioning element of its ecosystem, such as example C in Figure 1 where the large central group is extirpated. Extirpation of the PCFG would be more analogous to removing one of the smaller groups outside of the main group (e.g., example B). Further discussion is needed to better define the intent of the MMPA with respect to maintaining marine mammals within different parts of their range.

The second document discussed by the TF, as pertains to the agency's definition of population stock, was the report of a 2006 workshop entitled "Conservation Units of Managed Fish, Threatened or Endangered Species, and Marine Mammals" (Eagle *et al.* 2008). This workshop was convened by NMFS with the objective of bringing together scientists, managers and policy advisers to discuss differences and recommend revisions to how NMFS defines units to conserve under three statutes – the MMPA, ESA and Magnuson-Stevens Act (MSA). The workshop sought to address two overarching questions: (1) why are conservation units different under the three statutes? and (2) is there a biological paradigm that can be used to explain the differences?

In brief, it was agreed by the participants of the 2006 workshop that the differences in how NMFS defines conservation units under the three statutes are appropriate given the differing objectives of the three laws. Under the ESA, major objectives are to prevent *species* extinction and preserve evolutionary potential. Thus, conservation units under this Act should be substantially reproductively isolated. Under the MMPA, objectives correspond to maintaining population and ecosystem goals. Therefore, conservation units align with demographically independent units (DIPs), which are demographically discrete from other populations but not necessarily genetically discrete due to a low but sufficient degree of interbreeding between them. Participants of the 2006 workshop concluded that while the GAMMS guidelines "*…clearly support the use of DIPs as stocks of marine mammals […] the MMPA does not indicate to what extent breeding should occur within a stock instead of among stocks*" and that future revisions to the GAMMS guidelines "*should, therefore, include a rationalization for recognizing DIPs as stocks in cases where males from one stock may breed with females from the same and other stocks*".

There was discussion amongst the TF regarding where to reasonably draw the line in defining small stocks, given that for some marine mammal species very small groups of animals could be considered DIPs. For example, individual pods of killer whales (*Orcinus orca*) could potentially be considered demographically independent. However, other TF members noted that the intent of the GAMMS guidelines was not to recognize very small population units – such as individual killer whale pods or a small group of animals occupying a small habitat fragment – as population stocks. It was similarly suggested that other criteria besides demographic independence, such as whether the unit can be considered a significant functioning element of the ecosystem, should also be considered in defining stocks. The TF understood that most biological "populations" and "stocks" do not exist as truly distinct groups, nor are individuals within the same population typically part of a truly panmictic group (Waples and Gaggiotti 2006). Rather, population differentiation occurs along a continuum, and placing discrete boundaries along this continuum for management purposes is a challenge. The TF acknowledged that marine mammal social structure can further complicate determining whether a unit should be considered demographically independent. In these areas of uncertainty, decisions will likely be case specific, and ultimately rely on scientific judgment and the factors identified for consideration in the MMPA and GAMMS guidelines.

The TF considered the report by Eagle *et al.* (2008) and the recommendations from that workshop as support for the NMFS interpretation of "interbreed when mature" as one that includes cases where individuals interbreed primarily within their stock but occasional interbreeding amongst stocks may occur and agreed to use such as the operational definition for the purposes of their work.

3. Overview of Eastern, Western and Pacific Coast Feeding Group Gray Whales

Like many species of baleen whales, gray whales exhibit seasonal movements between high-latitude summer feeding grounds and low- latitude wintering areas. The current distribution of this species is limited to the North Pacific, where a small western population (<150 individuals) and a much larger eastern population (~19,000 individuals) are recognized.(Reilly *et al.* 2008).

Lang (SWFSC) presented a brief overview of information on the biology of ENP, WNP, and PCFG gray whales. The purpose of this overview was not to discuss gray whale stock structure in detail but rather to provide a summary of relevant background information.

3.1 Eastern North Pacific (ENP) gray whales

During summer and fall most ENP whales feed in the Chukchi, Beaufort and northwestern Bering Seas (Figure 2). An exception is the relatively small number (100s) of whales that summer and feed along the Pacific coast between Kodiak Island, Alaska and northern California (Darling 1984; Calambokidis *et al.* 2002; 2012; Gosho *et al.* 2011). By late November, the southbound migration of the ENP stock is underway as whales begin to travel from summer feeding areas to winter calving areas off the west coast of Baja California, Mexico (Rugh *et al.* 2001; Swartz *et al.* 2006). The southbound migration is segregated by age, sex and reproductive condition (Rice and Wolman 1971). The northbound migration begins about mid-February and is also segregated by age, sex and reproductive condition.

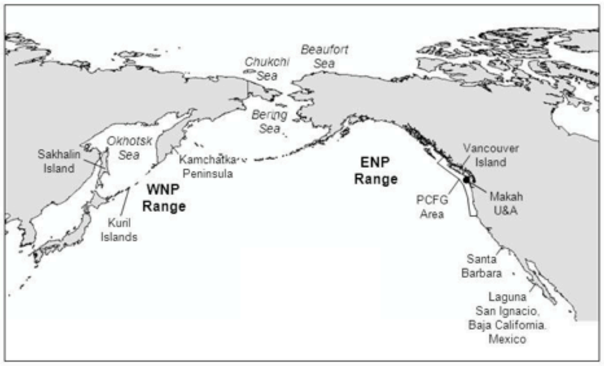

Figure 2. Geographic range of ENP, WNP and PCFG whales. In summer, WNP whales are typically found in feeding areas off the coasts of Sakhalin Island and the Kamchatka Peninsula, in Russia. Most ENP whales are typically found in summer north of St. Lawrence Island (in the northern Bering Sea), including the Bering Strait, the Chukotka Peninsula in Russia, the Chukchi Sea, and along the Beaufort Sea coast (north slope) of Alaska. Additional summer ENP feeding areas include Kodiak, AK, and areas between Southeast Alaska and Northern California. ENP whales migrate to the Baja Peninsula, Mexico in the autumn and return to feeding areas in the spring. The region used by the PCFG is defined to be the area between northern California and northern Vancouver Island (from 41°N to 52°N).

Gray whale breeding and calving are seasonal and closely synchronized with migratory timing. Sexual maturity is attained between 6 and 12 years of age (Rice 1990; Rice and Wolman 1971). Gestation is estimated to be 13 months, with calving beginning in late December and continuing to early February (Rice and Wolman 1971). Some calves are born during the southbound migration while others are born near or on the wintering grounds (Shelden *et al.* 2004). Females produce a single calf, on average, every 2 years (Jones 1990). Calves are weaned and become independent by six to eight months of age while on the summer feeding ground (Rice and Wolman 1971). Three primary calving lagoons in the ENP are utilized during winter, and some females are known to make repeated returns to specific lagoons (Jones 1990).

The abundance of the ENP population, which includes the PCFG, is presently estimated to be about 19,000 whales (Laake *et al.* 2012). The potential biological removal (PBR) level for the ENP stock of gray whales is calculated as the minimum (20th percentile) estimate of population size, times one-half of the maximum theoretical net population growth rate (½ x 6.2% = 3.1%), times a recovery factor of 1.0 for a stock above its maximum net productivity level (MNPL) (Punt and Wade 2012). The minimum population estimate (N_{MIN}) for the ENP stock is calculated from Equation 1 from the PBR Guidelines (Wade and Angliss 1997): $N_{MIN} = N/\exp(0.842\times[\ln(1 + [CV(N)]^2)]^{1/2})$. Using the 2006/07 abundance estimate of 19,126 and its associated CV of 0.071, N_{MIN} for this stock is 18,017. Therefore, PBR is 558 animals. A recent analysis conducted by Punt and Wade (2012) estimated a probability of 0.884 that the ENP gray whale stock is above its MNPL, which means there is a 0.884 probability that it is at its OSP as defined by the MMPA.

Genetic studies suggest some sub-structuring may occur on the wintering grounds, with significant differences in mitochondrial DNA (mtDNA) haplotype frequencies found between females (mothers with calves) utilizing two of the primary calving lagoons and females sampled in other areas (Goerlitz *et al.* 2003). Other research, employing both mtDNA and microsatellites, identified significant departure from panmixia between two of the lagoons using nuclear data, although no significant differences using mtDNA were observed (Alter *et al.* 2009). Significant mtDNA and nuclear (nDNA) genetic differences have been found between whales in the WNP and those in the ENP (LeDuc *et al*. 2002; Lang *et al.*, 2011b).

In discussion, the TF agreed that the information presented by Lang represented an up to date overview of the ENP population and had no follow up questions.

3.2 Western North Pacific (WNP) gray whales

Information on the distribution and migration patterns of gray whales in the WNP is incomplete. There is no doubt that the historical distribution of gray whales in the Okhotsk Sea once greatly exceeded what is found at present (Reeves *et al*. 2008). Today, the main feeding ground is in the Okhotsk Sea off the northeastern coast of Sakhalin Island, Russia (Figure 2) but some animals also occur off eastern Kamchatka and in other coastal waters of the northern Okhotsk Sea (Weller *et al.* 2002; Vertyankin *et al.* 2004; Tyurneva *et al.* 2010). Whales associated with the Sakhalin feeding area can be absent for all or part of a given feeding season (Bradford *et al.* 2008), indicating they probably use other areas during the summer and fall feeding period. For example, some whales observed off Sakhalin have been sighted off the northern Kuril Islands in the eastern Okhotsk Sea and Bering Island in the western Bering Sea (Weller *et al*. 2003).

The WNP migration route(s) and winter breeding ground(s) are poorly known (Weller *et al*. 2002; Weller and Brownell 2012). Information collected over the past century indicates that whales migrated along the coasts of Japan and South Korea (Andrews 1914; Mizue 1951; Omura 1984) to wintering areas somewhere in the South China Sea, possibly near Hainan Island (Wang 1984). At present, observations of gray whales off Japan are rare. Nambu *et al*. (2010) reported 13 known sighting or stranding records in Japanese waters between 1990 and 2007. Between 2005 and 2007, four female gray whales were fatally entrapped in set nets along the Pacific coast of Honshu, Japan. One of these females, entrapped in January 2007, was matched to earlier photographs of it as a calf (with its mother) while on the Sakhalin feeding ground in July and August 2006 (Weller *et al*. 2008). This match provided the most contemporary link between the summer feeding ground off Sakhalin and a winter location along the coast of Asia. More recently, in March 2012 a gray whale was sighted and photographed in Mikawa Bay (Aichi Prefecture), east of Ise Bay near Nagoya on the Pacific coast of Honshu (Japan Times, 3 May 2012).

Observations of gray whales in China are also exceptionally rare. Although 24 capture, sighting or stranding records exist since 1933 (Wang 1984; Zhu 2002), including observations of two mother-calf pairs, some of these (especially the sightings) have not been reported in sufficient detail to validate species identification. More recently, an 11.5 m female stranded live at Zhuanghe (Bohai Sea ca. 39˚N) in December 1996 (Zhao 1997) and a 13 m female gray whale was taken in fishing gear offshore of Baiqingxiang (Pingtan County), in the Taiwan Strait in November 2011 (Zhu 2012). The last known sighting of a gray whale off Korea was in 1977 (Park 1995).

The WNP gray whale population is redlisted by the IUCN as Critically Endangered. The most recent population assessment (for 2012), using a Bayesian individually-based stage- structured model, resulted in a median 1+ (non-calf) estimate of 155 individuals, with 95% CI = 142-165 (IUCN 2012). A collaborative Russia-U.S. research program on WNP gray whales summering off northeastern Sakhalin Island, Russia, has been ongoing since the mid-1990s. When data collected between 1994-2011 are combined, a catalog of 200 photo-identified individuals has been compiled. Beginning in 2002, photo-identification studies off Sakhalin have also been conducted by Russia scientists working with oil and gas companies (Tyurneva *et al*. 2010). This research largely corroborates the work of the Russia-U.S. team and in some cases collaborative analyses utilizing combined datasets have been conducted.

Recently, results from photo-identification (Urbán *et al.* 2012; Weller *et al.* 2012), genetic (Lang 2010; Lang *et al.* 2011b), and telemetry studies (Mate *et al.* 2011) have documented spatial and temporal overlap between WNP and ENP gray whales. Observations of such overlap include: (1) six whales photographically matched from Sakhalin Island to southern Vancouver Island, (2) two whales genetically matched from Sakhalin to Santa Barbara, California, (3) 13 whales photographically matched from Sakhalin Island to San Ignacio Lagoon, Mexico, and (4) 2 satellite tagged whales that migrated from Sakhalin Island to the west coast of North America. In combination, these studies have recorded a total of 23 gray whales observed in both the WNP and ENP. Despite this overlap, significant mtDNA and nDNA differences are found between whales in the WNP and those summering in the ENP (Lang *et al.* 2011b). Although it is clear that some whales feeding off Sakhalin Island during the summer/fall migrate to the west coast of North America during the winter/spring, past and present observations of gray whales in the WNP off Japan, Korea and China during the winter/spring suggest that not all gray whales in the WNP share a common wintering ground (Weller and Brownell 2012).

In discussion, the TF agreed that the occurrence of WNP gray whales in U.S. waters presented previously unexpected implications with respect to the SAR process and the Makah waiver request. More specifically, two questions were discussed at length, including: (1) given the occurrence of WNP gray whales in U.S. waters, is a WNP gray whale SAR required? and (2) given the potential occurrence of WNP gray whales in the proposed Makah hunt area, what are the implications regarding the existing wavier request?

TF members also noted that these new findings of gray whales moving between Sakhalin Island and the ENP had significance to our understanding of the status of gray whales in the WNP. That is, given that some of the whales sighted off Sakhalin appear to overwinter in the ENP, the number of animals remaining in the WNP year-round may be much smaller and of greater conservation concern than is currently recognized (Weller and Brownell 2012).

3.3 Pacific Coast Feeding Group (PCFG)

Gray whales using the Pacific Northwest area during summer and autumn include two components: (1) whales that return frequently and account for most of the sightings between 1 June and 30 November, and (2) whales that are sighted only in one year, tend to be seen for shorter time periods in that year, and are encountered in more limited areas. For the purposes of their work to evaluate the proposed Makah Indian Tribe gray whale hunt, the International Whaling Commission (IWC) defined PCFG gray whales as: whales observed between 1 June to 30 November within the region between northern California and northern Vancouver Island (from 41°N to 52°N) and photo-identified within this area during two or more years (IWC 2011; IWC 2012a). This same definition has been adopted in the analyses of Calambokidis *et al.* (2012). In this report, the TF defines "PCFG whales" following the IWC definition.

Recent research has provided new information on movements and habitat utilization of PCFG whales (for example Frasier *et al.* 2011; Lang *et al.* 2011a; Calambokidis *et al.* 2012). While PCFG whales are known to feed during summer and fall off the Pacific coast between northern California and southeastern Alaska, they also occasionally occur as far north as Kodiak (Gosho *et al.* 2011) and Barrow, Alaska (Calambokidis *et al.* 2012). The sighting from Barrow suggests that some PCFG whales (meaning whales seen in summer in the defined area used by the PCFG and in more than one year), at least occasionally occur in one of the most northern gray whale feeding areas in the ENP (Calambokidis *et al.* 2012). Similarly, of the 121 whales identified off Kodiak from 1998-2010, there have been 30 sightings of 17 individuals between June-November in areas extending from northern California to northern British Columbia (Table 9, Calambokidis *et al.* 2012). These observations indicate that at least some PCFG whales have used both the Kodiak feeding area in addition to the 41°N to 52°N area defined for the PCFG.

Satellite tagging studies between 3 September and 4 December 2009 off Oregon and California provide additional movement data for whales considered to be part of the PCFG (Mate *et al.* 2010). While duration of tag attachment differed between individuals, some whales remained in relatively small areas within the larger PCFG seasonal range while others traveled more widely. All six individuals whose tags continued to transmit through the southbound migration utilized the wintering area within and adjacent to Laguna Ojo de Liebre (Scammon´s lagoon). Three whales were tracked north from Ojo de Liebre and displayed the following movement patterns: (1) one whale traveled at least as far as Icy Bay, Alaska, and (2) two whales were tracked to coastal waters off Washington (Olympic Peninsula) and California (Cape Mendocino). In combination, satellite tag and photo-identification data suggest that the range of the PCFG may, at least for some individuals, exceed the pre-defined 41°N to 52°N boundaries that have been used in a number of PCFG-related analyses (e.g., abundance estimation).

Further support of the PCFG range extending beyond the pre-defined 41°N to 52°N boundaries comes from a study of six whales satellite tagged off the central west coast of Vancouver Island in March. This study was designed to determine northern migration routes in the greater Vancouver Island area (Ford *et al.* 2012). Three of the tagged whales had been previously sighted within the seasonal range used by PCFG whales (41°N to 52°N) and two had multi-year sighting histories there. These three whales moved north to between ~55°N to 57° N before their tags stopped transmitting. One of these whales was later observed in the seasonal range of the PCFG off southern Vancouver Island. These findings suggest that in the spring at least some PCFG whales may migrate northward, past the defined seasonal range used by the PCFG, along with the larger ENP stock before “circling back” to within the range of the PCFG summer feeding area.

It is unknown how long gray whales have used the PCFG area in summer and autumn; it may have been colonized as recently as the last century or during the Little Ice Age (~1540-1850) or other glacial periods when it was difficult or impossible for gray whales to feed further north. Records of gray whales feeding between northern California and Alaska during summer/fall date back to at least 1926 (Howell and Huey 1930), including reports of whales feeding on the southern feeding ground during the 1940s, 1950s, and 1960s (Gilmore 1960; Pike and MacAskie 1969; Rice and Wolman 1971). The consistent return of individuals to the southwestern coast of Vancouver Island, British Columbia, was first documented in the early 1970s (Hatler and Darling 1974).

A unique characteristic of PCFG whales is an apparent flexibility in their feeding habits. That is, whales summering in the seasonal range of the PCFG consume a varied diet including mysids, amphipods, crab larvae, and herring eggs/larvae. This is in contrast (generally speaking) to gray whales feeding in the arctic where they seem to be more focused on an amphipod food base (Nerini 1984). That being said, whales that utilize the seasonal range of the PCFG in only a single year (i.e., non-PCFG whales) must also be flexible, at least to some degree, in their feeding habits.

Abundance estimates of PCFG gray whales reported by Calambokidis *et al.* (2012) show a high rate of increase in the late 1990s and early 2000s, but have been relatively stable, albeit with some decline, since about 2003. No statistical analysis of trends in abundance is currently available for this population. The PCFG is estimated to contain about 200 individuals (Calambokidis *et al*. 2012). As stated in the 2012 gray whale SAR "because the PCFG appears to be a distinct feeding aggregation and may warrant consideration as a distinct stock in the future, a separate PBR was calculated" (Carretta *et al*. 2013). Calculation of a PBR for the PCFG allows NMFS to assess whether levels of HCM are likely to cause local depletion of this group. In keeping with that management objective, NMFS used the 2008 abundance estimate of 194 (SE = 17.0)[3] from Calambokidis *et al*. (2010) and the range of the PCFG (between 41°N to 52°N) as defined by the IWC to calculate a potential PBR for PCFG whales (Carretta *et al*. 2013). This calculation used the minimum population size (180 animals), times one half the maximum theoretical net population growth rate (½ x 6.2% = 3.1%), times a recovery factor of 0.5 (for a population of unknown status), resulting in a PBR of 2.8 animals (NMFS 2012). Further, a review of annual HCM in the PCFG between 2006 and 2010 was estimated and averaged 0.6 animals/year known deaths (Carretta *et al*. 2013).

In discussion, the TF asked Lang if there was any evidence that oceanographic changes have influenced the abundance or recruitment of whales into the PCFG. Lang replied that Calambokidis *et al.* (2012) reported a higher than usual "pulse" of animals recruited into the PCFG in the years following the 1999-2000 gray whale Unusual Mortality Event (UME). This UME has been theorized to be the result of limited food resources on the northern feeding grounds (see Gulland *et al.* 2005), and as such, this "pulse" of gray whale immigration[4] into the PCFG could potentially be considered a response to oceanographic changes. Given that the photo-identification effort on PCFG whales expanded greatly in 1998 (data from years prior to 1998 exist but not at the same level of effort), coinciding closely in time with the UME, it makes it impossible to resolve with certainty the occurrence or magnitude of the hypothesized pulse recruitment.

In response to the observations of PCFG whales in northern areas such as Kodiak and Barrow, Alaska, some members of the TF asked why the boundaries of the PCFG area defined by the IWC were not extended further north? The TF noted that the IWC definition was not intended to define the stock but rather to provide a conservative basis on which to evaluate the gray whale hunt proposed by the Makah Indian Tribe. With respect to low survey effort north of 52°N, the TF agreed that the PCFG could have a higher abundance than currently estimated and that this might affect a number of analyses including determination of annual sighting patterns of individual whales (e.g., a PCFG whale may have been present in a larger area but not photographed because it was located in an region not surveyed). The TF concurred that these issues are important to assignments of PCFG whales (i.e., those seen in two or more years between 41°N and 52°N) and highlighted the importance of expanding the spatial and temporal coverage of the photo-identification effort. In addition, further satellite tagging of known PCFG whales would also help to better define habitat use and delineate the seasonal feeding range.

Additional discussion was devoted to addressing the possibility that HCM (e.g., ship strikes and commercial fisheries bycatch) for whales in the PCFG area could be higher than for whales that migrate through the area. That is, PCFG whales spend more time near shore where ship traffic and fishing gear are concentrated. Despite this concern, little information is available on where

---

[3] This estimate will be updated in the 2013 SAR to include the now available 1999-2010 time series presented in Calambokidis *et al*. (2012).

[4] Immigration, as used here, means a permanent change of feeding ground fidelity and is considered interchangeable with "external recruitment".

HCM actually occurs. The TF asked Carretta how whales were classified as being PCFG in his analysis. He replied that the estimate was based on NMFS stranding data for the most recent 5-year period and included whales that stranded within the defined PCFG time period (1 June and 30 November) and range (41°N to 52°N). Carretta noted that his estimate of 0.6 animals/year, based on only the most current 5-year period (as per protocol of the SAR guidelines), is lower than the 20-year average of 1.5 animals/year reported elsewhere (IWC 2012a). The TF agreed that both of these estimates of HCM for the PCFG were likely to represent minimum estimates because there is no correction for incidents that go unobserved or unreported.

Related to the issue of HCM, the TF also discussed the results presented in Connor *et al.* (2011), which found that PCFG whales had higher rates of scarring than other gray whales. It was noted that crab pots are common off the Washington and Oregon coasts and as such may pose an increased threat in some parts of the PCFG range. Carretta noted that when looking through the HCM records, a fair number of southern California crab pot interactions were reported, which suggests that fisheries interactions of this nature could be a pervasive issue along the coast. The TF noted that PCFG animals could have more interactions (compared to non-PCFG whales) with crab pots and coastal fishing gear given their extended residency in nearshore areas. Therefore, the TF recommended that the existing photo-identification time series be used to examine scarring patterns of PCFG whales to possibly provide a better assessment of their interactions with fishing gear.

4. Population Dynamics of the Pacific Coast Feeding Group

Laake (AFSC) provided a summary of information regarding the PCFG (following the IWC definition) based on photo-identification research as described in Calambokidis *et al.* (2012). Photo-identification studies from 1998 to 2010 between northern California and northern British Columbia have categorized gray whales using that region during summer and autumn in two components: (1) whales that frequently return to the area, are seen in more than one year between 1 June and 30 November, and account for most of the sightings during that time period, and (2) whales that are sighted only in one year, tend to be seen for shorter time periods in that year, and are encountered in more limited areas.

4.1 Definition of Pacific Coast Feeding Group whales based on timing and area

Defining the PCFG involves analysis that spans both time and space. The temporal component of the PCFG range is better defined than the spatial component, but neither can be considered absolute. As mentioned previously, the IWC defines the PCFG as: gray whales observed between 1 June to 30 November within the region between northern California and northern Vancouver Island (from 41°N to 52°N) and photo-identified within this area during two or more years (IWC 2012a). The spatial boundaries of the PCFG range under the IWC definition were chosen for the following reasons: (1) samples used for the genetic analyses were taken from whales across this range, (2) the work of Calambokidis *et al.* (2012) showed movements of whales throughout the area (Figure 3), (3) only a small number of PCFG whales have been observed north or south of the area during the 1 June to 30 November time period, and (4) few if any whales are still migrating north through the 41°N to 52° N region from 1 June to 30 November. The temporal definition (1 June to 30 November) was based, in part, on the disparity in sighting rates across months. Whales observed after 1 June were more likely to be sighted (i.e., photographed) more than one time, in more than one year, and in more than one region (Figure 4).

In discussion, the TF asked whether the results presented in Figure 3 were effort-corrected. Laake explained that the proportions are only dependent on the effort in the region from the Makah U&A to Southern Vancouver Island (SVI) and not in the other areas. Variation in effort in areas outside of the Makah U&A-SVI region will change the sample size that could be detected in the Makah U&A-SVI but not the proportion of individuals resighted in the Makah U&A-SVI.

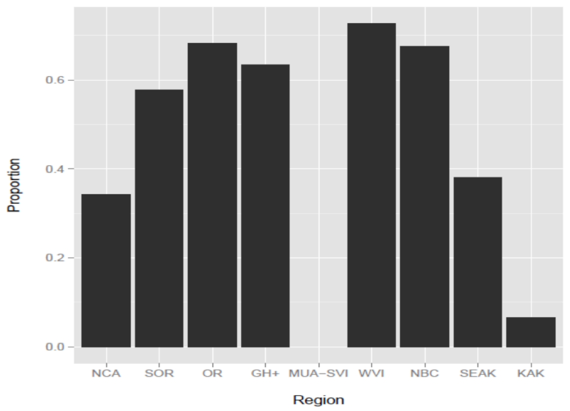

Figure 3. Proportion of whales sighted in the MUA-SVI region of whales seen in the identified areas. MUA and SVI were collapsed due to their proximity and high exchange rate. NCA = Northern California, SOR = Southern Oregon, OR = Central Oregon, GH+ = Gray's Harbor and surrounding coastal waters, MUA-SVI – Makah Usual and Accustomed Area to Southern Vancouver Island, WVI = West Vancouver Island, NBC = Northen Vancouver Island and coastal areas of British Columbia, SEAK = Southeast Alaska, KAK = Kodiak, Alaska.

The spatial range of PCFG whales was then discussed by the TF, including apparent gaps in survey coverage. Surveys in the seasonal range of the PCFG tend to focus on regions where gray whales have been seen and so the surveys are not randomly designed to cover the entire possible range. There is a large gap in survey effort north of 52° N (i.e., between northern Vancouver Island and Kodiak, Alaska). Because only a limited amount of gray whale survey effort has been undertaken in this region, it is unknown whether this area represents a true distributional gap. Even with this limitation, it is nevertheless possible to document observed movements of known individuals and estimate a related minimum range. Figure 5 presents the observed range of maximum distances between sighting locations for individual whales. Overall, approximately 40% of PCFG whales are known to have utilized areas spanning at least one degree of latitude. Further, there are documented movements of PCFG whales to Kodiak (Gosho *et al.* 2011) and Point Barrow, Alaska (Calambokidis *et al.* 2012), in years they were not seen in the PCFG area. Finally, information from tagging (see section above) also supports the idea that the range of some PCFG whales extends outside of the presently defined boundaries.

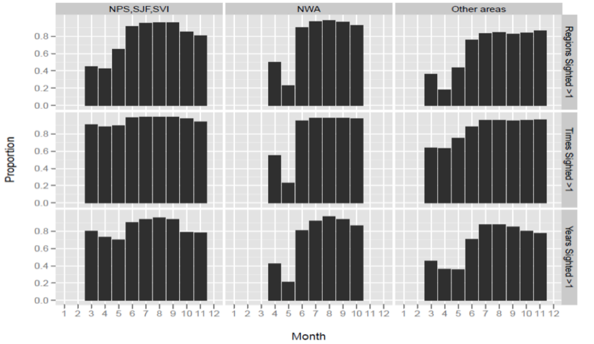

Figure 4. Proportion of whales sighted in more than one region (top), on more than one day (center) and in more than one year (bottom) as defined by the region and month they were seen. NPS = Northern Puget Sound, SJF = Strait of Juan de Fuca, SVI = Southern Vancouver Island, NWA = Northern Washington Coast.

It was noted by the TF that site fidelity of known reproductive mothers to the WNP Sakhalin Island feeding area is very strong (Weller *et al.* 2002). The TF therefore recommended that the existing PCFG photo-identification data be examined to see if moms/calves demonstrate higher levels of fidelity than other whales.

4.2 Pacific Coast Feeding Group abundance and survival

The photo-identification data collected annually in the seasonal range of PCFG whales (following the IWC definition) between 1998 and 2010 have been used to estimate abundance. In these analyses, the term “transient whale” was used to refer to whales seen in only one year and never seen again in any other year, and “non-transient whale” was used to refer to whales seen in at least two years, such that an estimate of the number of non-transient whales would be equivalent to an estimate of the number of whales defined to be in the area used by the PCFG. The total number of gray whales in the area used by the PCFG in summer would include both transient and non-transient whales, and is therefore higher than the number of defined PCFG whales in the area. In the following discussion of abundance estimates, whether an estimate is biased or not is relative to the true number of defined PCFG whales (not to the total number of gray whales in the area).

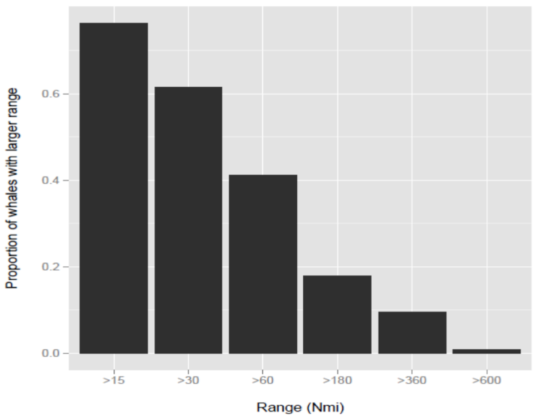

Figure 5. Distribution of maximum distance, in nautical miles, between photo-id locations for PCFG gray whales during 1 June – 30 November 1998-2010. The distance for 40% of the whales exceeded 1 degree latitude (60 nautical miles).

A number of different estimators were used including: (1) Lincoln-Peterson (LP), (2) Limited Lincoln-Peterson (LLP), and (3) Modified Jolly-Seber (JS1). The first two estimators constructed estimates from consecutive years of data. The LP estimator assumes a closed population and is unbiased if there are only losses or only gains. There are both losses and gains to the PCFG due to transient whales and therefore induces a positive bias. The LLP estimator removes the positive bias of the LP estimator by restricting the data to whales seen during the 2-year period but also in another year prior or after the 2-year period. This restriction eliminates whales that were transients in either of the years. The JS1 estimator is an open population model that estimates the abundance of non-transient whales. A fourth estimator, JS2, is an alternate JS modification that produced similar results except at the end of the time series (Calambokidis *et al*. 2012).

Calambokidis *et al.* (2012) considered the JS1 estimator to be the best suited for analysis of the PCFG (Figure 6). The Jolly Seber 1 (JS1) estimator assumes that any gray whale joining the PCFG is seen the first year it enters. The assumption is made to model the data adequately with the strong relationship between minimum tenure (time between first and last sighting in the year) and the probability it remains in the PCFG. The magnitude and trend of the LP abundance estimates do not match up well with the limited LP and the JS1 estimates; this is due to the fact that the LP

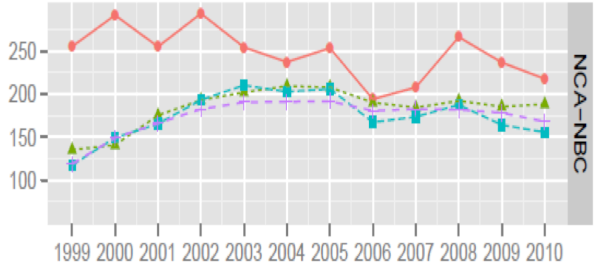

Figure 6. Estimates of the abundance of PCFG gray whales between northern California and northern British Columbia (NCA – NBC) using four different estimators based on photo-id data collected annually between 1998 and 2010. LP = Red Circle, JS1=Green Triangle, LLP=Blue Square, JS2=Purple Dotted Line

estimator was positively biased and the bias was greater at the beginning of the time series when there was more immigration and emigration into and out of the area used by the PCFG.

In discussion, the TF focused on whether the increase in the JS1 abundance estimates from 1999-2002 (Figure 6) was real or a reflection of the discovery of "new" whales that were present in the area used by the PCFG but not observed (i.e., photographed). Some of that discussion also focused on the related topic of recruitment described below. Laake responded that there were 13 whales not sighted in 1998 that were seen after 1998 (most of them were sighted in 1999) and were in the catalog for sightings prior to 1998. These results indicate that the assumption of JS1 (i.e., that any gray whale joining the PCFG is seen the first year it enters) was not met entirely. That being said, Laake argued that the bias was small or negligible after 1999 for the following reasons: (1) values from the JS1 estimator correspond closely to the value from the limited LP estimator which does not make the same assumption, (2) simulation results using similar values for capture probability estimated from the data showed a minimal amount of bias after 1999, and (3) the UME in 1999-2000 provides a plausible explanation for the coincident increase in PCFG abundance.

4.3 Pacific Coast Feeding Group IWC implementation review

Wade (AFSC) presented a brief overview of the status of the Implementation Review (IR) process conducted by the IWC. The IR includes trials based on three hypotheses: (1) Hypothesis P (Pulse) assumes that there is no bias in the PCFG abundance estimates (but dropping 1998) and that a pulse of immigration occurred in 1999 and 2000; (B) Hypothesis B (Bias) assumes a strong time-varying bias in the abundance estimate but no pulse of immigration; and (3) Hypothesis I (Intermediate) includes a moderate time-varying bias in the abundance estimates and a pulse of 10 immigrants into the PCFG in both 1999 and 2000. These hypotheses were evaluated because the model used in the IWC IR trials could not produce simulated abundance trajectories that fit the abundance estimates without incorporating a pulse or a bias into their model. For these trials the IWC Scientific Committee agreed that a sufficient fit to the data could be achieved with maximum annual immigration of up to six animals.

Wade noted that for the most part there was broad similarity between the population trajectories in the IWC trials and the population trajectories in the OSP determinations performed by Moore and Punt (pers. comm.), which only use Hypothesis P (a pulse of immigrants in 1999 and 2000, see related item below). The IWC implementation trials produce final statistics related to conservation status and catches.

There was some discussion about the need to evaluate trials that produced worrying conservation statistics and that it would be valuable to look at what the depletion level could be in those trials. Wade noted that the trials incorporating a low growth rate with little immigration or the trials in which the probability of taking a PCFG whale were doubled were the trials which do not do well with respect to conservation statistics such as final depletion level. Note that "final depletion level" is defined by the IWC to be the final population level as a percent of K. This is related to, but can be slightly different from, the U.S. MMPA definition of "depletion", which is defined to be a population level below the Maximum Net Productivity Level (MNPL). In U.S. MMPA depletion determinations, MNPL is generally assumed to either be a range from 50-70% of K, or a single value such as 50% or 60% of K. The only practical difference occurs when a range is used in MMPA determinations, where one calculates the probability a population is below MNPL over a range of percentages of K. If a single value is used for MNPL (e.g., 60%), than the IWC final depletion level is identical.

Some of the simulations conducted by the IWC with worrisome conservation performance (with respect to final depletion below 60%) are those using Maximum Sustained Yield Rate (MSYR) of 1% or 2%, implying a relatively low maximum population growth rate (Annex E, IWC 2012b). Note that the IWC Scientific Committee parameterizes population models with MSYR rather than Rmax (used in U.S. MMPA calculations). MSYR is the population growth rate at the Maximum Sustained Yield level, which is equivalent to MNPL if human-caused removals are unbiased with respect to age. Therefore, if MNPL is 50% of K, a population with an MSYR of 2% has an Rmax of 4%, and a population with an MSYR of 1% has an Rmax of 2%. Taylor noted that although she would have initially thought population growth rates that low were unlikely, after seeing some of the results presented she felt that relatively low population growth rates cannot be ruled out. She also noted that all trials in the table (which was a summary of trials that performed poorly with respect to conservation statistics) have annual immigration = 0 to 2, at the low end of the range considered. It appears that rates of annual immigration higher than 2 provide just enough of an offset to low MSYR rates of 1 or 2%.

The TF asked how the rescaled final depletion level was related to final depletion level in the IWC results. The rescaled final depletion statistic is used by IWC in trials whose specifications cause the population to decline even in the absence of catches. To evaluate those trials, the final population level for the trial (with catches) is compared to the final population level that would have been obtained in the absence of catches. That ratio is termed the rescaled final depletion, and represents the fraction of the population size that would have been obtained in the absence of catches. Since a low MSYR rate results in low population growth, the IWC found it is useful to compare depletion levels both with and without catches. The rescaled final depletion results for the PCFG only differ from the final depletion statistic for trials with a low value for MSYR, where the PCFG would decline and become depleted regardless of whether a hunt occurred due to the combination of a low population growth rate and bycatch.

4.4 Pacific Coast Feeding Group recruitment

Although new whales are identified each year in the range of the PCFG, about 50% of these individuals are seen in only one year and considered "transients" or "visitors" (Figure 7). Other whales are resighted in subsequent years and are considered "recruits" into the PCFG. Whales with a longer minimum tenure in the first year they were sighted have higher first year apparent survival and higher probability of return (i.e., do not permanently emigrate). This relationship might be expected given a hypothesis that whales are more likely to return if they find a suitable prey base during their first year in the seasonal range of the PCFG.

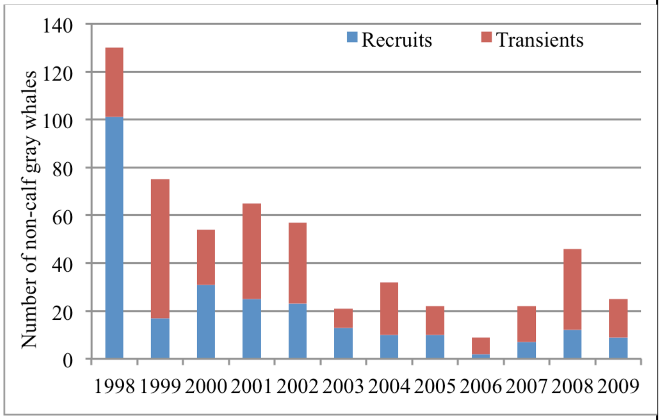

Figure 7. Number of "new" whales seen each year in the PCFG area that are transients (only seen in one year) and recruits (seen in more than one year).

Whales that recruited into the PCFG in 1999 or a subsequent year had lower first year apparent survival than whales that were first identified in 1998. Approximately 75% of the whales whose minimum tenure was 100 days or more in 1999 or later were resighted in a following year. For whales identified in 1998 (the first year of the study) whose minimum tenure was 100 days, nearly 100% were

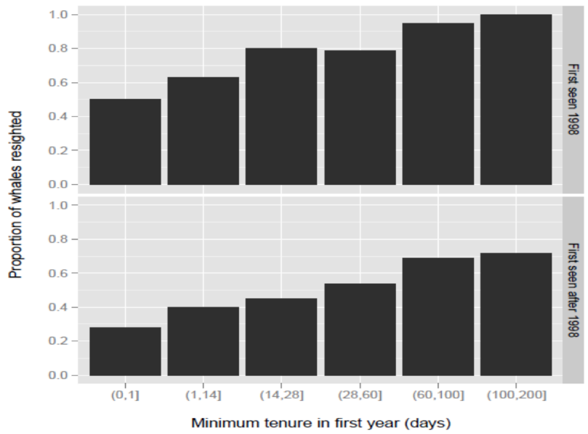

Figure 8. Relationship between minimum tenure in first year (# of days between first and last sighting plus 1) and the proportion resighted in at least one following year. The data series starts in 1998 so all whales are "new" so while the pattern is similar, the proportions are higher for 1998 because most whales are not truly new to the PCFG.

resighted in a following year (Figure 8). This suggests that some of the animals that recruited into the PCFG in 1999 or later may have subsequently emigrated out; this could explain why the abundance has declined somewhat in the later years (Figure 6). The high number of new whales identified in the seasonal range of the PCFG between 1999 and 2002 is hypothesized to have been in response to the 1999-2000 UME.

The TF discussed several alternative explanations for the relatively high numbers of recruits into the PCFG in the early part of the time series (1999-2002). For example, whether the increase in abundance during early years could be due to a "discovery" effect, such that it took a number of years for all the whales which were part of the PCFG to be photographed and "discovered". Alternatively, the heterogeneity in survey coverage over time and space could lead to some animals being considered "new" in a given year even if they had been utilizing areas with limited or no survey coverage in previous years. However, overall capture probabilities are high, suggesting it is unlikely a whale would be in the area for several years and not photographed. The TF concurred that on an annual basis, whales observed in the area used by the PCFG could be characterized as a collection of individuals whose residence patterns vary along a continuum such that some whales use the area for a single year (e.g., transients), some for a few years, and others on a consistent long-term basis.

By way of an analogy, Laake characterized the PCFG as a "leaky bucket", in that some whales are immigrating in while others are emigrating out. The "leaky bucket" phenomenon is not a random process, however, because a "core group" of whales appear to stay in the bucket over time. The dataset cannot discriminate between PCFG whales that die versus those that emigrate. Animals that recruit into the PCFG as non-calves may be more likely to emigrate out of the area than calves recruited to the PCFG in the year they were born. That is, calves of the year have been taught to feed on prey types common to the PCFG area (various swarming prey for instance) by their mothers and may obtain "local knowledge" that allows them to be successful long-term inhabitants of the PCFG area. To evaluate this, the TF recommended that the existing PCFG photo-identification time series be examined to see if moms/calves demonstrate higher degrees of fidelity than other whales.

In thinking about the "core group" of PCFG whales that return to the area on a consistent basis, the TF questioned if biopsy efforts in the area could be potentially biased towards these whales. If sampling efforts are unintentionally concentrating on the "core group" of PCFG whales, then the results of genetic comparisons may be driven by matrilineal fidelity of this "core group". In addition, the biopsy efforts are not spread evenly over time and space (more heterogeneity than the photo-identification survey efforts). If "core group" animals predominantly use the areas with high biopsy effort, then this potential bias could be magnified.

Some newly seen whales are calves with their mothers (Figure 9). As described in Calambokidis *et al.* (2012), much of the sighting effort occurs in August and later when many calves are likely to already be weaned and thereby more difficult to identify as a calf (versus a yearling). The TF noted that many of the whales identified as calves off Sakhalin Island in the WNP are not resighted for many years subsequent to their birth year but eventually they are again resighted in the area. This pattern suggests that young animals (1+ years old) may use other areas to feed during their first several years. Therefore, in the case of the PCFG, if a whale was not seen as a calf but returned in a later year it would appear to be an external rather than internal recruit. With that in mind, the TF recommended that the existing PCFG photo-identification time series be examined following a protocol developed by Bradford et al. (2011) that uses barnacle and pigmentation characteristics on young gray whales to reliably distinguish calves of the year from yearlings.

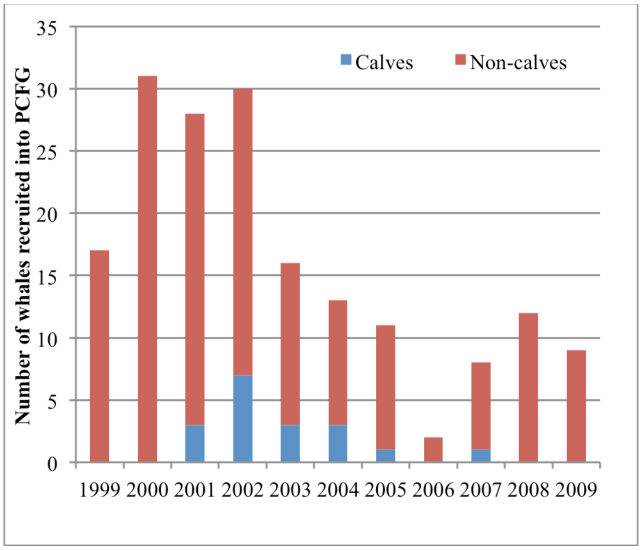

Figure 9. Number of whales first seen and recruited (seen in a following year) by year and calf and non-calf designation.

In summary, the TF discussion about the magnitude and source of recruitment into the PCFG focused on: (1) incomplete survey coverage of the entire seasonal range used by the PCFG and the potential for whales to be missed and then “recruited” in a subsequent year, (2) the proportion of “recruited” whales that were calves of mothers from the PCFG that may have been missed as a calf or misidentified as an external recruit, (3) the potential of the 1999/2000 UME to create a pulse of immigration into the PCFG, (4) to what degree gray whales recruited in 1999 or later were either emigrating back to the northern feeding areas or experiencing higher mortality, and (5) whether the biopsy sampling effort was prone to sample whales that spent more time in the range used by the PCFG.

All of these issues are relevant to assessing the amount of external recruitment into the PCFG and thereby especially pertinent to determining if it should be recognized as a population stock under the MMPA and GAMMS guidelines. That is, if the PCFG experiences little external recruitment then it would be considered demographically independent and should be recognized as a stock. If most of the recruitment into the PCFG were external, however, then it would not be considered demographically independent and would not be recognized as a stock. The TF concurred that the resolution of the existing photo-identification data in combination with uncertainly surrounding the accuracy of assigning whales as external or internal recruits prevent this question from being fully resolved. Increased genetic sampling in tandem with increased photo-id effort over both space and time may be the only way to better address this question.

4.5 Pacific Coast Feeding Group trend and optimum sustainable population determination

Moore presented an update on work he conducted in collaboration with Andre Punt (University of Washington) to determine if the PCFG, as a putative stock, is at OSP. The OSP assessment is based on the two-stock population model that has been developed as part of the IWC gray whale

Implementation Review (see section 4.3). Both assessments use the same definition for a PCFG whale. There are some differences, however, between the IWC model framework and the one used for the OSP assessment. First, in the OSP analysis, a Bayesian approach is used in which prior distributions are specified for input parameters and the time series of abundance estimates (for the ENP and PCFG) are used to the update priors and output posterior distributions. This contrasts with the IWC approach of generating outputs for many models each based on alternative fixed combinations of values for some parameters. Second, the IWC trials consider several hypotheses that attempt to explain the rapid increase in abundance estimates in the first few years of the time series; these include bias in the early abundance estimates, a pulse of immigration, and a combination of these two factors. In the OSP assessment, only the pulse immigration hypothesis is considered, based on work by Calambokidis *et al.* (2012) which suggested that the most recent abundance estimates should be fairly unbiased apart from the first estimate in 1998, which is not used in the OSP analysis.

At the time of the workshop, the OSP analysis considered two hypotheses pertaining to the regular annual immigration rate: one in which there is no immigration (PCFG is closed) and one in which the annual immigration rate is estimated, given a uniform prior distributed between 0 and 6 individuals per year. Different versions of the model allow the density-dependent (or inflection point) parameter θ to be estimated separately for each putative stock (PCFG vs. rest of the ENP) or to be constrained so that the two groups share a common θ. Outputs from both versions and immigration rate considerations (none vs. U[0, 6]) are similar in models run thus far. The primary parameter of interest in the OSP assessment is the probability that PCFG abundance is above MNPL (MSYL in IWC terms).

The analysis was not able to generate useful assessment results because, apart from the rapid population increase in the late 1990s attributed to an immigration pulse, the abundance time series is fairly flat and therefore not very informative for estimating *in situ* population growth parameters. The data have also not been informative for estimating population carrying capacity (K), a parameter necessary to determine whether current abundance is above MNPL. Posterior distributions for K have been strongly dependent on the upper bound used for the prior. Given that the abundance has been stable throughout most of the 2000s, it appears to be regulated at this level (of around 200 - 250 animals) by some factor, and thus it is somewhat puzzling that the data do not seem more informative with respect to estimating K. Moore suggested that annual levels of incidental take included in the model (about 2 animals per year) could be making it difficult to estimate whether the population is being regulated at K or some level below K, given that the data do not inform the estimates of MSYR (the population growth parameter in IWC models). For example, given annual bycatch mortality of 1%, a combination of being well below K and having a low MSYR may describe the data equally well as being close to K and having a high MSYR, since in both cases, the realized value for population growth would be low and potentially balanced by the additive mortality. It was also suggested that the population might be regulated at its current level as a result of emigration and bycatch offsetting the combination of immigration and *in situ* growth.

Moore and Punt were continuing to troubleshoot the problem by running alternative models that, for example, exclude incidental take from the model or constrain estimates of MSYR for the PCFG to be equal to those of the ENP. The goal of this troubleshooting is to explain why estimates of K and hence probability of being at OSP are elusive, which in turn may enable a decision as to whether an OSP assessment may be possible.

The TF thanked Moore and Punt for their work on this complicated matter and raised several points for clarification. It was asked where the estimates of incidental mortality for the model had come from. Moore reported that the bycatch estimate being used is based on a summary compiled at the 2011 IWC Aboriginal Whaling Management Procedure (AWMP) intersessional workshop (IWC 2012a). Carretta clarified that those estimates included data from over a 20-year period that tried to assign animals as being part of the PCFG (or not) based on time and space. Carretta also noted that the bycatch values used in the OSP analysis (as well as the SARs) account for only observed bycatch, which is likely to be an underestimate of actual bycatch.

It was also noted that emigration is a possible explanation for the difficulty in estimating K in spite of apparent PCFG population size stability. That is, all recruits are assumed in the model to have the same annual survival rate but as discussed above, whales that recruited into the PCFG in 1999 or later had lower first year survival than whales that were first identified in 1998. Not including this extra survival parameter may explain some of the lack of fit of the model to the abundance time series (plots show that the model underestimates abundance in the first half of the time series and overestimates abundance in the second half of the series).

The TF asked if the model assumed immigration was constant across years in the assessment given that in reality immigration into the PCFG is thought to vary across years. In the model, immigration to the PCFG occurs at a constant rate, with the number of immigrants being proportional to the northern stock (non-calf) abundance. The rate is equal to the estimated immigration parameter (I, specified with the uniform [0,6] prior) divided by 20,000. In other words, for recent abundance levels of the northern stock, annual immigration to the PCFG is approximately I individuals. Emigration from the PCFG group is similarly assumed to occur at a constant rate, specified by an additional survival parameter ($1 - S$), with the number of emigrants proportional to PCFG abundance. S is set so that when both stocks (northern and PCFG) are at carrying capacity, immigration and emigration to the PCFG is balanced, i.e., $IK_{\mathrm{north}}/20000 = (1 - S)K_{\mathrm{PCFG.}}$

Some members of the TF commented that based on this model it seems plausible that the pulse of immigration into the PCFG is larger than what the IWC is modeling or what the genetic simulations have modeled. If that were the case, then the estimates of regular annual immigration would be lower than estimated in the genetic simulations. In the light of this discussion, the TF noted that the genetic simulations should try pulses of 30 animals to see if that is consistent with the empirical genetic data. This line of thinking led to additional discussion as to how common pulse immigration events might be, and whether, for the purposes of the workshop and deliberations on internal versus external recruitment, the TF should be considering the pulse as part of the average level of immigration or if the pulse should be considered a one-time event and only annual immigration should be considered (in assessing how demographically independent the PCFG is).

It was further noted that if a UME event the size of the one in 1999-2000 had occurred previously, some record of it would be expected. Wade noted that it was due to this reasoning that they did not incorporate additional mortality events in the northern stock OSP analysis conducted by Punt and Wade (2012). Wade also noted, however, that there had been a drop in the northern stock abundance in earlier years of the time series but these were not accompanied by a record of increased strandings. The TF suggested that pulses could occur regularly on decadal time scales or as a result of a variety of other environmental or anthropogenic factors.

The TF discussed if the genetic data may reflect a sampling bias toward "core" PCFG animals. This follows other lines of evidence showing that there is a relationship between minimum tenure and probability of photographically capturing animals in the PCFG area (see section 4.4 above). If "core" PCFG whales are more approachable, then they are potentially more likely to be biopsied, meaning that these whales may be disproportionately selected for in the biopsy process.

Lang noted that she had looked at the current genetic sample set to see if the rare haplotypes found in the PCFG sample set came from animals that were sighted in 1999 or later, which might suggest that they were immigrants as the expectation would be that immigrants would be likely to bring in rare haplotypes. The results were mixed, with some rare haplotypes found in long-term PCFG whales while others were found in animals that came into the PCFG in 1999 or later.

This led to a discussion about what additional information might help the PCFG OSP assessment and improve inference generally about the level of internal versus external recruitment to the PCFG. The TF agreed that additional genetic sampling to improve estimates of immigration and residency times (emigration), and improved estimates of incidental mortality would be useful.

5. Probability of a Western North Pacific Gray Whale Being Taken by the Makah

Mixing of whales identified in the WNP and ENP has recently been reported (Weller *et al.* 2012). Lang (2010) reported that two adult individuals from the WNP, sampled off Sakhalin in 1998 and 2004, matched the microsatellite genotypes, mtDNA haplotypes, and sexes (one male, one female) of two whales sampled off Santa Barbara, California in March 1995. In 2010 and 2011, Mate and colleagues (Mate *et al.* 2011) satellite-tracked three whales from the WNP to the ENP (Mate *et al.* 2011; IWC 2012a; IWC 2012b). Finally, photographic matches between the WNP and ENP, including resightings between Sakhalin and Vancouver Island and Laguna San Ignacio, have further confirmed use of areas in the ENP by whales identified in the WNP (Urbán *et al.* 2012; Weller *et al.* 2012). Despite this level of mixing, significant mtDNA and nuclear genetic differences between whales in the WNP and ENP have been found (Lang *et al.* 2011b).

Observations of gray whales identified in the WNP migrating to areas off the coast of North America raise concern about placing the WNP population at potential risk of incurring mortality incidental to the ENP gray whale hunt proposed by the Makah Indian Tribe off northern Washington, USA (see IWC 2012a; IWC 2012b). Given the ongoing concern about conservation of the WNP population, in 2011 the Scientific Committee of the IWC emphasized the need to estimate the probability of a western gray whale being killed during aboriginal gray whale hunts (IWC 2012a). Additionally, NOAA is required by NEPA to prepare an Environmental Impact Statement (EIS) pertaining to the Makah's waiver request. The EIS will need to include an analysis of the likelihood of a western gray whale being killed during the proposed Makah gray whale hunt.

Moore summarized the work that he and Weller (SWFSC) have done to estimate the probability that a WNP whale might be taken during the proposed gray whale hunt (Moore and Weller 2013). Four alternative models were evaluated; these models made different assumptions about the proportion of WNP whales that would be available for the hunt or utilized different types of data to inform the probability of a WNP whale being taken. The probability of striking at least one WNP whale over the course of five years was estimated to range from 0.034 – 0.058 across different scenarios of the preferred model, with upper 95% CI estimates ranging from 0.107 –

0.170. This result may be compared to an estimate of PBR. If the recovery factor for calculating PBR is set to 0.1, and discounting the estimate for the proportion of the population that may be migrating through U.S. waters and the proportion of time (months out of a year) they are in U.S waters, then the 5-year PBR estimate is between 0.1 and 0.6 animals, depending on different assumptions about the amount of mixing between the WNP and ENP. Thus, if a WNP whale were to be struck during the 5-year period, PBR would be exceeded.

6. Status of Gray Whale Stocks as Defined by, MMPA, ESA and IUCN

At the request of the TF, Stone (NWR) provided a review of the status of ENP, WNP and PCFG gray whales under the MMPA, ESA, and the International Union for Conservation of Nature (IUCN) redlist.

(1) ENP – The ENP stock is not considered *"strategic/depleted"* under the MMPA and is listed as "*Least Concern*" by the IUCN. Gray whales in the ENP were delisted from the ESA in 1994. Although there have been two petitions (2001 and 2010) to relist the ENP stock under the ESA, both petitions were denied.

(2) WNP – The WNP stock is considered "*strategic/depleted*" under the MMPA and is redlisted as "*Critically Endangered*" by the IUCN. WNP whales are considered "*Endangered*" under the ESA, although there is no stand-alone SAR for WNP whales. Given that ENP whales were delisted in 1994, gray whales in the WNP would be considered a Distinct Population Segment (DPS) under the ESA. Use of the DPS terminology was not common at the time of the delisting and thus the listing documents do not describe the WNP as a DPS.

(3) PCFG - The PCFG does not have a formal status under the MMPA, IUCN nor ESA.

In addition to the above, the TF discussed the status of gray whale stocks as defined by the IWC. Under the IWC implementation review (IR) process, the IWC considers all plausible hypotheses of stock structure, and then determines which hypotheses have high or medium plausibility. Those stock hypotheses with high or medium plausibility are used to evaluate the management variants proposed by hunters. In the case of gray whales, the IWC traditionally considered only the hypothesis of a single ENP stock. New information presented to the IWC in 2010 (Frasier *et al.* 2011) suggesting that the PCFG could be a separate stock resulted in the IWC evaluating a two-stock hypothesis. Members of the TF reminded the group that the IWC does not have to decide if there are one or two gray whale stocks, but only if it is plausible that there is one stock and if it is plausible that there are two stocks (or three stocks). The objective of the IWC is to make sure that the stock or stocks are robust to the proposed hunt under all plausible scenarios. Thus, the IWC process is currently considering both stock hypotheses (1-stock and 2-stock). Future work by the IWC may need to incorporate a third stock (i.e., WNP) but for now the calculation of the probability of a WNP whale being killed during the Makah hunt (see section 5 above) is a stand-alone calculation.

7. Overview of Evidence Used in Recently Defined Population Stocks

Stone provided an overview of the lines of evidence used by NMFS to delineate stocks as inferred from the text of each SAR. It became clear during discussion of the summary that many of the SARs do not explicitly lay out the lines of evidence and justifications for originally delineating a stock but instead only present recent information. The killer whale SARs, for example, do not describe the acoustics data and other lines of evidence that were originally used to identify the stocks. There was general agreement that an updated summary, in spreadsheet form, would be useful as it could capture the history and provide a long-term record of how each stock was delineated, but this would not be a trivial task. In the end, the TF concurred that agency practices for delineating stocks were not based on a set standard but were more variable and fact-specific so as to use the best available information.

8. Review of Stock Definition Cases Relevant to the Pacific Coast Feeding Group

The TF reviewed several examples of stock delineations for other species exhibiting some similar characteristics to the PCFG. Similar characteristics included: (1) use of mtDNA as the sole genetic marker necessary for stock structure determination and (2) mixing with individuals from other stocks during parts of the year.

8.1 Atlantic harbor porpoises

Rosel (SEFSC) presented an overview of stock structure in Atlantic harbor porpoises (*Phocoena phocoena*) with a focus on the Gulf of Maine/Bay of Fundy stock. A single stock was designated in U.S. waters of the Northwest Atlantic based on published literature of Gaskin (1984) who hypothesized four populations in the Northwest Atlantic (three in Canadian waters and one in U.S. waters). While following Gaskin (1984), the first SAR for U.S. Gulf of Maine/Bay of Fundy harbor porpoises stated "*Presently there is insufficient evidence to accept or reject this hypothesis*" (Blaylock *et al*. 1995). In subsequent years, mtDNA evidence supported four stocks in the Northwest Atlantic, including the Gulf of Maine stock, but nuclear microsatellite data did not (Rosel *et al.* 1999). Organopollutant levels (Westgate *et al.* 1997, Westgate and Tolley 1999) and life history characteristics (Read and Hohn 1995) also differed between the Gulf of Maine/Bay of Fundy and other populations in the Northwest Atlantic. The weight of evidence supported delineation of the Gulf of Maine/Bay of Fundy stock and the lack of nDNA differentiation between this stock and others in the Northwest Atlantic was taken to indicate female philopatry coupled with male-mediated gene flow. Microsatellite data indicated that porpoises from the Gulf of Maine/Bay of Fundy probably overlap in winter in the mid-Atlantic with porpoises from other regions of the Northwest Atlantic (Hiltunen 2006), but this is outside the breeding season.

8.2 Alaska harbor seals

Taylor summarized the history of recognizing stocks of harbor seals in Alaska. Harbor seals (*Phoca vitulina*) are continuously distributed throughout Alaskan waters, but mtDNA indicates that genetic differentiation among sampled sites increases with increasing geographic distance (O'Corry-Crowe *et al.* 2003). The continuous distribution implies that there will be movement of animals across stock boundaries drawn on a map, but if no stock boundaries are designated, there is the risk of local depletion and loss of portions of the species' range. The first SARs for Alaska harbor seals comprised three stocks- Bering Sea, Gulf of Alaska and Southeast Alaska (Hill and DeMaster 1998). In 2011, the three stocks were changed to twelve (Allen and Angliss 2012). MtDNA, satellite telemetry, trend and distributional data were used to delineate these 12 stocks. At that time, nDNA data were not available and mtDNA analyses were considered sufficient to meet the criteria of demographic independence under the GAMMS guidelines.

8.3 Humpback whales

Lang presented a review of humpback whale (*Megaptera novaeangliae*) stocks, with a focus on the North Atlantic. There are multiple humpback whale feeding grounds in the Northwest Atlantic, but individuals from these different feeding grounds share one breeding ground in the

West Indies. Humpback whales throughout the Northwest Atlantic were originally classified as a single stock (Waring *et al.* 1999). However, genetic studies have revealed small but significant differences in mtDNA between animals sampled on different feeding grounds (Palsbøll *et al.* 2001) and photo-identification studies have documented strong site fidelity of individuals to the Gulf of Maine feeding area (Clapham *et al.* 1993). The 2000 SAR recognized whales utilizing the Gulf of Maine feeding area as a separate stock (Waring *et al.* 2000). Although this SAR covers only Gulf of Maine whales, individuals from other feeding areas have been identified in U.S. mid-Atlantic waters (Barco *et al.* 2002).

The stock structure of humpback whales in the Pacific is complex (Baker *et al.* 2008; Calambokidis *et al.* 2008) and differs from the western North Atlantic with respect to the “interbreed when mature” criteria. That is, humpback whales from different feeding grounds in the NW Atlantic have the opportunity to interbreed with each other in a single breeding area, while in the North Pacific not all animals have the opportunity to interbreed with each other because there are multiple breeding areas. There is some similarity between North Pacific humpbacks and those in the central and eastern North Atlantic, in that whales on the Norway and Iceland feeding areas may breed in different areas (Palsbøll *et al.* 1997; Stevick *et al.* 1998; Wenzel *et al.* 2009). Three humpback whale stocks are currently recognized in the North Pacific, based on three feeding areas (Allen and Angliss 2012; Carretta *et al.* 2013). The SAR for the Central North Pacific stock includes calculations of PBR for three different feeding areas (Allen and Angliss 2012), as is done for the PCFG in the current SAR (Carretta *et al*. 2013).

9. Review of Gray Whale Genetic Research on Population Structure

Lang provided a chronological summary of genetic research performed on North Pacific gray whales. Steeves *et al*. (2001) used mtDNA control region sequence data to compare 16 samples collected in summer in Clayoquot Sound, British Columbia, representing the PCFG, to 41 samples collected elsewhere in the ENP. Some haplotypes were shared between the two groups and no significant differentiation was found between them. Additional genetic analysis utilizing an extended set of samples (n=45) collected from whales within the seasonal range of the PCFG indicated that the genetic diversity and the number of mtDNA haplotypes identified among these samples were inconsistent with measures that would be expected (based on simulations) if recruitment into the group were exclusively internal (Ramakrishnan *et al*. 2001). Alternative scenarios, such as limited dispersal of whales from other areas into the PCFG, were not explored. LeDuc *et al*. (2002) examined mtDNA control region differences between ENP and WNP gray whales. The ENP sample consisted primarily of stranded animals along the migratory route with some samples from Chukotka, Russia (no distinctions between PCFG and non-PCFG whales were made). The WNP samples were collected off the northeastern coast of Sakhalin Island, Russia. Seven of the 36 identified haplotypes were shared between the two regions and significant genetic differentiation was found. In addition, haplotypic diversity of the WNP sample was lower than that seen for the ENP samples.

Within the ENP, Goerlitz *et al*. (2003) made comparisons between two wintering lagoons and between females sampled in wintering lagoons and those sampled outside the lagoons (in Clayoquot Sound and along the migration route- *i.e.,* “non-lagoon females”). They found small but significant differences in mtDNA data between Laguna San Ignacio cows (females with calves) and non-lagoon females and between Laguna Ojo de Libre cows and non-lagoon females but not when cows from the two lagoons were compared. Alter *et al*. (2009) compared both mitochondrial and nuclear microsatellite markers across three wintering lagoons and found small but significant differences between only one of the three pairwise comparisons using the microsatellite data set only. Similar to Goerlitz *et al.* (2003), they did not find significant differentiation between Laguna San Ignacio and Laguna Ojo de Libre at mitochondrial or nuclear DNA.

More recently, Frasier *et al*. (2011) examined mtDNA differences between whales sampled in Clayoquot Sound, British Columbia (representing the PCFG) and a more carefully constructed data set of ENP whales from LeDuc *et al.* (2002) in which known PCFG whales were specifically removed. They found significant genetic differentiation between the two sample sets and high levels of haplotype diversity in the PCFG sample, comparable to samples thought to represent the larger ENP population. Using this dataset, Frasier *et al.* (2011) also performed a likelihood ratio test using Theta (Θ) as a proxy for effective population size to examine whether the two sample sets come from the same population. The likelihood ratio test indicated that Θ for the PCFG did not equal Θ for the ENP and the authors concluded that the two groups were demographically independent.

D'Intino *et al*. (2012) made a comparison of whales sampled off Vancouver Island and representing the PCFG to whales sampled at the calving lagoon at San Ignacio. Using 15 microsatellite loci, they found no evidence for population differentiation between these two areas and concluded that the two sampled groups come from the same interbreeding population and that maternally-directed site fidelity to different feeding areas leads to genetic differentiation at mtDNA among feeding areas. Lang *et al*. (2011a) expanded on this result and compared whales sighted over two or more years within the PCFG seasonal range to animals sampled on the feeding ground(s) north of the Aleutians using both mtDNA and nuclear microsatellite markers. Significant differentiation was seen for the mtDNA data but not the microsatellite data, supporting the conclusion of Frasier *et al.* (2011) that structure is present among different feeding areas and this structure may be directed by matrilineal fidelity[5] to feeding grounds. Of note, when all samples collected on the PCFG seasonal range (including those collected from animals seen in only one year) were utilized in the mtDNA analyses, no significant differences were detected in the comparison to samples collected from whales off Chukotka. When all samples collected on the PCFG seasonal range were compared to all samples collected north of the Aleutians, the mtDNA F_{ST} comparison detected a significant difference although the χ^2 test did not.

Finally, Lang *et al.* (2011b) re-examined differences between ENP and WNP gray whales, expanding on the previous study of LeDuc *et al.* (2002) by using larger sample sizes, better characterized sampling and both mtDNA and nuclear microsatellite data. Comparisons of whales sampled off Sakhalin Island with whales feeding north of the Aleutians (i.e., ENP whales) and with the PCFG demonstrated significant differentiation at both nuclear and mtDNA markers. The extent of mtDNA differentiation between ENP strata (PCFG and whales feeding north of the Aleutians) and Sakhalin Island was higher than that observed in comparisons within ENP strata. As with previous studies, significant differentiation among ENP feeding areas was not seen in the microsatellite data. The Sakhalin stratum again displayed reduced haplotype diversity compared to the ENP strata. The authors conclude that the mtDNA data support demographic

---

[5] Matrilineal fidelity as used here means the learned behavior of a calf (male or female) returning to the feeding ground of its mother.

independence for ENP and WNP gray whales. However, in examining the microsatellite genotypes, Lang *et al.* (2011b) found two individuals biopsied at the Sakhalin feeding ground and off the coast of southern California. These matches, in combination with recent photo-identification and telemetry data (Mate *et al.* 2011; Urbán *et al*. 2012; Weller *et al.* 2012), suggest that some animals summering off Sakhalin overwinter in the ENP in at least some years. Given that recent records document gray whales in the waters off Japan and China during winter and spring (see review in Weller and Brownell 2012) these results suggest that population structure in gray whales may be more complex than previously believed, such that not all of the animals that feed off Sakhalin share a common wintering ground, or that some animals may switch between wintering grounds.

In discussion, TF members suggested some further avenues for exploration including examining whether any microsatellite loci were out of Hardy-Weinberg equilibrium (HWE) for the Sakhalin samples, which might be an indication of mixing of multiple breeding populations on that feeding ground. It was noted that at the 2012 IWC Scientific Committee meeting a paper evaluating the use of HWE tests to look at mixing of stocks was presented and it might be worthwhile to see if the approaches in this paper could be applied to the Sakhalin dataset (IWC 2012b). There was also discussion regarding what proportion of mixing would have to take place before it would be detected by a relatively weak test like HWE.

9.1 Genetic modeling of immigration rates

Lang presented an overview of recent work utilizing a simulation-based approach to evaluate the plausible level of immigration (i.e., a permanent change of feeding ground fidelity, used interchangeably with external recruitment) that might be occurring into the PCFG. While the empirical studies summarized above have shown significant differences in mtDNA between the PCFG and other ENP gray whale feeding areas, suggesting that matrilineal fidelity is important in structuring feeding ground use, other evidence (some from genetics, mostly from photo-id) suggests that some immigration into the PCFG may be occurring. Lang and Martien (2012) used simulations to examine how much immigration into the PCFG could occur to produce results consistent with the empirical genetic (mtDNA) analyses. The results suggested that the plausible range of immigration is >1 and <10 animals/year on top of a two-year pulse of immigration (of 20 animals each year in 2000 and 2001). Annual immigration of 4 animals (with the 2 year pulse of immigration) produced simulated results that were most consistent with the empirical data. If the PCFG had been founded more recently or the abundance of the PCFG is greater than used in the simulations, it is plausible that no annual immigration could be occurring (still assuming the occurrence of a 2-year pulse of immigration).

In discussion of these results, the TF noted several important caveats to the approach used by Lang and Martien (2012), including: (1) the results may be overly precise because so many model parameters are set, and (2) the simulated abundance trajectories do not match well with the mark-recapture estimates (Calambokidis *et al*. 2012) when immigration is 4 immigrants/yr or more. The simulated population trajectories assumed that the PCFG split from the larger ENP population in 1930. Task Force members thought that the 1930 split might be unrealistic, as oceanographic conditions during the Little Ice Age (and earlier) would have limited access to the northern feeding ground(s) and thus may have caused some gray whales to utilize more southern waters for feeding. Lang commented that there were plans to model a split of the PCFG from the larger ENP in the Little Ice Age, but that this work is not yet complete. She also noted that there were many possible histories and it would be difficult to encompass all of them.

10. Discussion of Makah Documents Concerning the Pacific Coast Feeding Group

Weller introduced three documents drafted by or on behalf of the Makah Indian Tribe regarding the PCFG. These documents were provided to the TF in advance of the meeting for review and consideration. In combination, these three documents provided important summary information on the PCFG, including reviews of what is known about the history of the PCFG and summaries of the current status of the group.

The 2011 Makah document (Makah 2011) was drafted by the Tribe and their attorneys and provided to the Pacific and Alaska SRGs as a background paper to help inform their respective reviews of the draft 2012 gray whale SAR (NMFS 2012). This document provides the Makah perspective on whether the PCFG should be recognized as a stock and was therefore deemed important for the TF to review and consider. Information provided in Scordino *et al*. (2011) is largely the same as that presented in the Makah 2011 document.

The 2012 Makah document (Makah 2012) contains comments from the Makah Tribe and their attorneys on the 2012 draft gray whale SAR (NMFS 2012). This document was considered important for the TF to review. In response to the Tribe's request for government-to-government consultation, the SWFSC met with representatives from the Makah Tribe and their attorneys in person to review comments provided in the 2012 document. These comments, where appropriate, were incorporated as changes to the draft text of the SAR (NMFS 2012).

10.1 Discussion of genetics sections of Makah documents

In discussion of these documents, the TF agreed that it was most important to focus on the Makah comments and perspective regarding genetics research on the PCFG. Rosel agreed to lead the TF through the genetics sections of the Makah documents that called into question the strength of the genetic data presented with respect to demographic independence of the PCFG. These points were summarized as: (1) the samples used to represent the overall ENP stock may not be a random sample of the entire stock but could come from different and unknown feeding grounds. This calls into question what the PCFG is being compared to in the genetic analyses, (2) sample sizes from many locations are small relative to overall population size (i.e., relative to the size of the larger ENP population) and to the total level of genetic diversity and that this could cause misleading results, (3) many population comparisons of gray whales have yielded significant but low-level differences in haplotype frequencies; if this is considered sufficient evidence to classify the PCFG as a stock then every group of gray whales utilizing a particular feeding area should be considered a stock, and (4) the genetics results do not support reproductive isolation of the PCFG.

The first two points were related to sampling effects. In discussion, some members of the TF noted that it is not necessarily the sample size that is potentially problematic but rather if related animals are grouped together and multiple biopsies are taken from that "group" then the effective sample size is much smaller. It was further noted that small sample sizes may add variability, but it would only be a problem if there were additional (unrecognized) structure in the samples. From a genetic standpoint, many analyses rely on haplotype frequencies, but if a good sample relative to the genetic diversity of the group is not obtained then the genetic diversity may not be well characterized, especially if there are many rare haplotypes. Since haplotype frequency data also go into analyses for F_{ST} and Chi-square, then poor frequency estimates due to small sample size could affect the accuracy of the genetic differentiation results as well. Lang noted that there is some evidence from North Atlantic humpbacks that the migration to the West Indies is segregated according to feeding ground origin (Stevick *et al.* 2003).

The TF noted, however, that the recent PCFG genetic analyses show high diversity indicating that sampled animals have different haplotypes and are thus not related (maternally). The TF asked if the question at hand is whether gray whales have feeding aggregations or whether the group that migrates north of the Aleutians is different from the group that does not migrate north of the Aleutians. Lang noted that the original intent of the project was to compare samples collected from different feeding areas north of the Aleutians to the area used by the PCFG but in the end sample sizes were insufficient for areas other than Chukotka. Nevertheless, although there could be multiple feeding aggregations north of the Aleutians, one of the comparisons conducted by Lang *et al.* (2011a) used only samples collected off Chukotka to try to avoid including unrecognized structure.

The TF recognized the continuing need for additional data to be collected, but for the purposes of the workshop the focus was whether the lines of evidence from existing genetic analyses are strong enough to counter lines of evidence that put the demographic independence of the PCFG into question. The primary question in the short-term is what can be done with the information that is currently available.

The TF noted that Frasier *et al.* (2011) compared animals from the PCFG with a sample set primarily derived from stranded animals along the U.S. west coast during migration. They agreed that these samples might not be a random representation of the larger ENP, as was also pointed out in the Makah documents.

Overall, the TF felt it was important to recognize that the current research questions being addressed center around feeding-ground-based groups of animals. The genetics work has already shown that when the PCFG is compared to a sample set from northern feeding area (Chukotka) animals or to the Sakhalin animals (also a feeding area) differences have been found (Lang *et al.* 2011b). That is, the PCFG has been shown to be different from two other well-characterized feeding grounds.

While interpretation of the currently available genetic results as relevant to the PCFG has lead to debate amongst different groups, the TF concurred that it represents the best available science. In discussion, some members of the TF agreed that although more progress on this issue could be made over the next few years if resources were available for more intensive sampling, they did not think that the current interpretation of results would change much. That is, even if 1% of the 19,000 or so animals going through Unimak Pass were sampled, a mtDNA difference with the PCFG (as already observed) would remain. So far the PCFG has been compared to samples from feeding areas and from the migratory route and both comparisons detected a genetic difference. It was agreed that the critical issue for additional research to address was better determining the levels of internal versus external recruitment in the PCFG.

At this point the TF returned to discussing the remaining points raised by the Makah documents. The third point was that since multiple genetic comparisons have found low but significant differences, every group of gray whales should be considered a stock. The TF concurred and noted that there is nothing wrong with incrementally adding stocks as new evidence is uncovered, and that decisions have to be made based on the best available science.

The final point discussed was that the genetics results do not support reproductive isolation of the PCFG. The TF agreed in general that the pattern and timing of migration provide ample opportunity for breeding between PCFG whales and other ENP whales. Little is known about gray whale social and mating systems, however, and presently unrecognized mechanisms facilitating selective breeding could exist. If a form of selective breeding does exist, then it could be a long time before nDNA differences appear. A suggested approach to resolving this question is to look at the relatedness of animals in the PCFG. Despite this, the TF agreed that it is most likely that PCFG animals are interbreeding with animals coming from other areas.

11. Research Recommendations

The TF agreed that the following set of recommendations represent key research needs that could help provide additional insight regarding if the PCFG should be recognized as a population stock under the MMPA and GAMMS guidelines.

Given the limited photo-identification and biopsy effort north of 52°N but knowing that at least some observations of PCFG whales in northern feeding areas (e.g., Kodiak and Barrow, Alaska) have been recorded, the TF highlighted the importance of expanding the spatial and temporal coverage of the photo-identification and biopsy effort. In addition, the TF also recommended that further satellite tagging of known PCFG whales be conducted to better delineate habitat use and define the summer/fall feeding area boundaries.

The TF noted that PCFG animals might more regularly interact (compared to non-PCFG whales) with crab pots given their extended residency in coastal waters. Therefore, the TF recommended that the existing photo-identification time series be used to examine scarring patterns of PCFG whales to better understand the incidence of interactions with fishing gear.

Since much of the photo-identification sighting effort occurs in August and later, when many calves are likely to already be weaned and thereby more difficult to identify as a calf (versus a yearling), the TF recommended that the existing PCFG photo-identification time series be examined following a protocol developed by Bradford *et al*. (2011). This photo-based method uses barnacle and pigmentation characteristics on young gray whales to reliably distinguish calves of the year from yearlings.

Knowing that several lines of evidence demonstrate a relationship between minimum tenure and the probability of photographically capturing animals in the 42°N-52N° PCFG area, the TF recommended that the existing PCFG photo-identification time series be examined to see if moms/calves demonstrate higher degrees of fidelity than other whales.

Although photo-identification studies of the PCFG by Calambokidis and colleagues have been ongoing for over a decade, a relatively high number of "new" animals (not previously sighted in the area) are identified each year and subsequently show consistent return to the area (Calambokidis *et al*. 2012). These "new" animals could represent calves born into the group (i.e., internal recruitment) and not identified in their first year, or they could represent animals that traditionally feed in northern areas but now show fidelity to the seasonal range of the PCFG (i.e., external recruits). To better address this question, the TF recommended that relatedness analysis, in which microsatellite genotypes are used to identify animals that represent putative mother-offspring pairs, be used to assess the proportion of internal recruitment occurring within the PCFG. A sufficient understanding of recruitment to make a stock definition determination could potentially be achieved with a concerted effort to sample known mothers and recruits and determine their relatedness.

Related to the recommendation above, some TF members felt that it was plausible that the pulse of immigration into the PCFG could be larger than what the genetic simulations have modeled. If so, then the estimates of annual immigration into the PCFG could be lower than that estimated in the genetic simulations. With this in mind, the TF recommended that the genetic simulations should try pulses of 30 animals and see if that is consistent with the empirical genetic data.

12. Structured Decision-Making Process

At the request of the TF, Bettridge provided an overview of the FEMAT-style structured decision-making process[6]. In some NMFS status reviews, Biological Review Teams (BRTs) formed pursuant to the ESA have adopted formal methods to express plausibility for use in guiding its analysis of DPSs and in assessing the risks to the population(s). These formal methods are important in a setting where quantitative measures of uncertainty derived from the empirical data are unavailable. This point allocation method is often referred to as the "FEMAT" method because it is a variation of a method used by scientific teams evaluating options under the Northwest Forest Plan (Forest Ecosystem Management Assessment Team). In this approach, for example, each expert is asked to distribute plausibility points among the choices/scenarios for a given decision, reflecting his or her opinion of how likely that choice or option correctly reflected the population status. If the expert is certain of a particular option, or feels it is the only plausible scenario, he or she could assign all points to that option. An expert with less certainty about which option best reflected reality or best reflected the population's status could split the points among two or more options. This method has been used in all status review updates for anadromous Pacific salmonids since 1999, as well as in reviews of Southern Resident killer whales, West Coast rockfishes, Pacific herring (*Clupea pallasii*), Pacific groundfish, North American green sturgeon (*Acipenser medirostris*), black abalone (*Haliotis cracherodii*), Hawaii false killer whale (*Pseudorca crassidens*), and humpback whales.

In the humpback whale status review, BRT members distributed 100 likelihood points among the defined scenarios or options, reflecting their expert opinion of the relative likelihood that the status of a specific DPS falls into each of three risk categories. Then the team discussed how they had allocated points and subsequently had a chance to revise their scores. Scorer identity was known.

In the Hawaii false killer whale status review, BRT members distributed 10 points between the arguments for and against each factor. Team members agreed to view resulting scores with names associated to facilitate discussion and assure that linguistic uncertainty was not responsible for any disparate votes. The BRT discussed the scores and, in some cases, adjusted scores when prior articulation of the arguments had been unclear.

After presentation of the structured decision-making approach, Bettridge asked the TF the following questions: (1) Does the TF want to use this approach? (2) If so, how many points will each member allocate among scenarios? (3) Does the TF wish to disclose names, or keep scores anonymous? (4) Does the TF wish to allow for rescoring after discussion? The TF members agreed to employ the structured decision-making approach, allocating 100 points per person. The

---

[6] The TF agreed that Bettridge, as leader of the decision-making process, should refrain from allocating points on the decision questions.

group agreed to disclose names with scores for the purposes of internal discussion and possible rescoring but to retain anonymity in the final report.

The TF further agreed that they needed to carefully formulate the questions to be addressed and clearly understand what it means to put likelihood points in one category or another so as to provide the necessary advice for management-related issues such as: (1) how future NMFS stock assessment reports will be drafted with regard to gray whale stock structure in the North Pacific and (2) how to interpret any new information in the context of the Makah Indian Tribe MMPA waiver request to resume hunting gray whales off Washington State, USA.

Some TF members with experience using this approach in other situations found that when one or a few members allocated points very differently it was often due to misunderstanding of the question or what the answers implied. Therefore, it was agreed that the questions and the categories of answers should be as clear as possible to make the process both efficient and transparent.

12.1 Question formulation

In keeping with the objectives stated above for developing questions, the TF dedicated significant time during day 2 of the workshop agreeing on questions to be considered during the decision-making process. A key objective of this exercise was to focus on existing lines of evidence to help create the questions while at the same time being mindful of the existing definitions of the terms (e.g., demographic independence, interbreed when mature, functioning element of the ecosystem) contained in the MMPA and GAMMS guidelines. For instance, a simple example of this might be; "*evidence of demographic independence is when the number of internal recruits is greater than the number of external recruits*". In general, this philosophy of creating questions was adopted by the TF and maintained during its deliberations.

After considerable work, the TF agreed to 11 questions. Overnight, TF members privately completed their point allocations for each of the questions. Point allocations were tallied and ready for discussion on the final day of the workshop. Allocating points in this manner allowed individual TF members to express their level of certainty on each of the questions, such that placement of all points in a single category indicated relative certainty in the lines of evidence discussed during the workshop. The TF agreed to view resulting scores with names associated to facilitate discussion and assure that linguistic uncertainty was not responsible for any disparate votes. The TF discussed the scores and, in some cases, members adjusted them when prior articulation of the lines of evidence had been unclear. The final 11 questions and likelihood point allocations for each of the TF members (anonymous, labeled A – G), as well as the proportional distribution of points overall, are provided below.

Question 1.	Overall	A	B	C	D	E	F	G
	Does the ecosystem occupied by the PCFG when they are feeding differ from the ecosystems occupied by other ENP gray whales?							
Strongly Agree	53	100	0	80	100	90	0	0
Somewhat Agree	47	0	100	20	0	10	100	100
Neutral	0	0	0	0	0	0	0	0
Somewhat Disagree	0	0	0	0	0	0	0	0
Strongly Disagree	0	0	0	0	0	0	0	0

Question 2.	Overall	A	B	C	D	E	F	G
	If gray whales in the ENP continued to be managed as a single stock, would the future abundance of PCFG gray whales be maintained above 60% of their current abundance if annual HCM in the PCFG was 5?							
Strongly Agree	38	0	95	0	0	20	50	100
Somewhat Agree	23	20	5	5	0	80	50	0
Neutral	25	50	0	25	100	0	0	0
Somewhat Disagree	14	30	0	70	0	0	0	0
Strongly Disagree	0	0	0	0	0	0	0	0

Question 3.	Overall	A	B	C	D	E	F	G
	If gray whales in the ENP continued to be managed as a single stock, would the future abundance of PCFG gray whales be maintained above 60% of their current abundance if annual HCM in the PCFG was 10?							
Strongly Agree	10	0	50	0	0	0	0	20
Somewhat Agree	24	10	50	0	0	25	30	50
Neutral	21	40	0	0	0	25	50	30
Somewhat Disagree	17	40	0	10	0	50	20	0
Strongly Disagree	29	10	0	90	100	0	0	0

Question 4.	Overall	A	B	C	D	E	F	G
	If gray whales in the ENP continued to be managed as a single stock, would the future abundance of PCFG gray whales be maintained above 60% of their current abundance if annual HCM in the PCFG was 20?							
Strongly Agree	0	0	0	0	0	0	0	0
Somewhat Agree	4	0	25	0	0	0	0	0
Neutral	7	0	50	0	0	0	0	0
Somewhat Disagree	22	10	25	0	0	50	50	20
Strongly Disagree	67	90	0	100	100	50	50	80

Question 5.	Overall	A	B	C	D	E	F	G
	Given the lack of significant differences found in nuclear markers between PCFG whales and other eastern Pacific whales, how would you allot points to:							
There is complete random mating within the eastern NP	63	70	70	70	50	80	60	40
There could be some non-random mating within PCFG whales that is either too recent or at too low a level to be detected given current sample sizes and marker numbers	37	30	30	30	50	20	40	60
PCFG whales breed primarily with each other	0	0	0	0	0	0	0	0

Question 6.	Overall	A	B	C	D	E	F	G
	Based on the genetic data and simulations, how would you allot points to:							
Nearly all recruitment into the PCFG area results from external recruitment (immigration)	0	0	0	0	0	0	0	NA
Most recruitment into the PCFG area results from external recruitment	21	20	30	20	0	20	33	NA
Recruitment is about equal between internal (births) and external (immigration) recruitment	56	60	50	60	100	30	34	NA
Most recruitment into the PCFG area results from internal recruitment	24	20	20	20	0	50	33	NA

Question 7.	Overall	A	B	C	D	E	F	G
	Based on the photo-identification data, how would you allot points to:							
Nearly all recruitment into the PCFG area results from external recruitment (immigration)	0	0	0	0	0	0	0	0
Most recruitment into the PCFG area results from external recruitment	38	30	55	50	0	30	50	50
Recruitment is about equal between internal (births) and external (immigration) recruitment	48	40	35	35	100	50	35	40
Most recruitment into the PCFG area results from internal recruitment	14	30	10	15	0	20	15	10
Nearly all recruitment into the PCFG area results from internal recruitment	0	0	0	0	0	0	0	0

Question 8.	Overall	A	B	C	D	E	F	G
	Do the genetic and photo-identification data indicate that the PCFG is a demographically independent population?							
Strongly Agree	0	0	0	0	0	0	0	0
Somewhat Agree	35	25	10	80	100	30	0	0
Neutral	21	50	30	10	0	40	20	0
Somewhat Disagree	25	25	50	10	0	30	40	20
Strongly Disagree	19	0	10	0	0	0	40	80

Question 9.	Overall	A	B	C	D	E	F	G
	Given all lines of evidence, is the PCFG a "population stock" under the agency's interpretation of the MMPA?							
Strongly Agree	14	0	0	0	100	0	0	0
Somewhat Agree	22	25	10	80	0	30	10	0
Neutral	21	50	30	10	0	40	20	0
Somewhat Disagree	24	25	50	10	0	30	35	20
Strongly Disagree	18	0	10	0	0	0	35	80

Question 10.	Overall	A	B	C	D	E	F	G
	Given that some whales identified in the WNP migrate through U.S. waters to Mexico, should a separate SAR be developed for the WNP?							
Yes	79	100	70	100	100	50	80	50
No	21	0	30	0	0	50	20	50

Question 11.	Overall	A	B	C	D	E	F	G
	Given the differences found in mtDNA and nDNA between Sakhalin Island (WNP) and ENP gray whales, is there a "population stock" within the WNP under the agency's interpretation of the MMPA?							
Strongly Agree	100	100	100	100	100	100	100	100
Somewhat Agree	0	0	0	0	0	0	0	0
Neutral	0	0	0	0	0	0	0	0
Somewhat Disagree	0	0	0	0	0	0	0	0
Strongly Disagree	0	0	0	0	0	0	0	0

12.2 Question outcomes and discussion

The outcomes of each question above are discussed below and follow the convention of using "percentage of total points" to describe the results. For example, in Question 1 the "strongly agree" category was allotted 53% of the total available TF points (370 points allotted/700 total points = 53%).

Question 1

The TF expressed general agreement, by allocating 100% of the their combined points to the categories "somewhat agree" (47%) and "strongly agree" (53%) that PCFG whales seasonally feed in a unique ecosystem that differs from other gray whale feeding areas in the Pacific. Therefore, the TF concurred that it is reasonable to consider that if the PCFG no longer existed and the region was not reoccupied via immigration, summer feeding gray whales would no longer be a functioning element of the coastal Pacific Northwest ecosystem. Although such a circumstance is plausible, keeping all other things equal (e.g., habitat, prey availability), the current lines of evidence from photo-identification studies suggest it is unlikely that the level of annual immigration into the PCFG in the past decade would cease. Thus, the likelihood of gray whales not being found in the PCFG area seems low. However, the time it might take for "recolonization" of the PCFG via immigration is undetermined and thereby puts into question whether this scenario would meet the MMPA objectives of maintaining stocks not only for ecological purposes but also for aesthetic, recreational and economic reasons.

Questions 2, 3 and 4
These three questions were meant to address the MMPA objective of maintaining population stocks as significant functioning elements in the ecosystem of which they are part, and that population stocks should not be permitted to decline below OSP. GAMMS II state that where mortality is greater than a PBR level calculated from the abundance for the region where human caused mortality (HCM) occurs, serious consideration should be given to identifying an appropriate management unit in the region. While estimates of PBR and HCM for a putative PCFG stock have been generated (Carretta *et al*. 2013), there is uncertainty about both estimates, especially with respect to: (1) whether HCM (e.g., ship strikes and fisheries bycatch) for whales in the PCFG area is indeed higher than for whales that migrate through the area, and (2) where HCM actually occurs. In response to these questions, the TF expressed increasing concern about the ability of the PCFG to be maintained above 60%[7] of its current abundance once HCM exceeded 5 whales per year.

The point allocation in Question 2 indicates that the TF overall tended to agree that the future abundance of PCFG gray whales would be maintained above 60% of their current abundance if annual HCM in the PCFG was 5. However, the relatively equal distribution of likelihood points in all categories except "strongly agree" indicates a high level of uncertainty among the TF.

For Question 3, points were allocated more broadly across categories, indicating a higher level of uncertainty among TF members as to whether the PCFG could sustain levels of HCM at 10 whales per year.

There was increased consensus among the TF for Question 4 in that none of them responded "strongly agree". Overall, the TF concurred that it somewhat (22%) or strongly disagreed (67%) that the future abundance of PCFG gray whales would be maintained above 60% of their current abundance if annual HCM in the PCFG was 20.

Question 5
The TF found no evidence to suggest that PCFG whales breed primarily with each other. While there was general agreement (63%) that the lack of significant differences found in nuclear DNA markers between PCFG whales and other ENP whales suggests random interbreeding among all ENP whales, the allotment of 37% of the total points to the intermediate category suggests TF members thought it was possible that some breeding segregation may exist based on migratory timing (see Lang *et al*. 2011) but there is no direct evidence presently available to support or further test this theory.

Question 6
The TF found no evidence in the results from genetics studies to suggest that nearly all recruitment into the PCFG area results from external recruitment (immigration). Based on the genetic data and simulations discussed during the workshop, the highest average TF response (56%) indicates that TF members believe recruitment is most likely about equal between internal (births) and external (immigration) recruitment. That being said, the remaining 45% of the total points were split between most recruitment into the PCFG area resulting from either internal or

---

[7] The management goal of the MMPA is to prevent populations from "depletion". NMFS considers a population depleted if it fall below its Maximum Net Productivity Level (MNPL). For marine mammals, this level is thought to be between 50% and 85% of carrying capacity and is more likely to be in the lower portion of that range (Taylor and DeMaster 1993). Therefore, populations are considered depleted by the U.S. government if they are directly estimated to be below their MNPL, or if they are estimated to be below 50%-70% of a historic population size which it thought to represent carrying capacity (Gerrodette and DeMaster 1990).

external recruitment, indicating some overall uncertainty among members regarding the presently available lines of evidence about recruitment in the PCFG. It should be noted that one member of the TF refrained from assigning any points to this question, so these results represent 6 of 7 TF members actively involved in the point assignment process.

Question 7
Based on the photo-identification data, the TF found no evidence to suggest that nearly all recruitment was either external or internal, but rather some combination of the two. As with the genetics evidence, the highest average TF response (48%) indicates that the TF felt recruitment from internal (births) and external (immigration) sources are comparable. That being said, 38% of the total points were allocated to most recruitment into the PCFG area resulting from external recruitment. Therefore, a majority of the total points were allocated to either recruitment being about equal between internal (births) and external (immigration) recruitment (48%) or most recruitment into the PCFG area results from external recruitment (38%). As was also true with the genetic lines of evidence, these results from the TF suggest a fairly high level of uncertainty regarding recruitment into the PCFG.

Question 8
Based on the genetic and photo-identification data, the TF did not strongly agree that the PCFG is a demographically independent population. Although the highest average TF response (35%) was “somewhat agree” that the PCFG is a demographically independent population, the combined categories of “somewhat disagree” and “strongly disagree” elicited 44% of the total points allocated. Overall, these results from the TF suggest a high level of uncertainty regarding recruitment in the PCFG.

Question 9
Given all lines of evidence, the point allocation of the TF reflects broad uncertainty as to whether the PCFG should be regarded as a population stock under the MMPA and GAMMS guidelines. Perhaps more than all of the other questions considered, Question 9 reflects the highest degree of uncertainty. For instance, the “strongly agree” (14%) and somewhat agree (22%) categories are almost perfectly counter-balanced by the “somewhat disagree”(24%) and “strongly disagree” (18%) categories. An additional level of uncertainty is indicated by the “neutral” category (21%). Given these results, it seems clear that TF was unable to reach a definitive response with respect to the PCFG being a population stock. That is, members of the TF ranged in their opinions from strongly agree to strongly disagree as to whether the PCFG should be considered a separate stock.

Given that this question represents the primary purpose of the workshop, the following two sections provide insight into the deliberations of the TF with regard to arguments for and against the PCFG being a demographically independent unit.

❖ *Arguments for the PCFG being a demographically independent unit*

The return of individual whales to specific feeding areas for as long as the PCFG has been studied (30+ years) strongly suggests that site fidelity is key to maintaining gray whales as a functioning element of this ecosystem. There was agreement that this ecosystem differs from other feeding ecosystems occupied by gray whales. Gray whales are unique among the great whales in being found in only a single ocean basin. Within this ocean basin the PCFG is the only feeding group that does not rely on the dynamics of a sub-arctic ecosystem. As such, the PCFG deserves the protections afforded by being an MMPA stock because the ecosystem role of these animals is unique and also because it provides gray whales, as a species, the flexibility they may need given potential challenges in a changing sub-arctic ecosystem.

Although there is evidence of recruitment from other feeding aggregations, there is also evidence of direct internal recruitment because calves have been shown to return to the PCFG area and reside there. Furthermore, because photographic efforts take place after most claves would be weaned, the recruits into the population not first seen as calves are actually of unknown origin and cannot be definitively assigned as external recruits.

PCFG whales show a low but significant level of genetic differentiation at the mtDNA control region when compared to samples collected in Chukotka [representative of the ENP population and sampled at a single feeding location in the Bering Sea], and when compared to a set of samples collected primarily from animals that stranded along the west coast of the U.S. [representative of a broader sampling of the ENP population]. The significant differences found when the mtDNA haplotype data from the PCFG is compared with that of groups representing the larger ENP population provide indirect evidence of internal recruitment and matrilineally-directed site fidelity to feeding grounds. The level of differentiation is on par with levels identified among humpback whales feeding in different areas of the western North Atlantic (Palsbøll *et al*. 2001) as well as humpback whales using different breeding grounds in the Southern Hemisphere (Rosenbaum *et al*. 2009), suggesting that the PCFG exhibits demographic independence similar to what has been inferred for other large whales. Within the western North Atlantic, humpback whales feeding in the Gulf of Maine are managed as a separate stock despite the fact that they share a common breeding ground with humpbacks feeding in other areas. Although evidence for nuclear DNA differentiation between PCFG whales and other areas has not been found, nuclear genetic differentiation has not always been required for stock delimitation. Pacific harbor seal stocks were delimited on mtDNA differentiation alone (nuclear data were not available at the time), while the Gulf of Maine/Bay of Fundy stock of harbor porpoises was delimited based on significant differentiation at mtDNA, contaminant loads, and life history differences, and despite a lack of differentiation at nuclear markers.

❖ *Arguments against the PCFG being a demographically independent unit*

The evidence that external recruitment is not a rare event is quite strong. The genetic data have numerous rare haplotypes that are not consistent with a small, closed population. Indeed, simulations are not consistent with a closed population. A sizable number of individuals seen in the main feeding season are identified as transients, which is consistent with an on-going level of the main ENP population investigating this new habitat but then moving on. Further, when all samples collected in summer in the PCFG area are used there is not a significant difference found in mtDNA frequencies compared to all samples collected north of the Aleutian Islands. The number of recruits into the PCFG has been estimated, through genetic data, to be 4 to as high as 8 individuals per year. Photo-identification data suggest similarly high numbers of non-calf recruits per year (8-11). These numbers exceed the estimated number of internal recruits and, given that PCFG numbers appear to be relatively stable, an addition of 4 or more external recruits per year cannot be considered trivial. These external recruitment rates suggest the PCFG is not demographically independent from the larger ENP population.

Furthermore, unlike other large whale populations, the annual coastal migration of the vast majority of ENP gray whales brings most individuals into contact with the habitat used by the PCFG. Should there be increased removals from this area, the continual visitation to this area by a large number of gray whales would make it likely that external recruitment would increase to fill any voids. The apparent pulse recruitment in 1999-2000 when conditions in the sub-arctic feeding areas resulted in a large mortality event shows that gray whales can adapt to a new habitat when conditions dictate. Using data collected since 2002 (post-pulse recruitment event), an average of 29.3 new whales have been identified in summer in the area used by the PCFG, with 18.5 animals that are not seen in later years and 10.8 whales that are seen in later years. Given that an average of 18.5 new whales (at least, as this does not account for new whales not photographed) visit the PCFG area each summer but do not return, this suggests that something on the order of 10% of the whales that occur in the PCFG area each summer are transients that otherwise feed north of the Aleutians, and serve as a substantial and continuous source of potential recruitment into the PCFG.

To date, there is no evidence for nDNA differentiation between Chukotka and PCFG whales based on 8 microsatellite loci or between the PCFG and one Mexican calving lagoon based on 15 loci. These results may be interpreted as female directed site fidelity to the PCFG area coupled with random mating between PCFG and ENP whales on the breeding ground. Lack of nuclear differentiation diminishes support for demographic independence.

All lines of evidence (photo-identification and genetics) are consistent with ongoing external recruitment that could be at a magnitude that is not trivial to the persistence of the feeding aggregation (more than a percent or two per year). Uncertainty in the number of recruits per year and exactly who those recruits are (PCFG calves misidentified as recruits, true recruits of adults, temporary immigrants who do not stay more than a few years and may not even be contributing to the gene pool) creates significant uncertainty as to whether internal recruitment exceeds external recruitment. Given the high level of mtDNA haplotypic diversity, the precision of F_{ST} estimates is also uncertain. Taken together, the available evidence is weak for concluding the PCFG is demographically independent.

Question 10
Given that some whales identified in the WNP have been observed to migrate through U.S. waters to Mexico, in combination with the 1994 amendments to the MMPA requiring that SARs be published for all stocks of marine mammals in U.S. waters, the TF agreed to a high degree (79%) that a separate SAR should be developed in the future for the WNP stock of gray whales.

Question 11
Based on the differences found in mtDNA and nDNA between Sakhalin Island (WNP) and ENP gray whales, the TF unanimously (100%) agreed that it qualifies as a population stock under the MMPA and GAMMS guidelines.

13. Concluding Remarks

The implications of new data pertinent to stock structure, including considerable information related to the PCFG and WNP gray whales, were thoroughly reviewed during the workshop. Evaluating the new findings relevant to the status of the PCFG proved particularly complex. After review of results from photo-identification, genetics, tagging, and other studies within the context of the GAMMS guidelines there remains a substantial level of uncertainty in the strength of the lines of evidence supporting demographic independence of the PCFG. Consequently, the TF was unable to provide definitive advice as to whether the PCFG is a population stock under the MMPA and the GAMMS guidelines. Members of the TF ranged in their opinions from strongly agreeing to strongly disagreeing about whether the PCFG should be recognized as a separate stock.

In the case of WNP gray whales, the work of the TF was more straightforward. The mitochondrial DNA and nuclear DNA genetic differentiation found between the WNP and ENP stocks provided convincing evidence that resulted in the TF providing unambiguous advice that the WNP stock should be recognized as a population stock pursuant to the GAMMS guidelines and the MMPA.

Additional research may narrow the uncertainty associated with the question of whether the PCFG should be recognized as a population stock. To work towards this objective, the TF recommended further investigation of recruitment into the PCFG. Presently, both the photo-identification and genetics data indicate that the levels of internal versus external recruitment are comparable, but these are not quantified well enough to determine if the population dynamics of the PCFG are more a consequence of births and deaths within the group (internal dynamics) rather than related to immigration and/or emigration (external dynamics). The TF offered a number of research recommendations, using the existing photo-identification and genetics datasets, that could provide increased resolution on the issue of recruitment and, in turn, the question of stock identification.

While the need for additional data collection was apparent, especially with regard to recruitment into the PCFG, the purpose of the workshop was for the TF to determine whether the *existing* best available science was sufficient to advise that the PCFG be recognized as a population stock under the language of the MMPA and GAMMS guidelines. Therefore, the advice of the TF offered in this report should be viewed as a contemporary “snapshot” taken from an emerging and ever-changing body of knowledge regarding the PCFG.

The TF emphasizes that the PCFG is relatively small in number and utilizes a largely different ecosystem from that of the main ENP stock. While the status of the PCFG as a population stock has yet to be resolved, continued research on these whales should be undertaken with particular attention dedicated to collecting data relevant to the question of stock identification.

14. Acknowledgements

The Task Force appreciates the dedication and hard work of Aimee Lang and Annette Henry. Their contributions to the workshop and related report were indispensable. We also thank Lisa Ballance, Donna Darm, Jeremy Rusin, and Wayne Perryman for their advice and support in bringing the workshop to fruition. Jim Carretta and Steve Stone provided astute summaries of information that greatly benefitted the work of the Task Force. Cisco Werner and Kristen Koch provided encouragement for the workshop to be held and made available the facilities of the Southwest Fisheries Science Center. Barb Taylor kindly hosted a wonderful social gathering at her home.

16. Appendix 1 – Workshop Agenda

GRAY WHALE STOCK IDENTIFICATION WORKSHOP AGENDA

Southwest Fisheries Science Center
La Jolla, California
31 July-2 August 2012

Day 1 (31 July 2012)

8:30-8:45
1. Introductory Items
1.1 Convenor's opening remarks (Ballance)
1.2 Arrangements for the meeting (Henry)
1.3 Appointment of chair, task force and rapporteurs
1.4 Adoption of agenda
1.5 Documents available

8:45-9:15
2. Workshop Objectives
2.1 Provide scientific advice on gray whale stock structure (Weller)
2.2 Workshop relationship to stock assessment reports (Carretta/Bettridge)
    2.2.1 Confirm current stock structure
    2.2.2 Assess new information on putative or prospective stocks
    2.2.3 Provide advice on necessary changes to stock structure
2.3 Workshop relationship to Makah waiver request (Darm/Stone)
    2.3.1 History
    2.3.2 Key considerations
    2.3.3 Current status of waiver request
  2.3.4 Need to know information

9:15-10:30
3. Working Group on Stock Identification (Bettridge and Moore)
3.1 Overview of MMPA language and GAMMS guidelines pertaining to stock definition (Moore)
    3.1.1 Existing GAMMS language
    3.1.2 Proposed GAMMS revisions from the GAMMS III workshop
3.2 Overview of recent history pertaining to NMFS interpretation of "interbreed when mature" (Bettridge/Beale)
  3.2.1 Draft GAMMS II language pertaining to "interbreed when mature"
  3.2.2 Status of current legal analysis of NMFS proposed definition
3.3 Additional relevant history concerning definition of "population" for marine mammals (e.g., Taylor 1997, excerpts from Eagle *et al.* 2008) (Moore/ Taylor)

BREAK 10:30-10:45

10:45-12:00
3.4 Current status of gray whale SAR development (Bettridge)
3.5 Discuss key concepts: interbreed when mature, population, demographic independence, functioning element of ecosystem
3.6 Proposed TF voting protocol and process: examples from FEMAT and the ESA (humpback whale BRT, false killer whale BRT) (Bettridge)

3.7. Proposed questions to be voted on by the Task Force

12:00-12:45
4. Working Group on Other Information (Weller and Brownell)
4.1 Overview of gray whale "population stocks" (Lang)
  4.1.1 Eastern North Pacific Stock
  4.1.2 Western North Pacific Stock
    4.1.2.1 Genetic lines of evidence as being a stock
    4.1.2.2 Movements of whales between the WNP and ENP
4.2 Brief overview of the Pacific Coast Feeding Group (PCFG) putative stock (Lang)
    4.2.1 History
  4.2.2 Range
  4.2.3 Abundance
  4.2.4 Diet
  4.2.5 Movements (tagging, photo-ID)
  4.2.6 Incidental Take (Carretta)
  4.2.7 Emerging issues and areas of uncertainty
    4.2.7.1 Probability of a WNP Being Taken by the Makah (Moore)
4.3 Status of the ENP, WNP and PCFG as stocks (NMFS/MMPA/ESA/IWC) (Stone)
4.4 Proposed questions to be voted on by the Task Force

LUNCH 12:45-1:30

13:30-14:15
5. Working Group on Genetic Population Structure (Taylor and Rosel)
5.1 Broad overview of evidence used in recently defined stocks (Stone)
5.2 Review of stock definition cases relevant to the PCFG case
  5.2.1 Atlantic harbor porpoises (Rosel)
  5.2.2 Alaska harbor seals (Taylor)
    5.2.3 Humpback whales (Lang)

14:15-15:00
5.3 Review of gray whale genetic research relating to population structure (Lang)
  5.3.1 Summary of early work (LeDuc, Ramakrishnan, Alter breeding lagoon)
  5.3.2 Summary of recent work
    5.3.2.1 Frasier and D'Intino
    5.3.2.2 Lang – empirical genetics
    5.3.2.3 Lang – modeling genetics
5.4 Proposed questions to be voted on by the Task Force

BREAK 15:00-15:30

15:30-17:00

6. Discussion of Documents Drafted by the Makah Tribe and Other General Matters (Task Force)
6.1 Makah Tribe documents (Weller)
  6.1.1 Introduce GWLJ33: "Is the Pacific feeding group of gray whales a "population stock" within the meaning of the Marine Mammal Protection Act?"
  6.1.2 Introduce GWLJ32: "Comments on Draft 2012 Stock Assessment Report for eastern North Pacific stock of gray whales"
  6.1.3 Introduce GWLJ34: "What is the PCFG? A review of available information"
  6.1.4 Discuss genetics sections of Makah Tribe document GWLJ33 (Taylor/Rosel)
6.2 General discussion of Day 1 information

Day 2 (1 August 2012)

9:00-10:30
7. Working Group on Population Abundance and Trends (Laake and Wade)
7.1 Photo-identification and population dynamics of the PCFG (Laake)
    7.1.1 Definition of PCFG whales based on timing/area
    7.1.2 Movements of know PCFG whales (photo-identification and telemetry)
    7.1.3 Abundance/survival estimates
    7.1.4 Trends (Wade)
    7.1.5 Recruitment
    7.1.6 PCFG Trend/OSP (Moore)
    7.1.7 Discuss photo-identification and telemetry sections of Makah Tribe document GWLJ33 (Laake/Wade)
7.2 Proposed questions to be voted on by the Task Force

BREAK 10:30-11:00

11:00-12:30
8. Review and Agree on Workshop Questions for Voting

LUNCH 12:30-13:30

13:30-15:30
9. Description of Vote Procedure (Bettridge)
10. TF Voting on Workshop Questions (TF Only)

Overnight
11. Compile and Tally Votes (Lang/Henry)

Day 3 (2 August 2012)

9:00-12:00
12. Review of Vote Outcomes (Lang/Henry)
13. Discussion of Vote Outcomes
14. Revision of Questions for voting if Necessary
15. Revote if Necessary

LUNCH 12:00-13:30

13:30-16:30
16. Review of Revote Results if Necessary (Lang/Henry)
17. Other Business
18. Workplan for Workshop Report Completion
19. Adjourn

17. Appendix 2 - Workshop Document List

International Convention
for the
Regulation of Whaling, 1946

Schedule

As amended by the Commission at the 67th Meeting

Florianópolis, Brazil, September 2018

INTERNATIONAL
WHALING COMMISSION

International Convention
for the
Regulation of Whaling, 1946
Schedule

EXPLANATORY NOTES

The Schedule printed on the following pages contains the amendments made by the Commission at its 67th Meeting in September 2018. The amendments, which are shown in ***italic bold*** type, come into effect on 29 December 2018.
In Tables 1, 2 and 3 unclassified stocks are indicated by a dash. Other positions in the Tables have been filled with a dot to aid legibility.
Numbered footnotes are integral parts of the Schedule formally adopted by the Commission. Other footnotes are editorial.
The Commission was informed in June 1992 by the ambassador in London that the membership of the Union of Soviet Socialist Republics in the International Convention for the Regulation of Whaling from 1948 is continued by the Russian Federation.
The Commission recorded at its 39th (1987) meeting the fact that references to names of native inhabitants in Schedule paragraph 13(*b*)(4) would be for geographical purposes alone, so as not to be in contravention of Article V.2(c) of the Convention (*Rep. int. Whal. Commn* 38:21).

I. INTERPRETATION

1. The following expressions have the meanings respectively assigned to them, that is to say:

A. Baleen whales

"baleen whale" means any whale which has baleen or whale bone in the mouth, i.e. any whale other than a toothed whale.

"blue whale" (*Balaenoptera musculus*) means any whale known as blue whale, Sibbald's rorqual, or sulphur bottom, and including pygmy blue whale.

"bowhead whale" (*Balaena mysticetus*) means any whale known as bowhead, Arctic right whale, great polar whale, Greenland right whale, Greenland whale.

"Bryde's whale" (*Balaenoptera edeni*, *B. brydei*) means any whale known as Bryde's whale.

"fin whale" (*Balaenoptera physalus*) means any whale known as common finback, common rorqual, fin whale, herring whale, or true fin whale.

"gray whale" (*Eschrichtius robustus*) means any whale known as gray whale, California gray, devil fish, hard head, mussel digger, gray back, or rip sack.

"humpback whale" (*Megaptera novaeangliae*) means any whale known as bunch, humpback, humpback whale, humpbacked whale, hump whale or hunchbacked whale.

"minke whale" (*Balaenoptera acutorostrata*, *B. bonaerensis*) means any whale known as lesser rorqual, little piked whale, minke whale, pike-headed whale or sharp headed finner.

"pygmy right whale" (*Caperea marginata*) means any whale known as southern pygmy right whale or pygmy right whale.

"right whale" (*Eubalaena glacialis*, *E. australis*) means any whale known as Atlantic right whale, Arctic right whale, Biscayan right whale, Nordkaper, North Atlantic right whale, North Cape whale, Pacific right whale, or southern right whale.

"sei whale" (*Balaenoptera borealis*) means any whale known as sei whale, Rudolphi's rorqual, pollack whale, or coalfish whale.

B. Toothed whales

"toothed whale" means any whale which has teeth in the jaws.

"beaked whale" means any whale belonging to the genus Mesoplodon, or any whale known as Cuvier's beaked whale (*Ziphius cavirostris*), or Shepherd's beaked whale (*Tasmacetus shepherdi*).

"bottlenose whale" means any whale known as Baird's beaked whale (*Berardius bairdii*), Arnoux's whale (*Berardius arnuxii*), southern bottlenose whale (*Hyperoodon planifrons*), or northern bottlenose whale (*Hyperoodon ampullatus*).

"killer whale" (*Orcinus orca*) means any whale known as killer whale or orca.

"pilot whale" means any whale known as long-finned pilot whale (*Globicephala melaena*) or short-finned pilot whale (*G. macrorhynchus*).

"sperm whale" (*Physeter macrocephalus*) means any whale known as sperm whale, spermacet whale, cachalot or pot whale.

C. General

"strike" means to penetrate with a weapon used for whaling.

"land" means to retrieve to a factory ship, land station, or other place where a whale can be treated.

"take" means to flag, buoy or make fast to a whale catcher.

"lose" means to either strike or take but not to land.

"dauhval" means any unclaimed dead whale found floating.

"lactating whale" means (a) with respect to baleen whales - a female which has any milk present in a mammary gland, (b) with respect to sperm whales - a female which has milk present in a mammary gland the maximum thickness (depth) of which is 10cm or more. This measurement shall be at the mid ventral point of the mammary gland perpendicular to the body axis, and shall be logged to the nearest centimetre; that is to say, any gland between 9.5cm and 10.5cm shall be logged as 10cm. The measurement of any gland which falls on an exact 0.5 centimetre shall be logged at the next 0.5 centimetre, e.g. 10.5cm shall be logged as 11.0cm.

However, notwithstanding these criteria, a whale shall not be considered a lactating whale if scientific (histological or other biological) evidence is presented to the appropriate national authority establishing that the whale could not at that point in its physical cycle have had a calf dependent on it for milk.

"small-type whaling" means catching operations using powered vessels with mounted harpoon guns hunting exclusively for minke, bottlenose, beaked, pilot or killer whales.

II. SEASONS

Factory Ship Operations

2. (a) It is forbidden to use a factory ship or whale catcher attached thereto for the purpose of taking or treating baleen whales except minke whales, in any waters south of 40° South Latitude except during the period from 12th December to 7th April following, both days inclusive.
   (b) It is forbidden to use a factory ship or whale catcher attached thereto for the purpose of taking or treating sperm or minke whales, except as permitted by the Contracting Governments in accordance with sub-paragraphs (*c*) and (*d*) of this paragraph, and paragraph 5.
   (c) Each Contracting Government shall declare for all factory ships and whale catchers attached thereto under its jurisdiction, an open season or seasons not to exceed eight months out of any period of twelve months during which the taking or killing of sperm whales by whale catchers may be permitted; provided that a separate open season may be declared for each factory ship and the whale catchers attached thereto.
   (d) Each Contracting Government shall declare for all factory ships and whale catchers attached thereto under its jurisdiction one continuous open season not to exceed six months out of any period of twelve months during which the taking or killing of minke whales by the whale catchers may be permitted provided that:
      (1) a separate open season may be declared for each factory ship and the whale catchers attached thereto;
      (2) the open season need not necessarily include the whole or any part of the period declared for other baleen whales pursuant to sub-paragraph (a) of this paragraph.
3. It is forbidden to use a factory ship which has been used during a season in any waters south of 40° South Latitude for the purpose of treating baleen whales, except minke whales, in any other area except the North Pacific Ocean and its dependent waters north of the Equator for the same purpose within a period of one year from the termination of that season; provided that catch limits in the North Pacific Ocean and dependent waters are established as provided in paragraphs 12 and 16 of this Schedule and provided that this paragraph shall not apply to a ship which has been used during the season solely for freezing or salting the meat and entrails of whales intended for human food or feeding animals.

Land Station Operations

4. (a) It is forbidden to use a whale catcher attached to a land station for the purpose of killing or attempting to kill baleen and sperm whales except as permitted by the Contracting Government in accordance with sub-paragraphs (*b*), (*c*) and (*d*) of this paragraph.
   (b) Each Contracting Government shall declare for all land stations under its jurisdiction, and whale catchers attached to such land stations, one open season during which the taking or killing of baleen whales, except minke whales, by the whale catchers shall be permitted. Such open season shall be for a period of not more than six consecutive months in any period of twelve months and shall apply to all land stations under the jurisdiction of the Contracting Government; provided that a separate open season may be declared for any land station used for the taking or treating of baleen whales, except minke whales, which is more than 1,000 miles from the nearest land station used for the taking or treating of baleen whales, except minke whales, under the jurisdiction of the same Contracting Government.
   (c) Each Contracting Government shall declare for all land stations under its jurisdiction and for whale catchers attached to such land stations, one open season not to exceed eight continuous months in any one period of twelve months, during which the taking or killing of sperm whales by the whale catchers shall be permitted; provided that a separate open season may be declared for any land station used for the taking or treating of sperm whales which is more than 1,000 miles from the nearest land station used for the taking or treating of sperm whales under the jurisdiction of the same Contracting Government.
   (d) Each Contracting Government shall declare for all land stations under its jurisdiction and for whale catchers attached to such land stations one open season not to exceed six continuous months in any period of twelve months during which the taking or killing of minke whales by the whale catchers shall be permitted (such period not being necessarily concurrent with the period declared for other baleen whales, as provided for in sub-paragraph (*b*) of this paragraph); provided that a separate open season may be declared for any land station used for the taking or treating of minke whales which is more than 1,000 miles from the nearest land station used for the taking or treating of minke whales under the jurisdiction of the same Contracting Government.

   Except that a separate open season may be declared for any land station used for the taking or treating of minke whales which is located in an area having oceanographic conditions clearly distinguishable from those of the area in which are located the other land stations used for the taking or treating of minke whales under the jurisdiction of the same Contracting Government; but the declaration of a separate open season by virtue of the provisions of this sub-paragraph shall not cause thereby the period of time covering the open seasons declared by the same Contracting Government to exceed nine continuous months of any twelve months.

(e) The prohibitions contained in this paragraph shall apply to all land stations as defined in Article II of the Whaling Convention of 1946.

Other Operations

5. Each Contracting Government shall declare for all whale catchers under its jurisdiction not operating in conjunction with a factory ship or land station one continuous open season~~s~~ not to exceed six months out of any period of twelve months during which the taking or killing of minke whales by such whale catchers may be permitted. Notwithstanding this paragraph one continuous open season not to exceed nine months may be implemented so far as Greenland is concerned. ***This paragraph shall not apply to aboriginal subsistence whaling under paragraphs 13(b)(3)(ii) and 13(b)(3)(iii).***

III. CAPTURE

6. The killing for commercial purposes of whales, except minke whales using the cold grenade harpoon shall be forbidden from the beginning of the 1980/81 pelagic and 1981 coastal seasons. The killing for commercial purposes of minke whales using the cold grenade harpoon shall be forbidden from the beginning of the 1982/83 pelagic and the 1983 coastal seasons.*

7. (a) In accordance with Article V(1)(*c*) of the Convention, commercial whaling, whether by pelagic operations or from land stations, is prohibited in a region designated as the Indian Ocean Sanctuary. This comprises the waters of the Northern Hemisphere from the coast of Africa to 100°E, including the Red and Arabian Seas and the Gulf of Oman; and the waters of the Southern Hemisphere in the sector from 20°E to 130°E, with the Southern boundary set at 55°S. This prohibition applies irrespective of such catch limits for baleen or toothed whales as may from time to time be determined by the Commission. This prohibition shall be reviewed by the Commission at its Annual Meeting in 2002.☼

(b) In accordance with Article V(1)(*c*) of the Convention, commercial whaling, whether by pelagic operations or from land stations, is prohibited in a region designated as the Southern Ocean Sanctuary. This Sanctuary comprises the waters of the Southern Hemisphere southwards of the following line: starting from 40 degrees S, 50 degrees W; thence due east to 20 degrees E; thence due south to 55 degrees S; thence due east to 130 degrees E; thence due north to 40 degrees S; thence due east to 130 degrees W; thence due south to 60 degrees S; thence due east to 50 degrees W; thence due north to the point of beginning. This prohibition applies irrespective of the conservation status of baleen and toothed whale stocks in this Sanctuary, as may from time to time be determined by the Commission. However, this prohibition shall be reviewed ten years after its initial adoption and at succeeding ten year intervals, and could be revised at such times by the Commission. Nothing in this sub-paragraph is intended to prejudice the special legal and political status of Antarctica.**+

Area Limits for Factory Ships

8. It is forbidden to use a factory ship or whale catcher attached thereto, for the purpose of taking or treating baleen whales, except minke whales, in any of the following areas:
   (a) in the waters north of 66°N, except that from 150°E eastwards as far as 140°W, the taking or killing of baleen whales by a factory ship or whale catcher shall be permitted between 66°N and 72°N;
   (b) in the Atlantic Ocean and its dependent waters north of 40°S;
   (c) in the Pacific Ocean and its dependent waters east of 150°W between 40°S and 35°N;
   (d) in the Pacific Ocean and its dependent waters west of 150°W between 40°S and 20°N;
   (e) in the Indian Ocean and its dependent waters north of 40°S.

Classification of Areas and Divisions

9. (a) *Classification of Areas*
   Areas relating to Southern Hemisphere baleen whales except Bryde's whales are those waters between the ice-edge and the Equator and between the meridians of longitude listed in Table 1.

   (b) *Classification of Divisions*
   Divisions relating to Southern Hemisphere sperm whales are those waters between the ice-edge and the Equator and between the meridians of longitude listed in Table 3.

   (c) *Geographical boundaries in the North Atlantic*
   The geographical boundaries for the fin, minke and sei whale stocks in the North Atlantic are:

FIN WHALE STOCKS
NOVA SCOTIA
South and West of a line through:
47°N 54°W, 46°N 54°30'W,
46°N 42°W, 20°N 42°W.

NEWFOUNDLAND-LABRADOR
West of a line through:
75°N 73°30'W, 69°N 59°W, 61°N 59°W,
52°20'N 42°W, 46°N 42°W and
North of a line through:
46°N 42°W, 46°N 54°30'W, 47°N 54°W.

WEST GREENLAND
East of a line through:
75°N 73°30'W, 69°N 59°W,
61°N 59°W, 52°20'N 42°W,
and West of a line through
52°20'N 42°W, 59°N 42°W,
59°N 44°W, Kap Farvel.

---

*The Governments of Brazil, Iceland, Japan, Norway and the Union of Soviet Socialist Republics lodged objections to the second sentence of paragraph 6 within the prescribed period. For all other Contracting Governments this sentence came into force on 8 March 1982. Norway withdrew its objection on 9 July 1985 and Brazil on 8 January 1992. Iceland withdrew from the Convention with effect from 30 June 1992. The objections of Japan and the Russian Federation not having been withdrawn, this sentence is not binding upon these governments.

☼At its 54th Annual Meeting in 2002, the Commission agreed to continue this prohibition but did not discuss whether or not it should set a time when it should be reviewed again.

**The Government of Japan lodged an objection within the prescribed period to paragraph 7(*b*) to the extent that it applies to the Antarctic minke whale stocks. The Government of the Russian Federation also lodged an objection to paragraph 7(*b*) within the prescribed period but withdrew it on 26 October 1994. For all Contracting Governments except Japan paragraph 7(*b*) came into force on 6 December 1994.

[+] Paragraph 7(*b*) contains a provision for review of the Southern Ocean Sanctuary "ten years after its initial adoption". Paragraph 7(*b*) was adopted at the 46th (1994) Annual Meeting. The first review was completed in 2004, and the second in 2016.

EAST GREENLAND-ICELAND
East of a line through:
Kap Farvel (South Greenland),
59°N 44°W, 59°N 42°W, 20°N 42°W,
and West of a line through:
20°N 18°W, 60°N 18°W, 68°N 3°E,
74°N 3°E, and South of 74°N.

NORTH NORWAY
North and East of a line through:
74°N 22°W, 74°N 3°E, 68°N 3°E,
67°N 0°, 67°N 14°E.

WEST NORWAY-FAROE ISLANDS
South of a line through:
67°N 14°E, 67°N 0°, 60°N 18°W,
and North of a line through:
61°N 16°W, 61°N 0°, Thyborøn
(Western entrance to Limfjorden, Denmark).

SPAIN-PORTUGAL-BRITISH ISLES
South of a line through:
Thyborøn (Denmark), 61°N 0°, 61°N 16°W,
and East of a line through:
63°N 11°W, 60°N 18°W, 22°N 18°W.

MINKE WHALE STOCKS
CANADIAN EAST COAST
West of a line through:
75°N 73°30’W, 69°N 59°W, 61°N 59°W,
52°20’N 42°W, 20°N 42°W.

CENTRAL
East of a line through:
Kap Farvel (South Greenland),
59°N 44°W, 59°N 42°W, 20°N 42°W,
and West of a line through:
20°N 18°W, 60°N 18°W, 68°N 3°E,
74°N 3°E, and South of 74°N.

WEST GREENLAND
East of a line through:
75°N 73°30’W, 69°N 59°W, 61°N 59°W,
52°20’N 42°W, and
West of a line through:
52°20’N 42°W, 59°N 42°W,
59°N 44°W, Kap Farvel.

NORTHEASTERN
East of a line through:
20°N 18°W, 60°N 18°W, 68°N 3°E, 74°N 3°E,
and North of a line through:
74°N 3°E, 74°N 22°W.

SEI WHALE STOCKS
NOVA SCOTIA
South and West of a line through:
47°N 54°W, 46°N 54°30’W, 46°N 42°W,
20°N 42°W.

ICELAND-DENMARK STRAIT
East of a line through:
Kap Farvel (South Greenland),
59°N 44°W, 59°N 42°W, 20°N 42°W,
and West of a line through:
20°N 18°W, 60°N 18°W, 68°N 3°E,
74°N 3°E, and South of 74°N.

EASTERN
East of a line through:
20°N 18°W, 60°N 18°W, 68°N 3°E, 74°N 3°E,
and North of a line through:
74°N 3°E, 74°N 22°W.

(d) *Geographical boundaries in the North Pacific*

The geographical boundaries for the sperm, Bryde’s and minke whale stocks in the North Pacific are:

SPERM WHALE STOCKS
WESTERN DIVISION
West of a line from the ice-edge south along the 180° meridian of longitude to 180°, 50°N, then east along the 50°N parallel of latitude to 160°W, 50°N, then south along the 160°W meridian of longitude to 160°W, 40°N, then east along the 40°N parallel of latitude to 150°W, 40°N, then south along the 150°W meridian of longitude to the Equator.

EASTERN DIVISION
East of the line described above.

BRYDE’S WHALE STOCKS
EAST CHINA SEA
West of the Ryukyu Island chain.

EASTERN
East of 160°W (excluding the Peruvian stock area).

WESTERN
West of 160°W (excluding the East China Sea stock area).

MINKE WHALE STOCKS
SEA OF JAPAN-YELLOW SEA-EAST CHINA SEA
West of a line through the Philippine Islands, Taiwan, Ryukyu Islands, Kyushu, Honshu, Hokkaido and Sakhalin Island, north of the Equator.

OKHOTSK SEA-WEST PACIFIC
East of the Sea of Japan-Yellow Sea- East China Sea stock and west of 180°, north of the Equator.

REMAINDER
East of the Okhotsk Sea-West Pacific stock, north of the Equator.

(e) *Geographical boundaries for Bryde’s whale stocks in the Southern Hemisphere*

SOUTHERN INDIAN OCEAN
20°E to 130°E,
South of the Equator.

SOLOMON ISLANDS
150°E to 170°E,
20°S to the Equator.

PERUVIAN
110°W to the South American coast,
10°S to 10°N.

EASTERN SOUTH PACIFIC
150°W to 70°W,
South of the Equator (excluding the Peruvian stock area).

WESTERN SOUTH PACIFIC
130°E to 150°W,
South of the Equator (excluding the Solomon Islands stock area).

SOUTH ATLANTIC
70°W to 20°E,
South of the Equator (excluding the South African inshore stock area).

SOUTH AFRICAN INSHORE
South African coast west of 27°E and out to the 200 metre isobath.

Classification of Stocks

10. All stocks of whales shall be classified in one of three categories according to the advice of the Scientific Committee as follows:
    (a) A Sustained Management Stock (SMS) is a stock which is not more than 10 per cent of Maximum Sustainable Yield (hereinafter referred to as MSY) stock level below MSY stock level, and not more than 20 per cent above that level; MSY being determined on the basis of the number of whales.

    When a stock has remained at a stable level for a considerable period under a regime of approximately constant catches, it shall be classified as a Sustained Management Stock in the absence of any positive evidence that it should be otherwise classified.

    Commercial whaling shall be permitted on Sustained Management Stocks according to the advice of the Scientific Committee. These stocks are listed in Tables 1, 2 and 3 of this Schedule.

    For stocks at or above the MSY stock level, the permitted catch shall not exceed 90 per cent of the MSY. For stocks between the MSY stock level and 10 per cent below that level, the permitted catch shall not exceed the number of whales obtained by taking 90 per cent of the MSY and reducing that number by 10 per cent for every 1 per cent by which the stock falls short of the MSY stock level.

    (b) An Initial Management Stock (IMS) is a stock more than 20 per cent of MSY stock level above MSY stock level. Commercial whaling shall be permitted on Initial Management Stocks according to the advice of the Scientific Committee as to measures necessary to bring the stocks to the MSY stock level and then optimum level in an efficient manner and without risk of reducing them below this level. The permitted catch for such stocks will not be more than 90 per cent of MSY as far as this is known, or, where it will be more appropriate, catching effort shall be limited to that which will take 90 per cent of MSY in a stock at MSY stock level.

    In the absence of any positive evidence that a continuing higher percentage will not reduce the stock below the MSY stock level no more than 5 per cent of the estimated initial exploitable stock shall be taken in any one year. Exploitation should not commence until an estimate of stock size has been obtained which is satisfactory in the view of the Scientific Committee. Stocks classified as Initial Management Stock are listed in Tables 1, 2 and 3 of this Schedule.

    (c) A Protection Stock (PS) is a stock which is below 10 per cent of MSY stock level below MSY stock level.

    There shall be no commercial whaling on Protection Stocks. Stocks so classified are listed in Tables 1, 2 and 3 of this Schedule.

    (d) Notwithstanding the other provisions of paragraph 10 there shall be a moratorium on the taking, killing or treating of whales, except minke whales, by factory ships or whale catchers attached to factory ships. This moratorium applies to sperm whales, killer whales and baleen whales, except minke whales.

    (e) Notwithstanding the other provisions of paragraph 10, catch limits for the killing for commercial purposes of whales from all stocks for the 1986 coastal and the 1985/86 pelagic seasons and thereafter shall be zero. This provision will be kept under review, based upon the best scientific advice, and by 1990 at the latest the Commission will undertake a comprehensive assessment of the effects of this decision on whale stocks and consider modification of this provision and the establishment of other catch limits.*•#

---

*The Governments of Japan, Norway, Peru and the Union of Soviet Socialist Republics lodged objection to paragraph 10(*e*) within the prescribed period. For all other Contracting Governments this paragraph came into force on 3 February 1983. Peru withdrew its objection on 22 July 1983. The Government of Japan withdrew its objections with effect from 1 May 1987 with respect to commercial pelagic whaling; from 1 October 1987 with respect to commercial coastal whaling for minke and Bryde's whales; and from 1 April 1988 with respect to commercial coastal sperm whaling. The objections of Norway and the Russian Federation not having been withdrawn, the paragraph is not binding upon these Governments.

•Iceland's instrument of adherence to the International Convention for the Regulation of Whaling and the Protocol to the Convention deposited on 10 October 2002 states that Iceland 'adheres to the aforesaid Convention and Protocol with a reservation with respect to paragraph 10(*e*) of the Schedule attached to the Convention'. The instrument further states the following:

> 'Notwithstanding this, the Government of Iceland will not authorise whaling for commercial purposes by Icelandic vessels before 2006 and, thereafter, will not authorise such whaling while progress is being made in negotiations within the IWC on the RMS. This does not apply, however, in case of the so-called moratorium on whaling for commercial purposes, contained in paragraph 10(*e*) of the Schedule not being lifted within a reasonable time after the completion of the RMS. Under no circumstances will whaling for commercial purposes be authorised without a sound scientific basis and an effective management and enforcement scheme.'

#The Governments of Argentina, Australia, Brazil, Chile, Finland, France, Germany, Italy, Mexico, Monaco, the Netherlands, New Zealand, Peru, San Marino, Spain, Sweden, UK and the USA have lodged objections to Iceland's reservation to paragraph 10(*e*).

[1] No whales may be taken from this stock until catch limits including any limitations on size and sex are established by the Commission.

[+] The catch limits of zero introduced in Table 3 as editorial amendments as a result of the coming into effect of paragraph 10*(e)* are not binding upon the governments of the countries which lodged and have not withdrawn objections to the said paragraph.

Baleen Whale Catch Limits

11. The number of baleen whales taken in the Southern Hemisphere in the ***2018/2019 and 2019/2020*** pelagic season and the ***2019 and 2020*** coastal season shall not exceed the limits shown in Tables 1 and 2.

12. The number of baleen whales taken in the North Pacific Ocean and dependent waters in ***2019 and 2020*** and in the North Atlantic Ocean in ***2019 and 2020*** shall not exceed the limits shown in Tables 1 and 2.

13. (a) Notwithstanding the provisions of paragraph 10, catch limits for aboriginal subsistence whaling to satisfy aboriginal subsistence need for the 1984 whaling season and each whaling season thereafter shall be established in accordance with the following principles:

(1) For stocks at or above MSY level, aboriginal subsistence catches shall be permitted so long as total removals do not exceed 90 per cent of MSY.

(2) For stocks below the MSY level but above a certain minimum level, aboriginal subsistence catches shall be permitted so long as they are set at levels which will allow whale stocks to move to the MSY level.[1]

(3) The above provisions will be kept under review, based upon the best scientific advice, and by 1990 at the latest the Commission will undertake a comprehensive assessment of the effects of these provisions on whale stocks and consider modification.

(4) For aboriginal whaling conducted under subparagraphs (*b*)(1), (*b*)(2), and (*b*)(3) of this paragraph, it is forbidden to strike, take or kill calves or any whale accompanied by a calf. For aboriginal whaling conducted under subparagraphs (*b*)(4) of this paragraph, it is forbidden to strike, take or kill suckling calves or female whales accompanied by calves.

(5) All aboriginal whaling shall be conducted under national legislation that accords with this paragraph.

(6) Commencing in 2026, and provided the appropriate Strike Limit Algorithm has been developed by then, strike/catch limits (including any carry forward provisions) for each stock identified in sub-paragraph 13(b) shall be extended every six years, provided: (a) the Scientific Committee advises in 2024, and every six years thereafter, that such limits will not harm that stock; (b) the Commission does not receive a request from an ASW country relying on the stock ('relevant ASW country'), for a change in the relevant catch limits based on need; and (c) the Commission determines that the relevant ASW country has complied with the approved timeline and that the information provided represents a status quo continuation of the hunt.

(7) The provisions for each stock identified in sub-paragraph 13(b), especially the provisions for carryover, shall be reviewed by the Commission in light of the advice of the Scientific Committee.

(b) Catch limits for aboriginal subsistence whaling are as follows:

(1) The taking of bowhead whales from the Bering-Chukchi-Beaufort Seas stock by aborigines is permitted, but only when the meat and products of such whales are to be used exclusively for local consumption by the aborigines and further provided that:

(i) For the years ~~2013, 2014, 2015, 2016, 2017 and 2018~~ ***2019, 2020, 2021, 2022, 2023, 2024 and 2025***, the number of bowhead whales landed shall not exceed ~~336~~ ***392***. For each of these years the number of bowhead whales struck shall not exceed 67, except that any unused portion of a strike quota from ~~any year (including 15 unused strikes from the 2008–2012 quota)~~ ***the three prior quota blocks*** shall be carried forward and added to the strike quotas of ~~any~~ subsequent years, provided that no more than ~~15~~ ~~strikes~~ ***50 percent of the annual strike limit*** shall be added to the strike quota for any one year.

~~(ii) This provision shall be reviewed annually by the Commission in light of the advice of the Scientific Committee.~~

(2) The taking of gray whales from the Eastern stock in the North Pacific is permitted, but only by aborigines or a Contracting Government on behalf of aborigines, and then only when the meat and products of such whales are to be used exclusively for local consumption by the aborigines.

(i) For the years ~~2013, 2014, 2015, 2016, 2017 and 2018~~ ***2019, 2020, 2021, 2022, 2023, 2024 and 2025***, the number of gray whales ***landed*** ~~taken~~ ~~in accordance with this sub-paragraph~~ shall not exceed ~~744~~ ***980***, provided that the number of gray whales ***struck*** ~~taken~~ in any one of the years ~~2013, 2014, 2015,~~ ~~2016, 2017 and 2018~~ ***2019, 2020, 2021, 2022, 2023, 2024 and 2025*** shall not exceed 140, ***except that any unused portion of a strike quota from the prior quota block shall be carried forward and added to the strike quotas of subsequent years, provided that no more than 50 percent of the annual strike limit shall be added to the strike quota for any one year***.

~~(ii) This provision shall be reviewed annually by the Commission in light of the advice of the Scientific Committee.~~

(3) The taking by aborigines of minke whales from the West Greenland and Central stocks ***from the East Greenland hunt*** and fin whales from the West Greenland stock and bowhead whales from the West Greenland feeding aggregation and humpback whales from the West Greenland feeding aggregation is permitted and then only when the meat and products are to be used exclusively for local consumption.

(i) The number of fin whales struck from the West Greenland stock ~~in accordance with this subparagraph~~ shall not exceed 19 in each of the years ~~2015, 2016, 2017 and 2018~~ ***2019, 2020, 2021, 2022, 2023, 2024 and 2025, except that any unused portion of a strike quota from the prior quota block under a Strike Limit Algorithm management advice shall be carried forward and added to the strike quotas of subsequent years, provided that no more than 50 percent of the annual strike limit shall be added to the strike quota for any one year***.

(ii) The number of minke whales struck from the Central stock ~~in accordance with this sub-paragraph~~ shall not exceed ~~12~~ ***20*** in each of the years ~~2015, 2016, 2017 and 2018~~ ***2019, 2020, 2021, 2022, 2023, 2024 and 2025,*** except that any unused portion of ~~the~~ ***a*** strike quota ~~for each year~~ shall be carried forward ~~from that year~~ and added to the ***strike*** quota***s*** of ~~any~~ subsequent years, provided that no more than 3 ***strikes*** shall be added to the ***strike*** quota for any one year. ***Commencing in 2020, and provided a Strike Limit Algorithm for this stock has been developed by then, any unused portion of a strike quota from the prior quota block under a Strike Limit Algorithm management advice shall be carried forward and added to the strike quotas of subsequent years, provided that no more than 50 percent of the annual strike limit shall be added to the strike quota for any one year.***

(iii) The number of minke whales struck from the West Greenland stock shall not exceed 164 in each of the years ~~2015, 2016, 2017 and 2018~~ ***2019, 2020, 2021, 2022, 2023, 2024 and 2025,*** except that any unused portion of ~~the~~ ***a strike*** quota ~~for each year~~ ***from the prior quota block under a Strike Limit Algorithm management advice*** shall be carried forward ~~from that year~~ and added to the strike quota**s** of ~~any of the~~ subsequent years, provided that no more than ~~15 strikes~~ ***50 percent of the annual strike limit*** shall be added to the strike quota for any one year. ~~This provision will be reviewed if new scientific data become available within the 4 year period and if necessary amended on basis of the advice of the Scientific Committee.~~

(iv) The number of bowhead whales struck off West Greenland ~~in accordance with this sub-paragraph~~ shall not exceed 2 in each of the years ~~2015, 2016, 2017 and 2018~~ ***2019, 2020, 2021, 2022, 2023, 2024 and 2025,*** except that any unused portion of ~~the~~ ***a strike*** quota ~~for each year~~ ***from the prior quota block under a Strike Limit Algorithm management advice*** shall be carried forward ~~from that year~~ and added to the ***strike*** quota**s** of ~~any~~ subsequent years, provided that no more than ~~2 strikes~~ ***50 percent of the annual strike limit*** shall be added to the ***strike*** quota for any one year. ~~This provision will be reviewed if new scientific data become available within the 4 year period and if necessary amended on basis of the advice of the Scientific Committee.~~

(v) The number of humpback whales struck off West Greenland ~~in accordance with this sub-paragraph~~ shall not exceed 10 in each of the years ~~2015, 2016, 2017 and 2018~~ ***2019, 2020, 2021, 2022, 2023, 2024 and 2025,*** except that any unused portion of ~~the~~ ***a strike*** quota ~~for each year~~ ***from the three prior quota blocks under a Strike Limit Algorithm management advice*** shall be carried forward ~~from that year~~ and added to the strike quota**s** of ~~any of the~~ subsequent years, provided that no more than ~~2 strikes~~ ***50 percent of the annual strike limit*** shall be added to the strike quota for any one year. ~~This provision will be reviewed if new scientific data become available within the remaining quota period and if necessary amended on basis of the advice of the Scientific Committee.~~

(4) For the seasons ~~2013-2018~~ ***2019-2025*** the number of humpback whales to be taken by the Bequians of St. Vincent and The Grenadines shall not exceed ~~24~~ ***28***. The meat and products of such whales are to be used exclusively for local consumption in St. Vincent and The Grenadines.

14. It is forbidden to take or kill suckling calves or female whales accompanied by calves.

Baleen Whale Size Limits

15. (a) It is forbidden to take or kill any sei or Bryde's whales below 40 feet (12.2 metres) in length except that sei and Bryde's whales of not less than 35 feet (10.7 metres) may be taken for delivery to land stations, provided that the meat of such whales is to be used for local consumption as human or animal food.

(b) It is forbidden to take or kill any fin whales below 57 feet (17.4 metres) in length in the Southern Hemisphere, and it is forbidden to take or kill fin whales below 55 feet (16.8 metres) in the Northern Hemisphere; except that fin whales of not less than 55 feet (16.8 metres) may be taken in the Southern Hemisphere for delivery to land stations and fin whales of not less than 50 feet (15.2 metres) may be taken in the Northern Hemisphere for delivery to land stations, provided that, in each case the meat of such whales is to be used for local consumption as human or animal food. ***This paragraph shall not apply to aboriginal subsistence whaling under paragraph 13(b)(3)(i).***

Sperm Whale Catch Limits

16. Catch limits for sperm whales of both sexes shall be set at zero in the Southern Hemisphere for the 1981/82 pelagic season and 1982 coastal seasons and following seasons, and at zero in the Northern Hemisphere for the 1982 and following coastal seasons; except that the catch limits for the 1982 coastal season and following seasons in the Western Division of the North Pacific shall remain undetermined and subject to decision by the Commission following special or annual meetings of the Scientific Committee. These limits shall remain in force until such time as the Commission, on the basis of the scientific information which will be reviewed annually, decides otherwise in accordance with the procedures followed at that time by the Commission.
17. It is forbidden to take or kill suckling calves or female whales accompanied by calves.

Sperm Whale Size Limits

18. (a) It is forbidden to take or kill any sperm whales below 30 feet (9.2 metres) in length except in the North Atlantic Ocean where it is forbidden to take or kill any sperm whales below 35 feet (10.7 metres).
    (b) It is forbidden to take or kill any sperm whale over 45 feet (13.7 metres) in length in the Southern Hemisphere north of 40° South Latitude during the months of October to January inclusive.
    (c) It is forbidden to take or kill any sperm whale over 45 feet (13.7 metres) in length in the North Pacific Ocean and dependent waters south of 40° North Latitude during the months of March to June inclusive.

IV. TREATMENT

19. (a) It is forbidden to use a factory ship or a land station for the purpose of treating any whales which are classified as Protection Stocks in paragraph 10 or are taken in contravention of paragraphs 2, 3, 4, 5, 6, 7, 8, 11, 12, 14, 16 and 17 of this Schedule, whether or not taken by whale catchers under the jurisdiction of a Contracting Government.
    (b) All other whales taken, except minke whales, shall be delivered to the factory ship or land station and all parts of such whales shall be processed by boiling or otherwise, except the internal organs, whale bone and flippers of all whales, the meat of sperm whales and parts of whales intended for human food or feeding animals. A Contracting Government may in less developed regions exceptionally permit treating of whales without use of land stations, provided that such whales are fully utilised in accordance with this paragraph.
    (c) Complete treatment of the carcases of "dauhval" and of whales used as fenders will not be required in cases where the meat or bone of such whales is in bad condition.
20. (a) The taking of whales for treatment by a factory ship shall be so regulated or restricted by the master or person in charge of the factory ship that no whale carcase (except of a whale used as a fender, which shall be processed as soon as is reasonably practicable) shall remain in the sea for a longer period than thirty-three hours from the time of killing to the time when it is hauled up for treatment.
    (b) Whales taken by all whale catchers, whether for factory ships or land stations, shall be clearly marked so as to identify the catcher and to indicate the order of catching.

V. SUPERVISION AND CONTROL

21. (a) There shall be maintained on each factory ship at least two inspectors of whaling for the purpose of maintaining twenty-four hour inspection provided that at least one such inspector shall be maintained on each catcher functioning as a factory ship. These inspectors shall be appointed and paid by the Government having jurisdiction over the factory ship; provided that inspectors need not be appointed to ships which, apart from the storage of products, are used during the season solely for freezing or salting the meat and entrails of whales intended for human food or feeding animals.
    (b) Adequate inspection shall be maintained at each land station. The inspectors serving at each land station shall be appointed and paid by the Government having jurisdiction over the land station.
    (c) There shall be received such observers as the member countries may arrange to place on factory ships and land stations or groups of land stations of other member countries. The observers shall be appointed by the Commission acting through its Secretary and paid by the Government nominating them.

22. Gunners and crews of factory ships, land stations, and whale catchers, shall be engaged on such terms that their remuneration shall depend to a considerable extent upon such factors as the species, size and yield of whales and not merely upon the number of the whales taken. No bonus or other remuneration shall be paid to the gunners or crews of whale catchers in respect of the taking of lactating whales.

23. Whales must be measured when at rest on deck or platform after the hauling out wire and grasping device have been released, by means of a tape-measure made of a non-stretching material. The zero end of the tape- measure shall be attached to a spike or stable device to be positioned on the deck or platform abreast of one end of the whale. Alternatively the spike may be stuck into the tail fluke abreast of the apex of the notch. The tape-measure shall be held taut in a straight line parallel to the deck and the whale's body, and other than in exceptional circumstances along the whale's back,

and read abreast of the other end of the whale. The ends of the whale for measurement purposes shall be the tip of the upper jaw, or in sperm whales the most forward part of the head, and the apex of the notch between the tail flukes.

Measurements shall be logged to the nearest foot or 0.1 metre. That is to say, any whale between 75 feet 6 inches and 76 feet 6 inches shall be logged as 76 feet, and any whale between 76 feet 6 inches and 77 feet 6 inches shall be logged as 77 feet. Similarly, any whale between 10.15 metres and 10.25 metres shall be logged as 10.2 metres, and any whale between 10.25 metres and 10.35 metres shall be logged as 10.3 metres. The measurement of any whale which falls on an exact half foot or 0.05 metre shall be logged at the next half foot or 0.05 metre, e.g. 76 feet 6 inches precisely shall be logged as 77 feet and 10.25 metres precisely shall be logged as 10.3 metres.

VI. INFORMATION REQUIRED

24. (a) All whale catchers operating in conjunction with a factory ship shall report by radio to the factory ship:
    (1) the time when each whale is taken
    (2) its species, and
    (3) its marking effected pursuant to paragraph 20(b).

    (b) The information specified in sub-paragraph (a) of this paragraph shall be entered immediately by a factory ship in a permanent record which shall be available at all times for examination by the whaling inspectors; and in addition there shall be entered in such permanent record the following information as soon as it becomes available:
    (1) time of hauling up for treatment
    (2) length, measured pursuant to paragraph 23
    (3) sex
    (4) if female, whether lactating
    (5) length and sex of foetus, if present, and
    (6) a full explanation of each infraction.

    (c) A record similar to that described in sub-paragraph (b) of this paragraph shall be maintained by land stations, and all of the information mentioned in the said sub-paragraph shall be entered therein as soon as available.

    (d) A record similar to that described in sub-paragraph (b) of this paragraph shall be maintained by "small-type whaling" operations conducted from shore or by pelagic fleets, and all of this information mentioned in the said sub-paragraph shall be entered therein as soon as available.

25. (a) All Contracting Governments shall report to the Commission for all whale catchers operating in conjunction with factory ships and land stations the following information:
    (1) methods used to kill each whale, other than a harpoon, and in particular compressed air;
    (2) number of whales struck but lost.

    (b) A record similar to that described in sub-paragraph (a) of this paragraph shall be maintained by vessels engaged in "small-type whaling" operations and by native peoples taking species listed in paragraph 1, and all the information mentioned in the said sub-paragraph shall be entered therein as soon as available, and forwarded by Contracting Governments to the Commission.

26. (a) Notification shall be given in accordance with the provisions of Article VII of the Convention, within two days after the end of each calendar week, of data on the number of baleen whales by species taken in any waters south of 40° South Latitude by all factory ships or whale catchers attached thereto under the jurisdiction of each Contracting Government, provided that when the number of each of these species taken is deemed by the Secretary to the International Whaling Commission to have reached 85 per cent of whatever total catch limit is imposed by the Commission notification shall be given as aforesaid at the end of each day of data on the number of each of these species taken.

    (a) If it appears that the maximum catches of whales permitted by paragraph 11 may be reached before 7 April of any year, the Secretary to the International Whaling Commission shall determine, on the basis of the data provided, the date on which the maximum catch of each of these species shall be deemed to have been reached and shall notify the master of each factory ship and each Contracting Government of that date not less than four days in advance thereof. The taking or attempting to take baleen whales, so notified, by factory ships or whale catchers attached thereto shall be illegal in any waters south of 40° South Latitude after midnight of the date so determined.

    (b) Notification shall be given in accordance with the provisions of Article VII of the Convention of each factory ship intending to engage in whaling operations in any waters south of 40° South Latitude.

27. Notification shall be given in accordance with the provisions of Article VII of the Convention with regard to all factory ships and catcher ships of the following statistical information:
    (a) concerning the number of whales of each species taken, the number thereof lost, and the number treated at each factory ship or land station, and
    (b) as to the aggregate amounts of oil of each grade and quantities of meal, fertiliser (guano), and other products derived from them, together with
    (c) particulars with respect to each whale treated in the factory ship, land station or "small-type whaling" operations as to the date and approximate latitude and longitude of taking, the species and sex of the whale, its length and, if it contains a foetus, the length and sex, if ascertainable, of the foetus.

    The data referred to in (a) and (c) above shall be verified at the time of the tally and there shall also be notification to the Commission of any information which may be collected or obtained concerning the calving grounds and migration of whales.

28. (a) Notification shall be given in accordance with the provisions of Article VII of the Convention with regard to all factory ships and catcher ships of the following statistical information:
    - (1) the name and gross tonnage of each factory ship,
    - (2) for each catcher ship attached to a factory ship or land station:
        - (i) the dates on which each is commissioned and ceases whaling for the season,
        - (ii) the number of days on which each is at sea on the whaling grounds each season,
        - (iii) the gross tonnage, horsepower, length and other characteristics of each; vessels used only as tow boats should be specified.
    - (3) A list of the land stations which were in operation during the period concerned, and the number of miles searched per day by aircraft, if any.

    (b) The information required under paragraph (a)(2)(ii) should also be recorded together with the following information, in the log book format shown in Appendix A, and forwarded to the Commission:
    - (1) where possible the time spent each day on different components of the catching operation,
    - (2) any modifications of the measures in paragraphs (a)(2)(i)-(iii) or (b)(1) or data from other suitable indicators of fishing effort for "small-type whaling" operations.

29. (a) Where possible all factory ships and land stations shall collect from each whale taken and report on:
    - (1) both ovaries or the combined weight of both testes,
    - (2) at least one ear plug, or one tooth (preferably first mandibular).

    (b) Where possible similar collections to those described in sub-paragraph (a) of this paragraph shall be undertaken and reported by "small-type whaling" operations conducted from shore or by pelagic fleets.

    (c) All specimens collected under sub-paragraphs (a) and (b) shall be properly labelled with platform or other identification number of the whale and be appropriately preserved.

    (d) Contracting Governments shall arrange for the analysis as soon as possible of the tissue samples and specimens collected under sub-paragraphs (a) and (b) and report to the Commission on the results of such analyses.

30. A Contracting Government shall provide the Secretary to the International Whaling Commission with proposed scientific permits before they are issued and in sufficient time to allow the Scientific Committee to review and comment on them. The proposed permits should specify:
    - (a) objectives of the research;
    - (b) number, sex, size and stock of the animals to be taken;
    - (c) opportunities for participation in the research by scientists of other nations; and
    - (d) possible effect on conservation of stock.

    Proposed permits shall be reviewed and commented on by the Scientific Committee at Annual Meetings when possible. When permits would be granted prior to the next Annual Meeting, the Secretary shall send the proposed permits to members of the Scientific Committee by mail for their comment and review. Preliminary results of any research resulting from the permits should be made available at the next Annual Meeting of the Scientific Committee.

31. A Contracting Government shall transmit to the Commission copies of all its official laws and regulations relating to whales and whaling and changes in such laws and regulations.

*Time whales reported to catcher means the time when the catcher is told of the position of a school, and starts to move towards it to chase it.

SCHEDULE APPENDIX A

SCHOOLING REPORT TABLE 2

To be completed by pelagic expedition or coastal station for each sperm whale school chased. A separate form to be used each day.

Name of expedition or coastal station

Date Noon position of factory ship

Time School Found

Total Number of Whales in School

Number of Takeable Whales in School

Number of Whales Caught from School by each Catcher

Name of Catcher

Name of Catcher

Name of Catcher ....

Name of Catcher

Total Number Caught from School

Remarks:

Explanatory Notes

A. Fill in one column for each school chased with number of whales caught by each catcher taking part in the chase; if catchers chase the school but do not catch from it, enter O; for catchers in fleet which do not chase that school enter X.

B. A school on this form means a group of whales which are sufficiently close together that a catcher having completed handling one whale can start chasing another whale almost immediately without spending time searching. A solitary whale should be entered as a school of 1 whale.

C. A takeable whale is a whale of a size or kind which the catchers would take if possible. It does not necessarily include all whales above legal size, e.g. if catchers are concentrating on large whales only these would be counted as takeable.

D. Information about catchers from other expeditions or companies operating on the same school should be recorded under Remarks.

MONITORING IN 2019
BY THE RUSSIAN FEDERATION AND THE UNITED STATES
OF THE ABORIGINAL SUBSISTENCE QUOTA
FOR GRAY WHALES SET BY
THE INTERNATIONAL WHALING COMMISSION

The International Whaling Commission (IWC) at its Meeting in September 2018 set a seven-year block quota of 980 gray whales landed, based on a joint proposal by the Russian Federation and the United States (which was incorporated into the Schedule to the International Convention for the Regulation of Whaling, Article 13(b)(2)). . In addition, for each of the years 2019 through 2025, the IWC limited the number of gray whales that may be struck to 140, except that any unused portion of a strike quota from the prior quota block may be carried forward, provided that no more than 50 percent of the annual strike limit may be added to the strike quota for any one year. At the end of the 2018 harvest, there were zero strikes available for carry-forward, so the strike quota for 2019 is 140.

So that the 2019 quota of gray whale strikes is not exceeded, subject to domestic legal requirements, the Makah Indian Tribe may strike no more than five gray whales, and the Russian Natives may strike no more than 135 gray whales. Each side will ensure that the numbers specified in this paragraph for its Native group are not exceeded. Each side will consider any strikes or landings in excess of the specified numbers in discussing monitoring of the quota for 2020.

The U.S. side plans to inform the Russian side immediately upon learning if the Makah Indian Tribe has struck or landed a gray whale. The Russian side plans to inform the U.S. side once a month of the number of gray whales struck or landed by its Natives in the preceding month. In September-October, 2019, either side may initiate discussions on the transfer of unused strikes from one Native group to the other. During the last quarter of 2019, the two sides plan to confer on monitoring of the 2020 quota.

ADDENDUM TO MONITORING IN 2017
BY THE RUSSIAN FEDERATION AND THE UNITED STATES
OF THE ABORIGINAL QUOTA FOR GRAY WHALES SET BY
THE INTERNATIONAL WHALING COMMISSION

The above-captioned Monitoring in 2017 agreement provides for potential transfers of the unused takes of gray whales from the Makah Indian Tribe to the Russian Natives. Due to domestic legal obligations, the Makah Indian Tribe has been unable to harvest gray whales. This addendum formalizes the transfer a total of 8 unused takes of gray whales from 2016 and 2017 from the Makah Indian Tribe to the Russian Natives.

ADDENDUM TO MONITORING IN 2012 BY THE RUSSIAN FEDERATION AND THE UNITED STATES OF THE ABORIGINAL QUOTA FOR GRAY WHALES SET BY THE INTERNATIONAL WHALING COMMISSION

The International Whaling Commission (IWC) at its Annual Meeting in June 2007, set a five-year block quota of 620 gray whales, with an annual cap of 140 animals taken, based on a joint proposal by the Russian Federation and the United States. The IWC regulation does not address the number of allowed strikes. The requested quota and accompanying documentation assumed an average annual harvest of 120 whales by the Chutkotka people and an average annual harvest of four whales by the Makah Indian Tribe.

So that the 2012 quota of gray whales is not exceeded, subject to domestic legal requirements the Makah Indian Tribe may take no more than five gray whales, and the Russian Natives may take no more than 135 gray whales. Each side will ensure that the numbers specified in this paragraph for its Native are not exceeded. Each side will consider any landings in excess of the specified numbers in excess of the specified numbers in discussing monitoring of the quota for 2013.

During the remainder of 2012, either side may initiate discussions on the transfer of unused takes from one Native group to the other. In February 2012, discussions were initiated to transfer the unused takes of gray whales from the Makah Indian Tribe to the Russian Natives. Due to domestic legal obligations, the Makah Indian Tribe have been unable to harvest gray whales. This agreement formalizes the transfer of 20 unused takes of gray whales from the Makah Indian Tribe to the Russian Natives.

ADDENDUM to MONOITORING IN 2007 BY THE RUSSIAN FEDERATION AND THE UNITED STATES OF THE ABORIGINAL SUBSISTENCE QUOTA FOR GRAY WHALES SET BY THE INTERNATIONAL WHALING COMMISSION

The International Whaling Commission (IWC) at its Annual Meeting in May 2002 set a five-year block quota of 620 gray whales, with an annual cap of 140 animals taken, based on a joint proposal by the Russian Federation and the United States. The IWC regulation does not address the number of allowed strikes. The requested quota and accompanying documentation assumed an average annual harvest of 120 whales by the Chukotka people and an average annual harvest of four whales by the Makah Indian Tribe.

So that the 2007 quota of gray whales is not exceeded, subject to domestic legal requirements the Makah Indian Tribe may take no more than five gray whales, and the Russian Natives may take no more than 135 gray whales. Each side will ensure that the numbers specified in this paragraph for its Native group are not exceeded. Each side will consider any landings in excess of the specified numbers in discussing monitoring of the quota for 2008.

During the remainder of 2007, either side may initiate discussions on the transfer of unused takes from one Native group to the other. In February 2007, discussions were initiated to transfer the unused takes of gray whales from the Makah Indian Tribe to the Russian Natives. Due to domestic legal obligations, the Makah Indian Tribe have been unable to harvest gray whales. This agreement formalizes the transfer of 20 unused takes of gray whales from the Makah Indian Tribe to the Russian Natives.

gated there) in summer along the route of juvenile salmon, spawned in rivers to the south but bound for offshore feeding grounds to the north. Their trip takes 1 or 2 months, during which time considerable growth as well as locomotion is accomplished by the young fish.

Synopsis

The permanent halocline caps winter mixing and entrainment of nitrate from below, so the spring–summer bloom is thought to be supported by nitrate entrained during this period by topographic coastal processes (Fig. 9.15). Chlorophyll consistently tracks primary production rate and nitrate-based production is assumed to dominate during the whole productive period.

California Current Province (CALC)

Extent of the Province

The CALC province comprises the California Current from the bifurcation of the eastwards flow of the North Pacific Current south to the convergent front which lies southwest off the tip of Baja California at the root of the NEC. The California Front is the seaward limit, though this front is progressively less well defined toward the south. For this reason, the canonical boundary of the California Current is often set at 1000 km offshore, a definition I use where necessary.

Continental Shelf Topography and Tidal and Shelf-Edge Fronts

The continental shelf is narrow, with the 200-m isobath occurring as little as 10 km from the shore in southern California (or even closer, where Scripps Canyon runs into the beach) to a distance of about 75 km off Oregon and Washington. A continental borderland with deep (approx 200 m) basins, shallow banks, and islands occupies the bight (including the Santa Barbara Basin) south of Point Conception (34.5°N). Tidal fronts have not been described, but the entire coastal boundary province is populated by upwelling fronts and fronts associated with meanders of the coastal jet and their associated cyclonic eddies.

Defining Characteristics of Regional Oceanography

The California Current is the most intensively investigated of the eastern boundary currents, especially because of the results from the long time series (1950–present) of the California Cooperative Fisheries Investigations (CalCOFI) managed jointly by federal, state, and university research groups. Much of what follows is drawn from reports, atlases, and research papers arising from CalCOFI.

The California Current takes its source in the divergence of the west wind drift water of the North Pacific Current as this approaches the American continent within what Favorite *et al.* (1976) term the dilution zone, where precipitation greatly exceed evaporation. The eastward flow diverges northwards into the eastern limb of the Alaska gyre and southwards into the California Current as a cool, low-salinity, high-nutrient water mass entraining biota with the flow.

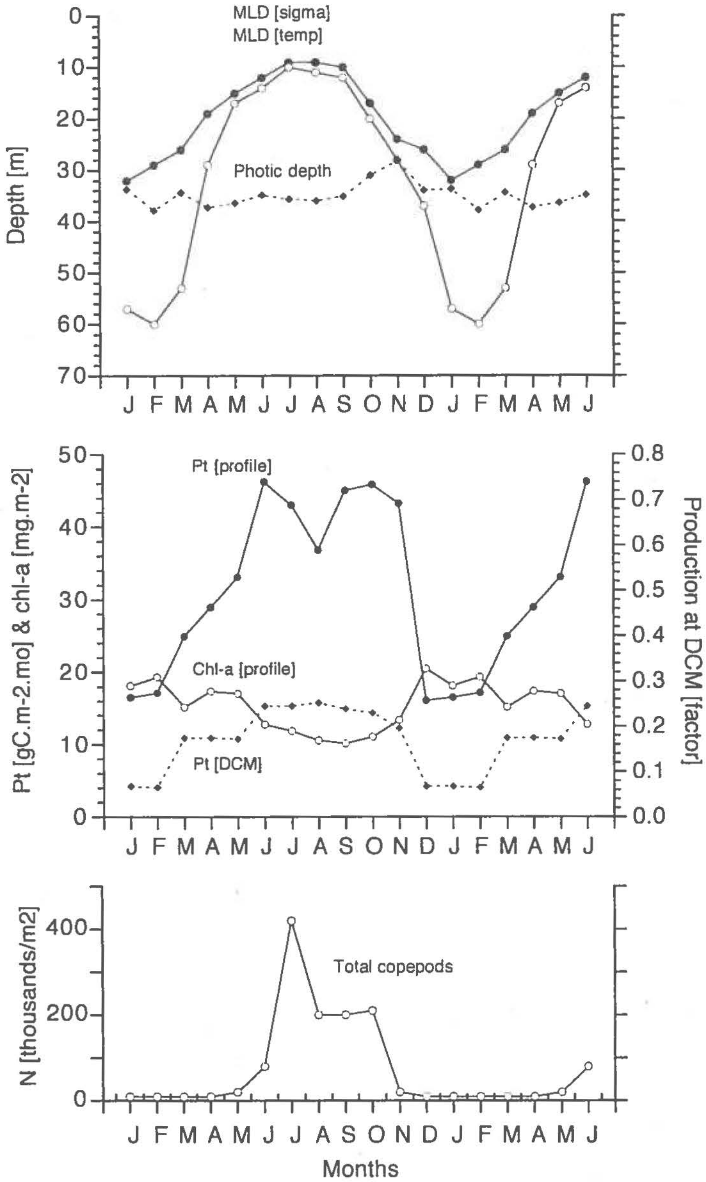

FIGURE 9.16 CALC: characteristic seasonal cycles of monthly averaged mixed layer and photic depths, chlorophyll at the surface, and rate of primary production, both depth-integrated and at the DCM. Data sources are discussed in Chapter 1.

The following account of the California Current describes the normal condition, when the trade wind regime is fully developed; during ENSO events, when trade wind stress is relaxed in the western Pacific, El Niño conditions prevail in the eastern boundary currents of the Pacific (see Chapter 6). The characteristics of the province derive from the conjunction between the southward geostrophic current, the coastal boundary, and an alternating wind

xed layer and photic
ated and at the DCM.

regime—equatorward upwelling winds in summer and poleward downwelling winds in winter.

The offshore California Current is a shallow, complex southerly flow of cool, low-salinity water extending about 1500 km seawards off central California but progressively closer to the coast toward the south: 850 km off Cape Mendocino and 500 km off Cape San Lazaro. The main core of the current occurs 200–400 km offshore, where southward wind stress is greatest, especially at 30–45°N and during summer. The zone of maximum wind stress coincides with zero wind-stress curl, which is anticyclonic (convergent) to the west of this line and cyclonic (divergence) to the east (Bakun and Nelson, 1991). A separate and narrower maximum flow occurs within 100–150 km of the coast as the inshore California Current, which partially reverses with the seasons.

The southward flow of the offshore current includes mesoscale eddies and meanders 120–150 km in dimension; these are anticyclonic on the seaward side and cyclonic on the landward side of the flow. Among the mesoscale features of the offshore current are intense jets and plumes originating at the coast, which entrain upwelled water and advect it far offshore (Burkov and Pavlova, 1980; Mooers and Robinson, 1984). At about 1500 km from the coast, mesoscale eddying gives way to flow to the south, which is less complex and slower. This transition is often marked by a salinity front which is continuous with the Subarctic Front and is often termed the California Front.

Upwelling at the coast is forced by coastal winds, modified by their response to blocking of the zonal westerlies by the coastal mountain chain. Thus, the coastal wind regime is not uniform: A local maximum of cyclonic curl is associated with the Southern California Bight, and a lobe of anticyclonic curl frequently reaches the coast at Punta Baja, where longshore equatorward wind stress is maximal. Off Oregon and Washington wind-stress curl is variable, with frequent brief episodes of anticyclonic curl related to storm tracks (Bakun and Nelson, 1991) which are reflected in event-scale variability of circulation within the coastal boundary province.

It remains critical to understanding circulation in this province, however, to distinguish the flow of the coastal current from the low-salinity velocity core of the offshore California Current. Equatorward transport in the separate coastal velocity core may be interrupted by discontinuous northward flow beginning seasonally in August–October. In early winter (November–January) continuous poleward flow occurs from the Mexican border almost to Cape Mendocino, with this continuity breaking down in February and March with the development of frequent cyclonic eddies between Point Conception and Cape Mendocino. In March or April the summer pattern of eddying southward flow becomes fully established. (Wyllie, 1966). When reversal of coastal flow is most strongly developed during early spring, the poleward current lies closest to the coast.

When transport is integrated over 200 or 500 m, the northward counterflow below the inshore California Current is continuous. Therefore, especially during spring and early summer, there is a shear zone between coastal poleward and offshore equatorward flow about 100–125 km offshore. Geostrophy requires that a pycnocline ridge (marked at the surface by a divergent front) should occur along this line of zero flow to compensate a depression in the sea surface, and this has consequences for the supply of nutrients to the photic layer. There is also, especially off Oregon, an upwelling front that occurs 5–15 km offshore during the summer coastal upwelling season which is forced by cross-shelf circulation over the very narrow continental shelf (Peterson *et al.*, 1979).

The southward flow of the coastal current in summer is a meandering jet with persistent eddies and cool filaments that may extend 200 km offshore and originate at prominent capes. Some of these topographically locked eddies, especially those at the Straits of Juan de Fuca, at Hecata Bank, and at Capes Blanco and Mendocino, often form cold filaments that may extend several hundred kilometers offshore, having a dipole termination, representing the development of a pair of counterrotating eddies. The actual development of these features is associated with variability of coastal winds. Upwelling winds normally occur for periods of 1–3 weeks, with relaxation periods of 2 or 3 days, and individual cold filaments may transport water from more than a single upwelling event (Lagerloef, 1992; Traganza *et al.*, 1981).

Coastal upwelling cells in the Southern California Bight are small and localized east of Point Conception, at Point Dume and in the bight lying between La Jolla and San Clemente; they are effective only 25–30 km from the coast. These cells, in the Southern California Bight, exhibit simultaneous upwelling (marked by dense sea fog and increased sales of wet suits in the beach towns of surfers' paradise) several times each summer, forced by events in the local wind field (Dorman and Palmer, 1981). Along the coast of Baja California, coastal upwelling cells occur during summer at Punta Eugenia, Punta Abreojos, Cape San Lazaro, and Punta Tosca.

Biological Response and Regional Ecology

The effects of wind-stress curl on nutrient dynamics are similar in each of the four principal eastern boundary currents (Bakun and Nelson, 1991). Though the paradigm of eastern boundary current nutrient dynamics is usually described simply as "coastal upwelling," the reality is far more complex and a variety of enrichment processes occur: (i) coastal upwelling cells, due to Ekman divergence at the coast, usually of small dimension and often topographically locked; (ii) continued upwelling in offshore-trending filaments of cool coastally upwelled water; (iii) upwelling in cyclonic eddies shed from meanders of the coastal current; (iv) and upwelling in the offshore divergent front at the shear zone between inshore poleward and offshore equatorward flows.

Of these, the offshore divergent front may be the most difficult feature to identify and is likely to be represented by a weak coastwise field of high chlorophyll but connected in various ways with the offshore-trending chlorophyll fields arising from eddies and filaments. It is often associated with the location of an offshore zooplankton biomass maximum.

Seasonal variation in algal growth within cyclonic eddies can be associated with seasonal variation in Ekman suction (Robinson *et al.*, 1993). However, in the offshore California Current, nutrient input appears to be principally advective in the cool, low-salinity, high-nutrient core of the southward flow. Both off California (especially at 35–42°N) and off northern Oregon–British Columbia (46–48°N and beyond), a winter bloom occurs which is unrelated to the effects of coastal upwelling plumes and filaments. rophyll values >1.5 mg chl m^{-3} occur over wide areas as far as 300 km from the coast. Between these two regions, chlorophyll values offshore are generally lower even at this season, and a "blue hole" region (covering several degrees of latitude) is persistent offshore, centered at about the Columbia River.

Because the processes leading to upwelling are not uniform throughout the coastal area, it is useful to review the processes that are characteristic of four compartments: Oregon–British Columbia, Point Conception to Cape Mendocino, the Southern California Bight, and the Baja California coast.

- *Oregon–British Columbia (42–48°N):* Winter storms are strong and frequent and seasonal current reversal occurs regularly; primary production is strongly seasonal. Upwelling occurs in summer at a coastwise front about 10 km offshore as well as at the coast itself, and response to wind events typically results after 4 or 5 days in the development of an upwelling cell, whose seawards front moves progressively offshore during development and returns shorewards during subsequent relaxation of upwelling. During this process, mean offshore flow is restricted to the surface 20–30 m (Brink, 1983; Smith, 1981). Upwelling occurs in persistent, topographically locked gyres during summer (e.g., at Juan de Fuca). During both summer and winter, frequent cold tongues of upwelled water on the scale of hundreds of kilometers extend westwards from the continent across and beyond the relatively broad continental shelf. Relatively high levels of nutrients occur throughout this region offshore, entrained toward the south from the subarctic zone.
- *Point Conception to Cape Mendocino (33–41°N):* Upwelling is strongest here but primary production is markedly seasonal. CZCS images show persistent offshore meanders, shed eddies (anticyclonic to the north and cyclonic to the south) and offshore cool filaments entraining coastally upwelled water. These most frequently occur in summer and south of Cape Mendocino, Point Arena, and Point Sur. Upwelling also occurs at the shallow banks off Point Reyes.
- *Southern California Bight (32 to 33°N):* The upwelling plume from Point Conception is frequently observed in summer, curving to the south around the outer limb of the eddy which occupies this bight. This plume has consistently lower surface chlorophyll values than those north of Point Conception or off Baja California. Off Southern California, the winter wind regime is established only relatively briefly, though (because the bight is wholly occupied by a quasi-permanent cyclonic eddy) poleward flow along the coast is more continuous here than elsewhere. Upwelling occurs as small coastal cells in summer (Point Dume and Del Mar) and at offshore islands and banks during all seasons. The inshore flow around the southern limb of the eddy may be marked as a chlorophyll feature.
- *Baja California (22–31°N):* The coastal wind regime is weaker but apparently favorable for upwelling year-round, though some seasonality in upwelling is evident in the chlorophyll field. Upwelling cells south of prominent capes are persistent: Cape Colonet, Punta Baja, Cape San Quintin, Punta Eugenia, Punta Abreojos, and Cape Falso all may generate such cells. The seasonal CZCS pigment fields (e.g., Thomas *et al.,* 1994) suggest that jets and filaments of upwelled water pass farther offshore from coastal upwelling cells from late summer (August) through early winter (November) and that south of Cape San

Lazaro even coastal upwelling ceases in autumn and winter (September–January).

Because of the large number of published studies of the California Current, in reviewing this province it is easier to concentrate on the individual processes rather than to see the whole. For instance, it is easy to lose sight of the fact that there is a seasonal cycle in the depth of the pycnocline that obtains over the whole area of the province (summer, 20–25 m; winter, ~75 m). At all seasons, if one ignores the effects of mesoscale features, the thermocline slopes downwards to the west, offshore, as it must. In upwelling cells, the density profile may be relatively featureless but wherever a significant mixed layer exists, a DCM occurs on the density gradient, usually with the depth of primary production a few meters shoaler. The offshore region has a seasonal cycle typical of subtropical oceans: Primary production rate and chlorophyll accumulation begin as soon as the mixed layer begins to deepen in the autumn. As noted previously, in the offshore areas chlorophyll values peak in midwinter, and primary production rate slows again with the shoaling of the thermocline in spring. Analysis of chlorophyll fields, integrated for the whole province, shows that this process—not summer upwelling at the coast—dominates the seasonal cycle. This observation recalls earlier suggestions that between-year variability in biological properties was forced primarily by changes in the advection of nutrients from the source of the California Current rather than by variation in the nutrients brought to the surface by coastal upwelling (Chelton, 1982).

Coastal upwelling is, nevertheless, a special case which merits special attention. The upwelling cells generate diatom–copepod assemblages of remarkably low diversity: In repeated net tows in one assemblage such as a few kilometers off Baja California (25°N), I could find no more than 29 species of zooplankton (and no more than 20 in any one haul), or about one-quarter the number taken 25 km farther offshore and examined with equivalent attention. Large, filter-feeding copepods, especially *C. pacificus* (which you will find described as *C. helgolandicus* in much of the Californian literature), at 115 ind m^{-3} comprised 77% of zooplankton dry weight at the coast. The seasonal ontogenetic migrations of this species cause the deep basins on the continental shelf to trap large concentrations of overwintering stage 5 copepodites; early in the winter these aggregate near the bottom, but the layers progressively shoal as oxygen concentration in the bottom water progressively declines, eventually forcing them over the sill depth of the basin (Osgood and Checkly, 1997). Compare this situation with that of *C. finmarchicus* in the deep basins of the Scotia Shelf in the Northwest Atlantic Shelves Province.

A few large species of diatoms (*Coscinodiscus, Nitzschia,* and *Tripodonesis*) formed 81% of algal cell volume. However, these rich diatom crops are also utilized by a very unusual organism—a bright red, swimming galatheid crab, *Pleuroncodes planipes*. These (in their pelagic phase) crowd into the surface layer off Baja California where they tail-flip up to the surface and then parachute down again with outstretched legs, filtering actively with their maxillipeds; this is a remarkable sight against the rich olive-green upwelled water. These crabs (at one per 3 m^3, each capable of clearing diatoms from 3 or 4 $liters^{-1}$ hr^{-1}) may comprise 90% of the total zooplankton/nekton biomass in nter (September–

upwelling cells and contribute 85% of all zooplankton/nekton grazing pressure. *Pleuroncodes* is directly preyed on, and a preferred food of, yellowfin tuna in the same region, so this is a remarkably direct link from diatoms to your table.

How copepods exploit upwelling cells off Oregon has been most elegantly described by Peterson *et al.* (1979), who were able to use the three-dimensional differential distribution of the five abundant species to clarify the details of water movement during upwelling. Over a very narrow continental shelf (100 m is 10 km from the coast) the pycnocline lies at 20–50 m, sloping up toward the beach: in an upwelling episode the pycnocline intersects the surface 5–10 km seawards and nitrate-replete deep water is brought to the surface. Within this system each copepod has a narrowly defined and specialized distribution, in which it is maintained by details of the circulation pattern and its reproductive behavior: *Acartia clausii* is restricted to the upper 5–10 m and within 5 km of the shore; *Acartia longiremis* occurs 10 km offshore and similarly near the surface; *Pseudocalanus* occurs out to 15 km from shore but also only within the pycnocline at 10–20 m; *Oithona similis* occurs at similar depths but not in the first 10 km offshore; and *C. pacificus* has wider ranges for both depth and distance offshore. In fact, off California the endemic *Calanus* has a life history like that of *Calanoides* elsewhere; during winter and other periods when upwelling is not active, it descends to 400–600 m as a population of copepodite 5's and remains dormant in the oxygen minimum layer which underlies the coastal California Current.

I have already discussed some of the consequences for the ecology of this province of an ENSO event in Chapter 6. Because the El Niño phenomenon was first described in relation to the Peruvian coastal region I shall reserve for the HUMB province a general account of the processes involved. Much of what appears in that section is relevant in general terms to the California Current.

Synopsis

Archived data does not capture details of upwelling cells, so the winter deepening of the mixed layer below the photic zone represents the seasonality of the California Current generally (Fig. 9.16). Offshore, an autumn–spring progressive increase in primary production rate is accompanied only initially by accumulation of chlorophyll. Herbivore abundance appears to be a negative correlate of chlorophyll biomass.

Central American Coastal Province (CAMR)

Extent of the Province

The Central American Coastal Province (CAMR) extends from the tip of Baja California at Cape San Lucas in Mexico to the Gulf of Guayaquil in Ecuador. For convenience, it also includes the long, narrow epicontinental sea of the Gulf of California which lies behind the peninsula of Baja California.

Continental Shelf Topography and Tidal and Shelf-Edge Fronts

The west coast of America is an active continental margin in the geological sense, so the continental shelf is narrow, usually a few tens of kilometers wide.

Biomass Yields and Geography of Large Marine Ecosystems

AAAS Selected Symposium **111**

There are 3 modes of transmission of AVHRR data. The High Resolution Picture Transmission (HRPT) mode broadcasts full-resolution data in real-time. As the satellite passes over a receiving station equipped with a tracking antenna, data can be received. There are currently 23 non-NOAA HRPT stations in the U.S. and 55 in other countries (NOAA, 1985). In Global Area Coverage (GAC) mode, every orbit is processed on board the satellite to a reduced resolution (nominally 4 km), recorded, and eventually dumped and archived by NOAA/NESDIS. In Local Area Coverage (LAC) mode, up to 10% of each orbit is recorded at full resolution and later dumped and stored by NOAA/NESDIS. NOAA/NESDIS can search by time and place to check data availability and deliver data to users. It is possible to request of NOAA/NESDIS that certain locations be recorded. It is also currently possible to receive GAC and LAC data shortly after dumping as they are uplinked from NOAA receiving stations to the NOAA central processing facility. This is done by listening to a geostationary satellite communications network. Table 14.2 summarizes products available from NOAA/NESDIS (see also Kidwell, 1985).

The operational nature of the Polar Orbiter program means that data coverage and data availability is more regular than for the CZCS. Orbits were regularly recorded, except for documented periods of data outage. Like the CZCS, however, the digital scenes are in the form of sensed radiances, and require further processing to produce full-resolution, earth-located geophysical measurements which can be directly incorporated into scientific analysis. The system described in Brown and Evans (1982) is one example of the many extant. At least three systems are available commercially. Basic processing steps are similar to the CZCS. The existence of HRPT mode has fostered a number of smaller collections of local data. HRPT stations usually have some local processing capability, spawning, in turn, aggregations of regional geophysical data.

CASE STUDY: THE WEST COAST TIME SERIES

Introduction

One example of a planned effort to create, utilize, and distribute useful satellite data in the context of LME study is the West Coast Time Series at NASA/JPL. This data set is being created to provide the repeated, synoptic, high-resolution data necessary to observe the high degree of temporal and spatial variability in the California

Table 14.2. CZCS and AVHRR products available through NOAA/NESDIS. Adapted from NOAA/NESDIS (1985).

Sensor	Format	Product
CZCS	Tape and Film	Level 1 radiances
	Tape and Film	Level 2 derived products
AVHRR	Tape	LAC Level 1b radiances
	Tape	GAC Level 1b radiances
	Film	LAC images
	Tape and Film	Polar projection - daily mosaics
	Tape	SST observations, analyses
	Tape	23 km resolution sampled global data

Current System, the eastern boundary current along the North American west coast. To the degree that the oceanographic issues of the California Current are representative of those in other LMEs, the relationship between the data set and its utilization by the scientific community is an instructive example of the possibilities of active use of satellite data in oceanography.

Rationale

The California Current System has been extensively studied by field programs. Foremost among these is the CalCOFI (California Cooperative Fisheries Investigations) sampling program (Reid et al., 1958; MacCall, 1986). Studies based on this long-term (35-year) data set have shown the importance of large-scale variability in the physics and biology of this economically important ecosystem. For example, interannual changes in the southward flow (Bernal and McGowan, 1981; Chelton et al., 1982) seem to be responsible for changes in zooplankton biomass. The large-scale spatial distribution of zooplankton appears to be related to upwelling (Chelton, 1982). Within such a system, biological interactions such as competition and predation may not be dominant in determination of the distributions of organisms because of the effects of variable physical processes (McGowan, 1974).

Regional studies in the California Current System have focused on a variety of physical and biological processes. For example, OPUS (Organization of Persistent Upwelling Structures) concentrated on the upwelling center near Point Conception, California (Jones et al., 1983); OPTOMA (Ocean Prediction through Observation, Modeling, and Analysis) examined the effects of mesoscale variability off Northern California (e.g., Mooers and Robinson, 1984); U.S. CODE (Coastal Ocean Dynamics Experiment) studied the wind-driven circulation off Point Arena, California (CODE Group, 1983); and Canadian CODE studied the interaction of physical and biological processes on the shelf off Vancouver Island (e.g., Freeland et al., 1984). In addition to these large, intensive field studies, there have been several long series of less extensive measurements (e.g., Eppley et al., 1979 in the Southern California Bight). There have also been numerous single expeditions to various regions in the California Current (e.g., Simpson et al., 1984; Denman et al., 1986).

Time series of CZCS and AVHRR data have been used for studying many mesoscale phenomena in the California Current. Kelly (1983) studied coastal dynamics using AVHRR; Laurs et al. (1984) applied CZCS imagery to fisheries studies; Ikeda and Emery (1984) used an AVHRR time series to describe and model meanders; Rienecker et al. (1985) tracked a jet using AVHRR imagery; Abbott and Zion (1985) studied the kinematics of an upwelling event using CZCS and AVHRR imagery; Emery et al. (1986) computed advective surface velocities from an AVHRR time series. Real-time satellite data can be used to guide ships to active areas of interest, which may include fronts, for fishery applications (Montgomery, 1981), or specific features for research (Denman et al., 1986).

Questions relating to the characterization of large-scale processes in the California Current System LME were listed by the West Coast Time Series Advisory Group (WCTSAG) (WCTSAG, 1985). The science issues are addressable directly using a synoptic multiyear time series of satellite data, in some cases with concurrent in situ measurements. Some of the issues were: further definition of the relationship between physical processes such as longshore transport, or wind stress, and their biological manifestations in phytoplankton and zooplankton distributions, productivity fluctuations, and fishery implications; refinement of satellite productivity estimates; the effect of phytoplankton variability on recruitment success of fish; estimates of cross-shore transport of materials, heat, and momentum; coupling between large-scale, mesoscale, and small-scale events; derivation of seasonal statistics of variability; study of the role of seasonal forcing in maintenance of observed features; the importance, characteristic time/space scales, and factors controlling the distribution of persistent features such as eddies and jets; the longshore coherence and phase relationships of variability within the current system and these relationships between the current system and other ocean areas; coherence between SST and pigment signals; and derivation of flow fields from SST and pigment isolines.

Studies of smaller regional processes are perhaps more common because processes that dominate these areas are better sampled by ships. In the California Current, time series of satellite images on this scale have been very useful (e.g., Kelly, 1983; Abbott and Zion, 1983). Certainly each region will have its local features of interest that merit study. WCTSAG (1985) named some general questions addressable with satellite data: the relative importance of mechanisms causing upwelling; the "life history" of upwelling centers and mesoscale eddies; decorrelation length and time scales for mesoscale variability and development of ship sampling strategies for these scales; the degree to which eddies are ecosystems separate from the surrounding ocean; and the use of SST and pigment images to estimate phytoplankton growth rates.

In summary, there is a very active research program studying the California Current System. This research is a mixture of intensive regional studies, medium-term, less extensive studies, and very long, large-scale studies. These lists show that long time series of satellite data have application to quantitative statistical analyses and qualitative descriptions of variability at these scales.

Since 1979, the west coast of North America has been one of the best-sampled in the world in regard to CZCS and AVHRR data. There is a comprehensive Level 1 archive of over 800 CZCS passes and over 4000 AVHRR passes at the Scripps Institution of Oceanography Satellite Oceanography Facility (SSOF). These passes cover the west coast and are received in real-time by the SSOF tracking antenna. Paradoxically, West Coast oceanographers lacked adequate access to the necessary CZCS and AVHRR data. The small number of academic sites with data processing systems were rightly focused on research issues and could not process the data in bulk. Acquisition and maintenance of such systems by many new investigators was not economically feasible.

Strategy

The West Coast Time Series (WCTS) was created to alleviate this problem. All available data from SSOF will be distributed as a comprehensive, consistently processed, documented time series of earth-gridded, geophysical pigment and SST quantities. The extent of the WCTS study area is bounded by 20°N, 55°N, 140°W, and 105°W for the period 1979-1986.

WCTS data are processed as follows. Data are acquired by copying the SSOF tapes. Each tape contains one "swath," the area visible to the satellite while in range of the receiving antenna. Browse images are created to assess cloud cover (neither sensor can see through clouds) and areal coverage (different swaths see slightly different areas of the earth). Swaths are divided into 5 x 5 "tiles" (Figure 14.2). Totally cloudy tiles are identified and excluded from further processing. Remaining tiles are processed to the geophysical quantities and separate cloud masks are created (procedure of Kelly 1985 for nighttime AVHRR swaths, albedo-based thresholds for other data). The tiles are mosaicked (Figure 14.3) at reduced resolution (nominally 7 km) to provide a single image for the entire swath. There are 35 possible non-land tiles in the study grid; on the average about half are useful.

The WCTS is coordinated with another NASA project to ensure that once created, the data are available to the community. Browse,

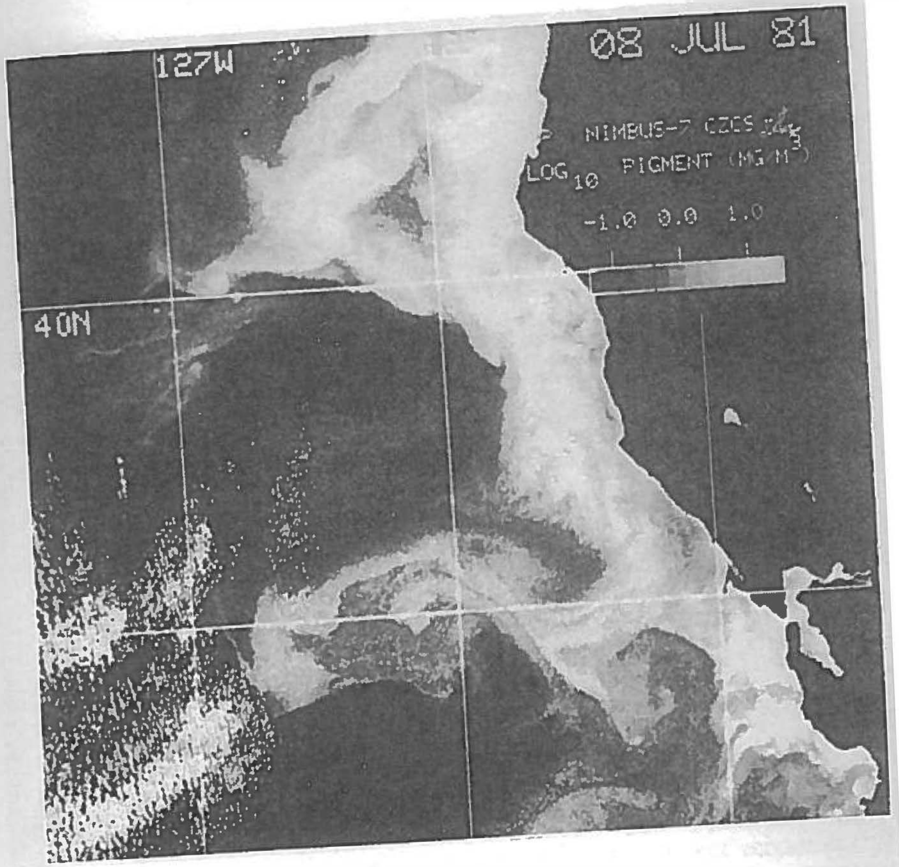

Figure 14.2. CZCS image off Central California, 8 July 1981. Mesoscale features such as eddies and jets are visible.

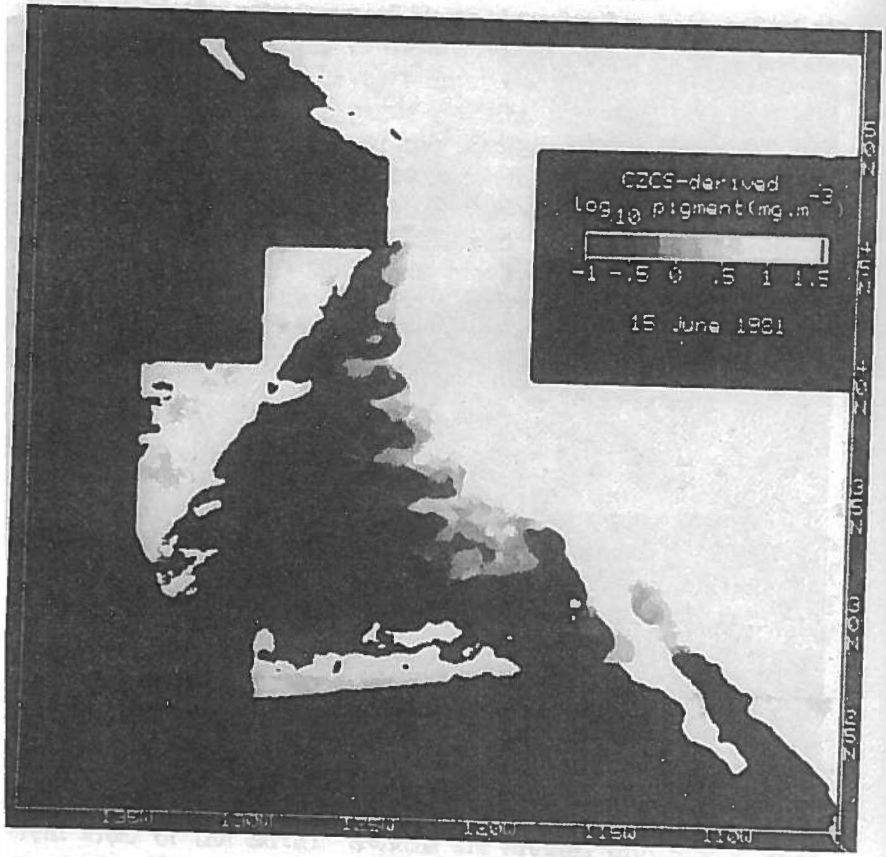

gure 14.3. CZCS mosaic image for the West Coast Time ries study area, 15 July 1981.

tile and mosaic products will be archived and distributed by the NASA Ocean Data System (NODS). Data can be searched by specifying space and time windows. Data can be ordered from a user's terminal for electronic or mail shipping to the user's site. Data access from NODS is described in NASA (1986b).

Results

Research based on WCTS products is at an early stage but shows promise. Abbott and Zion (unpublished data) have produced monthly means of pigment for the period 1979-1982 and noted the expected northward progression and southward retreat of phytoplankton blooming with the advance of the year. Abbott (1986) used WCTS imagery to map the length, orientation, and "root" of jets in the California Current System. Balch (1986) and Collins et al. (1986) have incorporated imagery into development of models of productivity based on satellite data. Denman and Abbott (1986) reported on decorrelation times of CZCS-derived pigment patterns. It is expected that data utilization will continue.

Summary

Several factors converged to promote the development of the WCTS. There was much data available as Level 1 tapes. The WCTS study area already was being researched, including investigations of interannual variability. There was already a realization that satellite data was a necessary tool for studying certain classes of problems. The scientific community was willing to codify a rationale for the project and to generate specific requirements. Also, separating the production work from research sites was accepted, with the proviso that scientific oversight of the project be maintained. Algorithms were at a stage of development to permit acceptable (though still improvable) data to be produced. Finally, improvements in price/performance ratios for computers made the project economically tractable. This experience may illuminate one set of conditions amenable to the development of effective utilization of satellite data.

STUDIES IN OTHER REGIONS

Satellite data have been used in many other areas of the world. The following brief survey shows that satellite methods have been applied to many diverse ecosystems.

plankton and prey fish. In some cases the proximity of land serves to delineate the region, as in the case of semi-enclosed seas, in which oceanographic properties are influenced greatly by the nearby terrestrial areas and the limited communication of the waters to other marine regions.

The concept of LMEs is undoubtedly sound from a biological standpoint, but it may be difficult to apply the idea of an LME to problems of fisheries management. According to customary international law and the Convention on the Law of the Sea (CLS) (United Nations, 1983) coastal states have sovereign rights over resources within 200 nm of their coastal baselines. This Exclusive Economic Zone (EEZ), defined and described in Articles 55-75 of the CLS, is, in effect, a management region, which in many cases does not coincide with the biological region, the LME.

THE PACIFIC OCEAN

As the world's largest ocean, the Pacific measures 15,500 km from Bering Strait to Cape Adare, Antarctica, and 17,200 km from Panama to Mindanao (Fairbridge, 1966). With those boundaries and dimensions it is one of only three oceans; the Atlantic and the Indian Oceans are the others. However, many oceanographers and geographers prefer to include the Arctic and the Antarctic (or Southern), on the basis of their distinguishing oceanographic characteristics.

There have been a number of schemes for subdividing the Pacific proposed over the past 100 or so years. One suggests that the Pacific be divided into northern, southern and intertropical sections, while others employ the more conventional north, south, east, and west subdivisions. Frequently, the term "Central Pacific" is employed also. The northern, southern, and intertropical division is logical when ocean currents are considered. In the North Pacific the clockwise gyre of Kuroshio, North Pacific, California, and North Equatorial Currents is dominant, while a counterclockwise gyre (Peru, South Equatorial, East Australia, and Antarctic Circumpolar Currents) prevails in the Southern Pacific. In the Equatorial Pacific there is a distinct pattern of currents, with the North and South Equatorial Currents flowing from east to west and the Equatorial Counter Current flowing in the opposite direction.

On the basis of water masses, large three-dimensional bodies of water with distinctive temperature-salinity relationships, five regions can be identified: Subarctic Water, Western North Pacific Water, Eastern North Pacific Water, Western South Pacific Water, and Eastern South Pacific Water. Along the west coast of the mainland United States there is a Transition Zone where Subarctic and Eastern North Pacific waters mix.

When more conventional sub-regions are discussed it can be seen that in the Eastern Pacific, both North and South, the coastlines of the North and South American continents are generally smooth, with only the Gulf of California qualifying as a semi-enclosed sea. There are few oceanic islands: the Galapagos, Clipperton, Easter Island, Sala y Gomez, the Juan Fernandez group, and a few others. In the Central Pacific, both North and South, the Polynesian islands, which form a large triangle with the apexes at Easter Island, the Hawaiian Islands, and New Zealand, are prominent. The Western Pacific is characterized by many island groups and a number of marginal, semi-enclosed seas. The presence of numerous island nations, some entitled to claim archipelagic nation status according to the Convention on the Law of the Sea, and the semi-enclosed seas in which jurisdictional claims overlap makes the Western Pacific a region fraught with management problems and potential political conflicts. In the Northwest Pacific the littoral states are in general at a much higher level of economic development than the small island nations of the Southwest Pacific. In general, however, countries in both regions view fishery resources as important.

PACIFIC LMEs

Figure 15.1 depicts 23 LMEs; no attempt has been made to delineate them precisely, since the current state of knowledge of distributions of the various species comprising the ecosystems is still general rather than specific. However, it is possible to classify the LMEs in some meaningful ways, despite an inability to draw exact boundaries.

Some are almost oceanwide in extent; the Eastern and Western Insular Pacific LMEs each cover a very large expanse of Pacific Ocean. Other LMEs are more or less delineated by the ocean currents in which the organisms thrive. The Humboldt, Kuroshio, and Oyashio Currents are good examples. Still others are delineated by the reasonably well-defined boundaries of semi-enclosed seas, such as the Sea of Japan, the East China Sea, the South China Sea Basin, and the Sea of Okhotsk. Another very large category of LMEs consists of those which could be termed "open seas." Examples are the Gulf of Alaska, the Western Isthmus, the Coral Sea, and New Zealand Seas.

Gray Whale

Eschrichtius robustus

MARY LOU JONES AND STEVEN L. SWARTZ
Southeast Fisheries Science Center,
Miami, Florida

The family Eschrichtiidae includes a single known genus and species, the gray whale, which now is found only in the North Pacific and Pacific Arctic Oceans (though it once lived in the North Atlantic until the 17th or early 18th century). Grays are by far the most coastal of all the great whales, and inhabit primarily inshore or shallow, offshore continental-shelf waters. They tend to be nomadic, highly migratory, and are tolerant of climatic extremes. Each year, they make the longest migration of any whale (up to 15,000–20,000 km round trip) largely without FEEDING, traveling along nearshore routes between a summer feeding zone of high productivity in Arctic or subarctic waters and a winter breeding zone in temperate or subtropical southern waters. Unlike other mysticetes, the gray is primarily a bottom feeder and influences the topography of the seabed in the Arctic (from sucking its prey out of the sediments). It is the only whale to bear its young in warm, shallow, coastal areas and lagoons.

There are two populations. The western North Pacific population (or Korean-Okhotsk) migrates along the coast of Asia. It was hunted to the verge of extirpation and is extremely rare. Another much larger, eastern North Pacific population (or California-Chukchi) migrates along the coast of North America and eastern Siberia (Fig. 1). It too was severely overexploited in the latter half of the 19th and early 20th centuries, but, following protection from commercial WHALING, has increased to about 26,600 (in 1999). The resilient eastern North Pacific gray whale is the only cetacean population that, following severe depletion, has sufficiently recovered under protection from commercial whaling to be removed from the list of endangered species. The western Pacific population, however, remains listed as critically endangered.

An active but gentle species, as long as they are not molested, the gray whale had a reputation for ferocity among the old whalers, who dubbed it "devilfish" for its habit of crashing into and staving in boats when harpooned or in defense of its young. Despite it being the trickiest and most dangerous prey, early whalemen developed a special affection for grays and found them to be the most interesting and intelligent of all the great whales. Grays seemed to learn quickly the dangers from whaling and performed a remarkable array of evasive maneuvers. They were admired for their fierce protection of their young and habit of giving assistance or "standing by" an injured companion, often reaching self-sacrificing measures. When attacked, they showed a power of resistance and tenacity of life that distinguished them from all other cetaceans. Today, many people have come to value gray whales more highly as a living resource than as one to slaughter, and they have become a WHALE-WATCHING phenomenon. Their coastal habits make them the most accessible of all the mysticetes and they can be seen most easily, often from shore. Gray whales are unusually sportive; breaching, spy-hopping, LOBTAILING, and mating extravaganzas are essential elements of their migratory and breeding-grounds repertoires. Their willingness to allow whale watchers to stroke them is an added attraction, and grays are now known as "friendly" whales.

I. Systematics

A. Evolutionary History and Classification

No fossils of a direct gray whale ancestor have been found. The family Eschrichtiidae is known only from the Recent and from a single Pleistocene specimen about 50,000–120,000 years old found in California, and a less certain one from Alaska. A long-held theory proposed that gray whales could have evolved from the Cetotheridae, an extinct family of whales dating back some 38 million years, and could be their closest living relatives. Due to the lack of any fossil remains linking the modern gray whale to the far more ancient cetothere, some challenge that view and are unwilling to link them to any of the known early whales. A highly distinctive species, the gray whale has been placed in its own family: Eschrichtiidae (Ellerman and Moirrison-Scott, 1951) (=Rhachianectidae, Weber, 1904).

Most experts have considered the gray whale to be more closely related to the rorquals (Balaenopteridae) than to the right

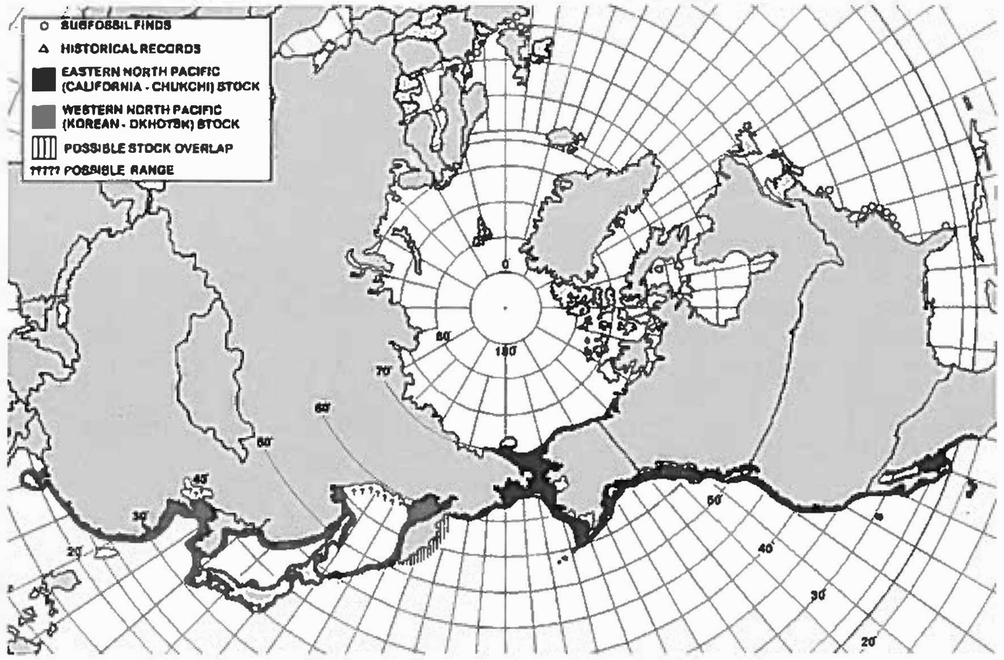

Figure 1 *Known distribution, historic and current, of the gray whale. The eastern North Pacific population (black) has recovered from depletion. The western North Pacific population (gray) remains critically endangered. The Atlantic gray whale is extinct and is known from subfossil finds (circles).*

whales (Balaenidae). Others have given it an intermediate position between the two. However, for the four modern families of baleen whales commonly recognized (Balaenopteridae: rorquals, or fin whales; Balaenidae: bowhead and right whales; Eschrichtiidae: the gray whale; and Neobalaenidae: the pygmy right whale), the pattern of phylogenetic relationships at the base of baleen whale divergence is unresolved. With respect to gray whales, analyses of their position within the Mysticeti conflict. Molecular studies position gray whales within the balaenopterids, while analyses based on morphology and including fossil and extant taxa differ in suggesting grays are linked with the balaenids and the pygmy right whale. Moreover, some biologists place the gray whale as a subfamily of Balaenopteridae.

B. Names

The gray whale has many English names, first applied by 19th century whalers. *Scrag* was used by old whalers on the Pacific coast of North America because they identified it with a whale called a scrag that was taken in the Atlantic Ocean in the 17th and 18th centuries. *Devil fish* and *hard head* were derived from the often violent reaction of the grays that commonly smashed boats with their heads and flukes when harpooned. *Mud digger* and *mussel digger* referred to the bottom feeding of the whales. *Gray* and *gray back* characterized its color. *Okhotsk* and *Korean* denoted the western population's feeding and presumed breeding grounds, and *Chukchi* and *California*, the feeding and breeding grounds for the eastern population (also the whaling grounds).

As for its scientific name, the generic name *Eschrichtius* (Gray, 1865) was given to honor a 19th century Danish zoologist, Daniel Eschricht; and the specific name *robustus* (Lilljeborg, 1861) is from the Latin for "oaken" or "strong." The gray whale first became known to science not through observations of living animals but through the discovery of subfossil skeletal remains from Europe where it had long been extinct. Conspecificity cannot be proven by purely anatomical data, but the SKELETON of the gray is distinctive and no anatomical difference has been found between extinct Atlantic and extant Pacific populations (or between the eastern and western populations of the Pacific) that would justify separating them on the basis of species, or even subspecies. Thus, the odd situation exists where the remains from the extinct Atlantic population serve as the type specimen for in the Pacific Ocean (=*Eschrichtius gibbosus* Erxleben, 1777).

II. Description

The gray whale is a robust, slow-moving whale with a flexible body, more slender than the right whales and more stocky than most rorquals (Fig. 2). This species is readily identified by the mottled gray color of the skin with numerous lighter patches scattered all over the body (although color may vary from gray-brown to slate-black). Grays have more external PARASITES and epizoites than any other cetacean. The barnacle, *Cryptolepas rhachianecti*, thought to be host specific, has been found on beluga whales (*Delphinapterus leucas*). As larvae, BARNACLES are free swimming but soon settle onto calves and adults alike, eventually forming large colonies that are deeply embedded in the skin. Grays also host three species of WHALE LICE (they are cyamids, not insects) that feed on skin and damaged tissue: *Cyamus scammoni* and *Cyamus kessleri* occur only on grays, whereas *Cyamus ceti* also lives on other whales (Fig. 3). The lice cling by the thousands in areas of reduced water flow, such as around barnacle clusters, blowholes, and folds of skin, and swarm into wounds. In the breeding lagoons, schools of topsmelt (*Atherinops affinis*) symbiotically clean lice and sloughing skin from the whales. Much of the whale's mottled appearance comes from the parasites or scars from previous infestations and abrasions. By photographing the skin pigmentation patterns on the backs and sides, it is possible to identify individual animals, which is important to the study of gray whales.

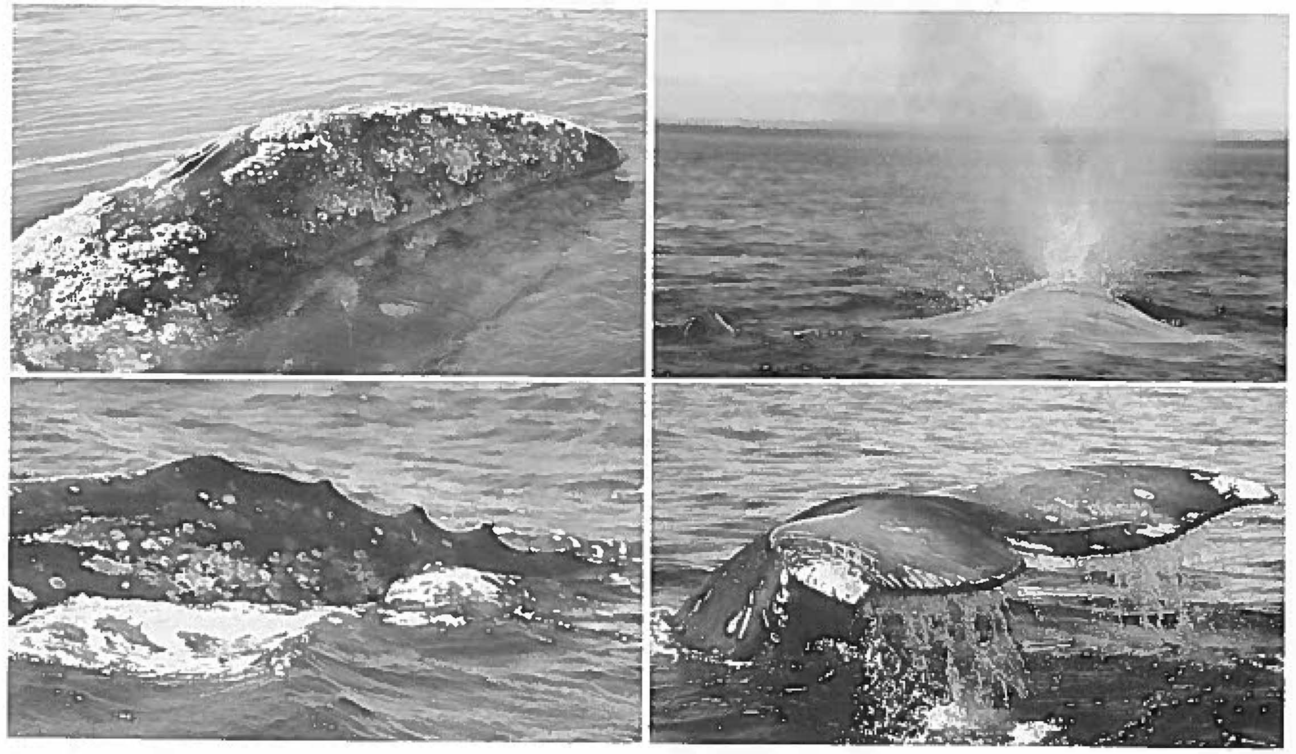

Figure 2 *The narrow head of the gray whale is usually covered with patches of barnacles and whale lice (top left). The blow is heart-shaped and 3–4 m high (top right). Instead of a dorsal fin, grays have a low hump followed by a series of bumps (bottom left). The flukes are over 3 m wide, frequently bear scars from the teeth of killer whales, and are often lifted before a deep dive (bottom right).*

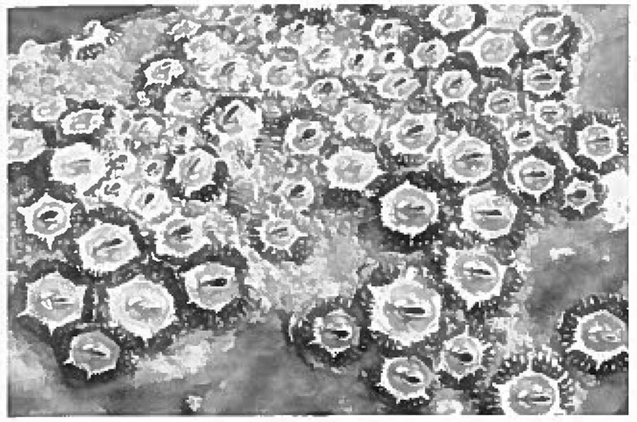

Figure 3 *Dense clusters of barnacles surrounded by whale lice develop shortly after birth. Barnacles leave white scars on the whale's skin, which slowly repigments over time.*

The gray whale's relatively short, narrow head is triangular (in top view) and moderately curved downward (in side view) (Fig. 4). It is encrusted with patches of barnacles and associated whale lice, particularly on top. Widely spaced bristles sprout from small dimples on the upper and lower jaw (no other whale has so many hairs); these short bristles, linked with sensory cells, are extra noticeable on calves. The skull comprises only about 20% of the total skeletal length. A unique feature is the presence of paired occipital tuberosities on the posterior part of the skull. Small eyes, with eyelids, are located just behind the corners of the mouth. Directly above them, on top of the head, is a pair of blowholes (nostrils). Barely visible, the ear opening is a tiny hole just behind the eye. The narrow upper jaw has 130 to 180 baleen plates hanging down on each side, separated in the front of the snout. A gray's BALEEN is the shortest (5–40 cm), thickest, and coarsest of all mysticetes and is cream-white to pale yellow. The lower jaw is broad, with a keel-like protuberance in front, and slightly arched. On the throat there are two to seven (commonly three) short, deep creases that stretch open and allow the mouth to expand a little during feeding, but they do not extend beyond the throat region and are insignificant compared with the many long ventral grooves found in balaenopterids.

Gray whales lack a dorsal fin but have a low hump followed by a series of 8–14 small bumps (knuckles) along the top of the tail stock. The ventral part of the body is smooth, without any longitudinal grooves. The paddle-shaped flippers are up to 200 cm long. Tail flukes are over 3 m wide on adults, with smooth trailing edges and a deep median notch. The flippers and flukes are often marred with tooth scars from killer whales (*Orcinus orca*). Unique to this species is a cyst-like structure (10–25 cm in diameter) beneath a swelling on the ventral surface of the tail stock, which may be similar to sebaceous glands of land mammals, or function as a track-laying scent gland, although its exact function

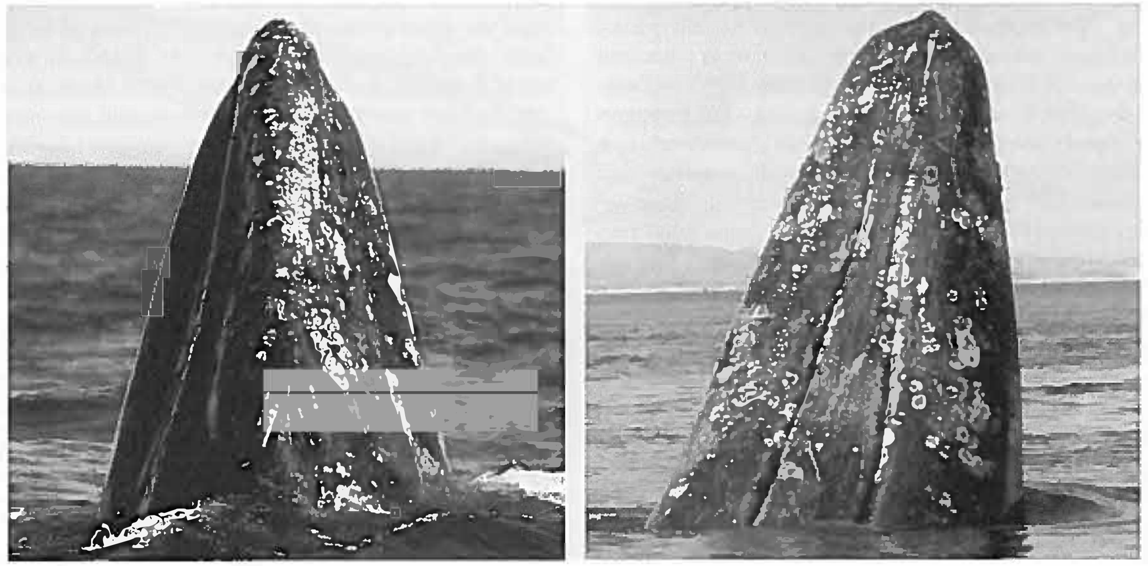

Figure 4 *Gray whales commonly spyhop, lifting the head vertically above the water. The head is narrow and triangular when viewed from the top (left), and they have from two to seven short creases on the throat (right), rather than the long, ventral throat grooves found in balaenopterids.*

is unknown. Grays, which survive in extremely cold water for about half of the year during the feeding season, are insulated with a layer of BLUBBER averaging 15 cm thick beneath the skin and can tolerate a great drop in their skin surface temperature to only a degree or so above that of the surrounding water.

Newborn grays (calves) average 4.6 to 4.9 m long and weigh about 920 kg. The sex ratio is parity at all ages. They reach puberty at anywhere from 6 to 12 years of age (average is 8), at a mean length of 11.7 m in females (called cows) and 11.1 m in males (called bulls). Adults weigh 16,000 to 45,000 kg and stop growing at about 40 years, when the average female is 14.1 m long and the average male is 13.0 m. The largest female recorded was 15 m, and the largest male 14.6 m long. Although adult females are slightly bigger than males, there is no significant difference in their appearance (the distance from the genital slit to the anus is wider in males). The maximum, as well as average, life span is unknown (age is calculated from growth layers in the waxy ear plugs that fill the auditory canal). One large female was estimated to have been 75–80 years old when she was killed and she was pregnant.

III. Ecology and Behavior

A. Social Organization

The gray whale is not a highly social species. Individuals may associate with many conspecifics, but they do not appear to form stable pairs or groups and come together for only part of the year during migration and on the winter breeding range. The only persistent social bond known is between a mother and a calf, which disappears at weaning. Now and then, short-term associations lasting several days or weeks are reported, but their significance is still a mystery to us. Very little research into the social organization of the gray whale has been done. It is possible that they communicate even over large distances, sending and receiving acoustic signals. No territoriality, dominance, or overt aggression toward conspecifics has been reported.

On the summer feeding grounds, grays are usually widely spaced, solitary (commonly pregnant females), or in pairs, and less often in small groups of 3–5, although many may be in proximity in the patchily distributed food-rich areas. Larger aggregations in tens or even hundreds can occur in a particularly rich feeding area but are likely related to a mutually available mass of food rather than to social cohesion or interaction (these aggregations fluctuate constantly). Occasionally, some grays stop feeding to form groups of 30–40 or 100–400 animals that engage in bouts of social activity (lasting 1–4 days) reminiscent of courting and mating; however, their function is unknown. During migration, singles, pairs, and trios are most common but grays sometimes form transient groups of up to 16 individuals.

On the winter breeding grounds, large aggregations of mothers with young and courting/mating whales are common, but are in constant flux (1000 or more will crowd into the largest breeding lagoon). Initially, mothers with neonates have little interaction with other mothers and calves, although many are concentrated in the nursery areas of the breeding grounds. When calves are 2–3 months old, however, they often form highly interactive social groups. In these encounters, mothers and young cavort en masse, rolling about on top of each other, rubbing and touching from head to flukes, and often emitting huge bursts of underwater air bubbles. Groups last from a few minutes to over 3 hr and involve up to 40 individuals at a time, with many others coming and going, and may play a role in the social development of the calf.

Overall, there is a low degree of cooperation among gray whales, except limited examples of joint defense against killer whale attacks and assistance or support behavior, mainly for the aid of the young and especially in the calving areas. This is evidenced by adults coming to the aid of a mother whose calf is in trouble. Standing by (whales in a pair or group assisting, supporting, or staying with an injured companion) also occurs occasionally among adults in times of distress.

B. Feeding

Gray whales do almost all of their feeding during summer and fall when they are in higher latitudes, where they forage on the ocean floor in shallow waters over continental shelves (4–120 m deep). They are adapted to exploit the tremendous seasonal abundance of food that results as the Arctic pack ice (sea ice that is unattached to land) retreats in spring, exposing the sea to the polar summer's continuous daylight, which triggers an enormous bloom of microorganisms in the water down to the sea floor. Unlike other baleen whales, the gray is mainly a bottom feeder and sucks small invertebrates and crustaceans out of the sand and mud. Their distribution in the feeding grounds coincides with the concentrations of these bottom-dwelling prey. As the summer advances and the edge of the pack ice recedes and uncovers more of the feeding grounds, the whales move. They feed heavily from about May through October, gaining enough stores of fat to sustain them during fasting or greatly reduced intake of food during the rest of the year, when the polar feeding grounds are ice covered and they migrate south to warm winter breeding grounds.

During about 5 months of intensive feeding in Arctic waters, an adult will consume roughly 170,000 kg of food. By the time the grays return to the feeding grounds (5 to 6 months later) they will have lost up to 30% of their body weight and must single-mindedly forage to replenish their fat reserves. The highest energy costs during migration are incurred by pregnant or lactating cows. For cows, the cost of reproduction includes the ENERGETIC requirements for gestation (producing a calf) and lactation (nursing young until weaning), which is far greater. During summer and fall, pregnant cows put on 25–30% more weight than other gray whales (exclusive of fetus).

An extraordinary aspect of the gray whale's feeding ecology is its apparent dietary flexibility. Over 80 species of prey have been identified, reflecting its opportunistic approach to foraging. On the summer feeding grounds, grays primarily consume benthic gammaridean amphipods (shrimp-like crustaceans that live on or buried in the sediment). Amphipods from four families account for about 90% of the food, but depending on the feeding area, 1 of 7 species is usually dominant. Four are from the family Ampeliscidae (*Ampelisca macrocephala*, *A. eschrichti*, *Byblis gaimardi*, *Haploops* sp.). They are tube builders that live in dense colonies or "tube mats" in the upper few centimeters of sea floor sediments. Overall, the amphipod *A. macrocephala* (up to 33 mm long) is probably the most commonly taken species (and occurs in concentrations as high as 23,780/m^2 in the Chirikov Basin in the Bering Sea). The other three species are from separate families: Haustoriidae (*Pontoporia femorata*), Lysianassidae (*Anonyx nugax*), and Atylidae (*Atylus bruggeni*), which are mobile scavenging amphipods that rove freely over the seafloor in search of prey. In some areas, polychaete tube worms (*Travisia forbesi*) are their main food. Planktonic prey items eaten in the peripheral feeding areas south of the main feeding grounds occur in swarms or schools and include mysids, crab larvae, red crab, mobile amphipods, herring eggs and larvae, squid, megalops, and bait fish. Some plant material also occurs in their stomachs.

To bottom feed, grays roll to one side, bringing the head parallel with the seabed, sweep the side of the mouth close over the bottom a few centimeters above it, and open the jaws slightly to suck sediment containing prey into the mouth (which has flexible lips) (Fig. 5). Water, sand, and mud are strained through the comb-like baleen, leaving the food trapped on its inner margin. The suction might be created by retracting the large, strongly muscled tongue (weighing 1400 kg). The grays move slowly along the bottom, sucking up infauna in pulses, and surface with clouds of sediment (called mud plumes) streaming from the mouth. Mud plumes mark the meandering path of the feeding whales. Seabirds feed on prey brought to the surface in the plumes.

Grays impact their feeding grounds more than any other cetacean. Bottom feeding leaves mouth-sized depressions or "feeding pits" in the sea floor, from which the top layers of sediment are removed. Foraging is a major source of physical disturbance to the benthic community and plays an important role in the rate of turnover of the epibenthos. In some areas of the Arctic, over 40% of the seafloor is pock-marked with feeding pits. It is thought that by clearing space in the bottom, whales open areas for recolonization, succession, and maturing of the prey community, thus promoting the growth and diversity of life on the seafloor. Periods of nonuse are presumed to correspond to rapid recovery of the habitat. However, if the resource is overutilized and the area is stripped, it could be a one-way street leading to the permanent loss of amphipod communities and changing feeding patterns. In this way, graywhales are an integral part of the coastal community and participate in a dynamic feedback loop, termed "niche construction," whereby their feeding activities function to shape their ecological niche through alteration of the benthos.

In addition to bottom feeding, grays also occasionally feed by surface skimming and engulfing planktonic prey out of the

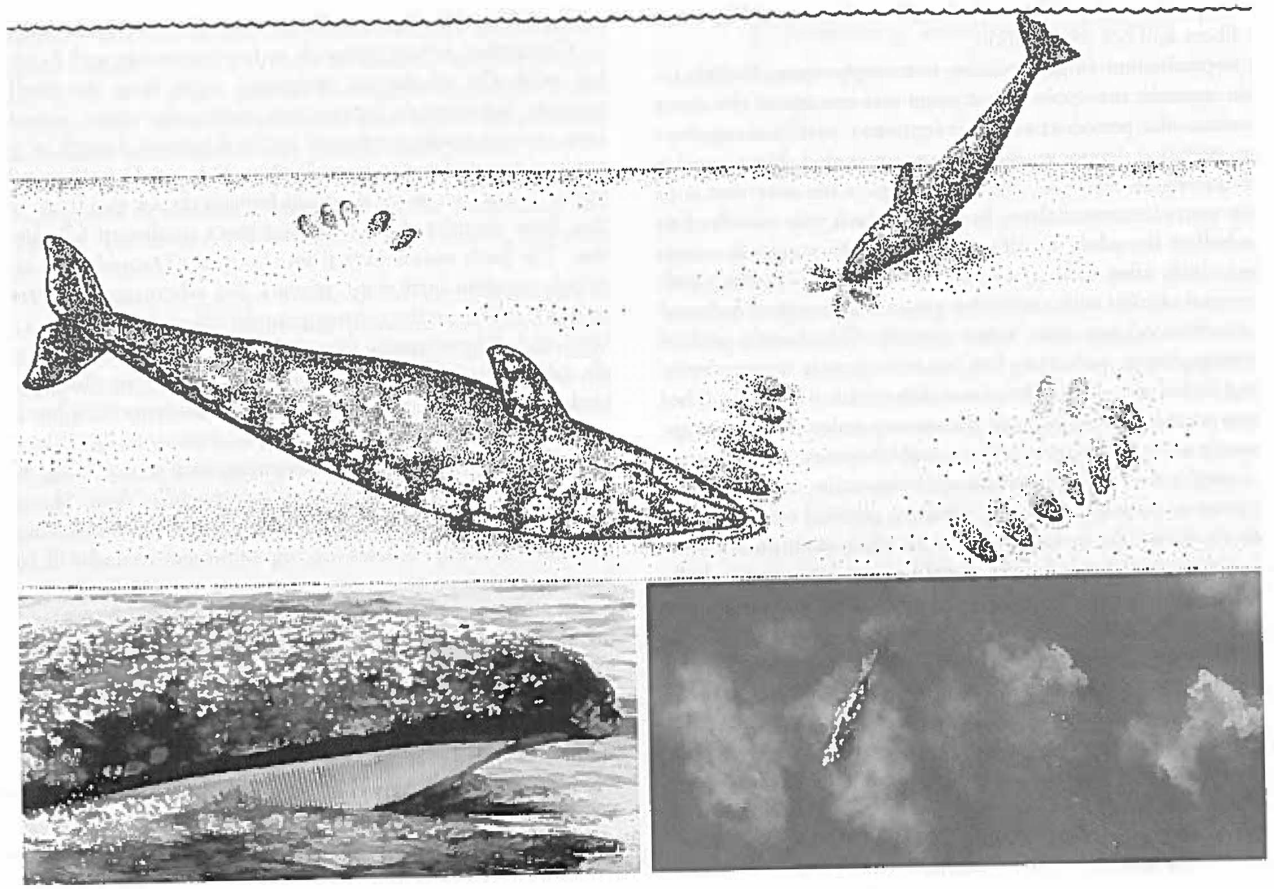

Figure 5 *A bottom feeding gray whale swims on one side to suck prey from the seafloor, creating mouth-sized depressions or feeding pits (top). The cream-white baleen plates are the coarsest, shortest, and fewest of any mysticete (bottom left). Sieving prey-laden sediments through the baleen creates billowing mud plumes (bottom right).*

water column. Zooplankton are only known to be utilized outside of the principle feeding grounds, in peripheral feeding areas throughout the migratory range. Instead of traveling the entire distance to the feeding grounds, some whales spend the summer feeding along the coast in other parts of their range. Also, whales destined for the summer grounds sometimes stop to feed periodically on the way if the opportunity arises. The importance of peripheral feeding areas is unclear. With three modes of feeding (benthic suction, engulfing, and skimming) the gray has perhaps a greater range of foraging techniques than any other of the great whales.

C. Reproduction

Gray whales are thought to have a promiscuous mating system: males and females do not form long-term pair associations and both sexes may copulate with several partners during the same breeding season. Because multiple inseminations can occur, it is proposed that *sperm competition* may be taking place in gray whale fertilization (sperm from two or more males compete to fertilize the ovum within a female). Adult males have relatively large testes weight (averaging 38 kg in mating season) to body weight ratios and presumably produce large quantities of sperm. In this mating strategy, copulating males attempt to dilute or displace the sperm of other males to increase the likelihood of being the male to fertilize the female. Their fibroelastic penis reaches 170 cm in length and is erected by muscle fibers and not vasodilation.

Reproduction in gray whales is strongly seasonal. The female reproductive cycle lasts 2 years and consists of the onset of estros (the period of sexual receptivity), ovulation, conception, gestation, lactation, and an anestros period. Most females bear young in alternate years, although some may rest 2 or more years between calves. In general, each year one-third to one-half of the adult females are birthing (they are not receptive to bulls after calving) and the remainder are mating, with a reversal of roles each successive year. Cows continue to breed at an advanced age. Bulls mate annually. They have a peak of spermatogenetic activity in late autumn or early winter, correlating with the time females come into estrus. Some sexual behavior on the feeding grounds and among males occurs that apparently serves nonreproductive social purposes.

Lengthy courting (precopulatory) behavior is part of the mating process, evidently requiring sufficient physical contact by the bulls to arouse the cows, but detailed information on the constituents of courtship is not yet available. Copulation occurs belly to belly. Pairs or trios of whales sometimes court and mate quite gently together. More often (or perhaps just more readily visible), there is a high level of activity, marked by whales rolling, touching, splashing, and cavorting energetically, at which times bulls with extended penises can be seen (Fig. 6). While some nudging and pushing may take place to get close to a cow, bulls do not appear to fight to keep others away. Bulls outnumber available cows by as much as two to one, leading to the belief of a ménage à trois mating group by early naturalists. In fact, although trios are common, so are pairs and groups of various sizes that can blossom into a giant free for all involving as many as 20 consorting adults at a time. The large groups constantly fluctuate, with some participants departing while others join in as if stimulated by the sexual activity of the initial core group.

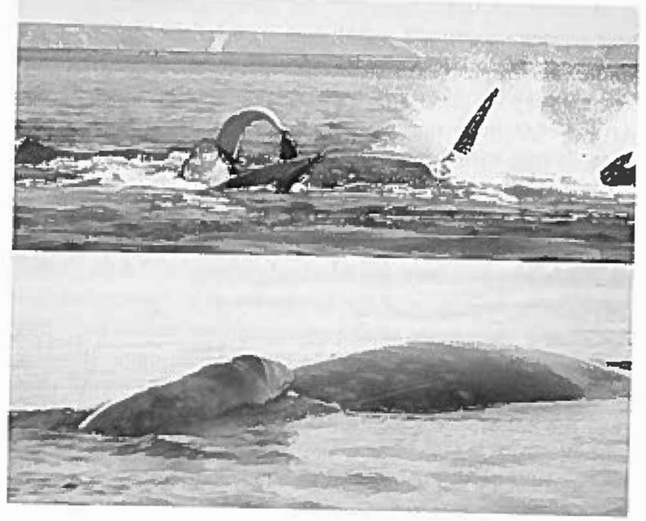

Figure 6 *Gray whales mate with multiple partners, often in large, energetic courting groups (top). Newborn calves have more uniformly dark skin and are supported on their mothers' backs for their first few breaths (bottom).*

Conception occurs primarily in late November and December while the whales are migrating south from the feeding grounds, but some do not conceive until in the winter assembly area, or even on the northward spring migration. Length of gestation is disputed, but is generally thought to last 11 to 13 months, which means that newly pregnant females do not give birth until they have completed the following year's southward fall migration. The birth season lasts from about late December to early March (median birth date: January 27), when most near-term cows are in or near the calving grounds, although some calves are born during the migration from California south. Cows bear a single calf, unattended, and provide sole parental care. Reports of births cite head-first deliveries, with the cow supporting her calf at the surface for the first few breaths of air. Initially, its movements are uncoordinated, but swimming soon steadies (Fig. 6).

A mother's bond with her calf is especially close. She displays an unusual degree of affection, often gently stroking it with her flippers. Mothers are highly protective and will fight fiercely to defend their young from danger. While in the lagoons and on migration, calves stay close to and almost touching their mothers. They drink about 189 liters of rich milk (about 53% fat and 6% protein) each day and grow rapidly, reaching 8.7 m when weaned. The calf remains dependent on its mother until it is weaned in the summer feeding area, at about 7–8 months of age, and perhaps 1 or 2 months longer, when they have solid food in their stomachs but remain with their mother. It is thought that calves begin to forage during the latter stages of nursing and thus may gain some experience while still with the mother. After the calves are weaned, around August, cows are anestrous for 3 to 4 months. Then in November to December a new mating period begins.

D. Sensory Perception

1. Acoustics Once reported to be almost silent, it is now known that gray whales are soniferous both day and night. They create a variety of phonations that sound like rasps, croaks, snorts, moans, groans, grunts, pops, roars, quick series of clicks, belches, and metallic knocks and bongs. These low-frequency broadband signals range from about 100 Hz to 4 kHz, but may go up to 12 kHz. The most prevalent sounds for whales feeding in the Arctic and those in the breeding lagoons are pulsive signals, usually emitted in bursts, that sound like a series of metallic knocks (broadband pulses, from about 100 Hz to 2 kHz). Tonal moans are the most common phonation from migrating whales. Some behaviors may also serve an acoustic function. Grays expel huge bursts of air bubbles underwater (explosive exhalations). These emissions are often released in profusion from the blowholes in social settings. Occasionally, large quantities of air are released from the sides of the mouth as the whale swims by, producing a spectacular display of bubbles. The functions are still obscure, but the joint effect of the acoustic and visual components could create a potent short-range communication signal. Other behaviors that may have an acoustic function include percussive jaw claps, head slaps, backslaps, BREACHING, flipper slapping, and LOBTAILING.

Gray whales are not known to echolocate by means of high-frequency click trains as odontocetes do. However, some low-frequency click-like sounds resembling ECHOLOCATION (which enables a whale to detect objects by listening to the reflected echo of its own sound pulses) have been recorded. These sounds are very tentatively proposed as evidence for primitive echolocation aptitudes that may serve a long-distance function limited to large targets (such as whales) or to detecting broad topographical or oceanic features useful for orientation and navigation. The theory of echolocation in gray whales, however, is as yet unsubstantiated.

Whalers have long stood in awe of the gray's sensitivity to sound. Even the water disturbance by an oar may put a whale to flight. The relatively low upper limit of the frequency range of their vocalizations suggests that they may hear well into the low sonic or infrasonic regions (below the range of human hearing, frequencies lower than 18 Hz). The use of mostly low-frequency sounds is thought to be an adaptive strategy whereby gray whales circumvent the high levels of natural background noise prevalent in their coastal environment by producing sounds that are generally at frequencies below it. Unfortunately, much of the man-made noise in the ocean also occurs in the lower frequency range and has a high level of output, which could interfere with or mask the gray whale's sounds or possibly damage their hearing. Gray whales appear to try to get around some man-made noise by increasing their call types, calling rates, and the loudness of calls to enhance signal transmission and reception.

2. Other Sensory Perception Gray whales can see moderately well both in air and water, but color VISION is probably weak. The position of the eyes suggests that they have stereoscopic vision forward and downward permitting efficient estimation of distance. The eyes are adapted for heightened sensitivity to dim light and for improving contrast and resolution underwater. Grays have retained some sense of smell but are micronosmic at best. In water, the nares are almost always closed (but whales may smell the air as they breathe). The sense of touch is well developed. Some taste buds occur at the back of the tongue, and the possibility of chemoreception through taste has been conjectured.

E. Sleep

It is not known if gray whales sleep. Whales on migration have not been observed to stop to rest for long periods of time. One exception is mothers and calves, which stop to nurse and rest during the north migration. In polar regions during summer when daylight is continuous, most gray whales remain active continually, usually foraging or moving between feeding areas, although occasionally a few resting animals are seen. It is speculated that grays, like some delphinids, may rest one hemisphere of the brain at a time (presumably essential to a voluntary breather). In the breeding grounds, there are more obvious indications that grays sleep, particularly near-term pregnant females and those with neonates. They rest, barely awash, floating at or just beneath the surface, with head and flukes hanging down, for up to an hour, and raise the head to breathe periodically in a slow rhythmic pattern.

F. Swimming, Breathing, and Diving

Overall, gray whales are relatively slow but steady swimmers on migration, although speeds vary from the beginning to the end of the route and there are periods of wandering, resting, milling, feeding, and breeding activity in addition to directed travel along the way. They make the southward trip from the feeding to the breeding grounds in an average of 55 days, swimming at about 7–9 km/hr, and cover a distance of about 144–185 km/day. On the north migration, grays move at a slower speed, averaging 4.5 km/hr (88–127 km/day), and may socialize and feed more, which effectively slows their diurnal rate of migration. Mothers and calves travel up to 96 km/day. Speed of directed travel is about the same as that of other whales, but mothers and calves pause to rest and nurse along the migration. When pursued, grays may reach about 13 km/hr but can only maintain this pace for a few hours. Speed under duress can surge to 16 km/hr, at least for short bursts (avoiding predators). Interestingly, gray whales are very efficient swimmers. They travel mostly at speeds that minimize their energy expenditure and maximize their range, and swim at depths that minimize total drag, important factors in successfully covering the long migratory distances they travel.

Gray whales usually are not exceptionally long or deep divers. The pattern of BREATHING between dives can vary greatly for different activities, with grays averaging only 3% of the time at the surface. When migrating, whales typically remain submerged during traveling–dives for 3 to 5 min during which they may travel 300 m. They surface to blow three to five times at intervals of 15 to 30 sec during a series of short, shallow, surface dives showing only a small portion of the back. The bushy spout is 3 to 4 m high (Fig. 2). Following the terminal blow in a series, traveling whales typically lift their flukes into the air (fluke up) to begin the next traveling dive. During prolonged dives, they may remain submerged 7 to 10 min (or longer) and travel 500 m or more before resurfacing to breathe. Usually, the longer the dive, the greater the number of blows, as the need to reoxygenate the system is greater. Their maximum known dive depth is 170 m.

Breathing and DIVING BEHAVIOR on the feeding and breeding grounds is more variable than on migration. When foraging on summer feeding grounds in shallow coastal waters of 50–60 m, grays dive to the bottom by submerging almost vertically and lifting their flukes above water, and stay under for 5 to 8 min while swimming very slowly. In the breeding lagoons, about 50% of the dives are less than 1 min and 99% are less than 6 min, whereas dives longer than 12 min are associated with resting animals. Mothers, for example, typically float at or slightly below the surface for periods of up to an hour and then submerge for 5 to 10 min, or up to 26 min. When evading detection, grays often surface cautiously, exposing only the blowholes, exhale quietly without a visible blow, and sink silently beneath the surface (called snorkeling).

The species is active at the surface; spyhopping (raising the head vertically out of the water), breaching (leaping vigorously into the air), and other aerial behaviors (head stands with tails in the air, flipper slaps on the surface, etc.) are commonly performed by adults and older calves, especially on the breeding grounds (Fig. 7, also Fig. 4). Throughout their range, grays often appear to "play" and surf in or near the breakers and shallow water along shore. Some grays regularly rub themselves on beaches and sandbars on the breeding grounds and on the rubbing beaches off Vancouver Island. They also rub on pebble beaches and rocks in the Arctic, leaving behind shed barnacles. Some enter brackish water in fjords, coastal lagoons, and the mouths of rivers and emerge cleaned of barnacles and lice. Gray whales are noted to frequent places so shallow that they appear to be lying on the bottom. Occasionally during the ebb tide, some are stranded (apparently unharmed) until the incoming tide refloats them.

G. Friendly Whale Behavior

Gray whales exhibit a sense of curiosity that appears early in life as calves investigate and "play" with floating objects such as balls of kelp and small logs. The whales, including mothers and calves, frequently approach whale-watching skiffs, particularly on the breeding grounds. Behaviors include stationing alongside the skiffs, rubbing against them, bumping, lifting, and blowing bubbles beneath the boats, and allowing the passengers to pet and stroke them (Fig. 8). This activity is popularly termed "friendly" behavior. In the lagoons, these curious grays seem to be initially attracted to the sounds made by the motors of the skiffs, which fall within the same frequency range as gray whale vocalizations. Since the first encounter with a friendly whale at the calving lagoons in the 1970s, friendly whales have become commonplace there and are also encountered to a lesser degree along the migratory route and even in the Bering Sea.

H. Predators and Mortality

Killer whales are the only predator of gray whales (besides humans), although several species of sharks, including the great white shark (*Carcharodon carcharias*) and tiger shark (*Galacocerdo cuvier*), scavenge on carcasses and might kill a small number of calves. Pods of killer whales cooperatively pursue grays, especially calves and juveniles, and seem to attack by repeatedly ramming along their sides, grasping the flukes and flippers to immobilize and drown them, and trying to open their mouths to bite into the tongue. Killer whales have frequently been reported feeding on the tongues of gray whales and then leaving the carcasses as carrion. Sometimes grays turn on their back and slash out with a powerful tail to ward off the swift wolf-like packs of killer whales. Oddly, if cornered, they may go into "shock," floating motionless at the surface, stomach up, while killer whales bite at the tongue and flippers. Rake-mark scars from teeth are often seen on living whales, indicating that many successfully ward off an attack. Some attacks may also represent practice or play by killer whales. A reduced risk of PREDATION from killer whales (more abundant at high latitudes in colder coastal seas) might be a primary benefit to females leaving polar waters to give birth in the subtropics. However, predation pressure does not appear to be a significant determinant in the gray whale's social organization.

Figure 7 *Gray whales breach frequently while migrating and on their winter breeding grounds. One animal was observed to breach 40 consecutive times.*

Figure 8 *A "friendly" gray whale cow and calf allow whale watchers to pet them (note the tip of the mother's lower jaw in the foreground).*

Other known causes of gray whale mortality include ship collisions, ENTANGLEMENT in fishing gear (particularly gill nets) and man-made debris, and whaling (legal aboriginal takes and poaching). Also, calves are sometimes severely struck by whales involved in courting/mating groups, which could result in accidental fatalities. No infectious diseases have been reported. Internal parasites occur but are not known to cause death. In 1999, 2000, and 2001 an unexplained, severe deterioration was seen in the physical condition and health status of some individuals in both eastern and western populations (gray whales were unusually thin, or emaciated). In the eastern population, mortality was unusually high, and some whales appeared to have died from starvation.

IV. Distribution, Migration, and Status

A. North Atlantic Population(s) (Extinct)

The gray whale once existed on both sides of the North Atlantic. Complete and partial skeletons of grays that are subfossils (not yet mineralized) have been found on the east coast of the United States (from New Jersey to Florida) and in the eastern Atlantic from the Baltic coast of Sweden, the Netherlands, Belgium, and the Channel coast of England, the most recent dated from about 1650 A.D. (see Fig. 1). In the western Atlantic, the gray whale is thought to have migrated all along the Atlantic seaboard from Florida to Canada. The youngest North American specimen is from colonial times about 1675 A.D., whereas the oldest are around 10,000 years old. The European gray whale may have disappeared around 500 A.D., but there is a credible record for Iceland in the early 17th century. Evidently, based on written accounts, the last few gray whales in the Atlantic were exterminated by the late 17th or early 18th century, apparently by early Basque, Icelandic, and Yankee whalers. The disappearance of grays from both sides of the Atlantic coincides with the development of WHALING, supporting the idea that overhunting in Europe, Iceland, and North America was responsible for, or at least contributed to, its demise.

B. Western North Pacific Population
(or Korean-Okhotsk)

1. Distribution and Migration Historic records suggest that the western North Pacific population of gray whales formerly occupied summer feeding grounds in the Okhotsk Sea as far north as Penzhinskaya Bay and south to Akademii and Sakhalinskiy Gulfs on the west and the Kikhchik River on the east (see Fig. 1). In autumn, the whales migrated south along the coast of eastern Asia from the Tatarskiy Strait to South Korea (passing Ulsan from late November to late January) to winter breeding grounds suspected to be along the coast of Guangdong Province and around nearby Hainan Island in southern China. The southern-most record was from the east coast of Hainan Island. The long-held belief that the western grays spent the winter on the south coast of Korea was unfounded. It was proposed that an additional migration corridor led down the east coast of Japan to winter breeding grounds in the Seto Inland Sea (where calving occurred) in southern Japan, but this is largely unsubstantiated. In spring, it is assumed that the whales undertook a reverse migration, passing back through the Sea of Japan to reach their summer feeding habitat in the Okhotsk Sea.

Today, the number of gray whales inhabiting the above region is severely reduced. Currently their only known summer–fall feeding ground is off the northeastern coast of Sakhalin Island, Russia. The winter calving and mating grounds are unknown, but may be in coastal waters of the South China Sea.

2. Exploitation and Population Status The western North Pacific gray whale was considered to be extirpated, or nearly so, during the 20th century but is known to survive today as a tiny remnant population. It is one of the most endangered and little-known whale populations in the world. This group was hunted intensely during the past three centuries, but its decline can be largely attributed to modern commercial whaling off Russia, Korea, and Japan between 1890 and 1960. Preexploitation abundance is unknown. Whaling pressure from the Japanese hand-harpoon fishery was underway by the 16th century. Japanese whalers continued to take grays in the 17th, 18th, and 19th centuries. A branch of the population speculated to have bred in the Seto Inland Sea of Japan was gone by 1900. Beginning in the 1840s, American and European whalers took grays in the Okhotsk Sea and western North Pacific until the early 20th century. The last major whaling period occurred between 1910 and 1933, when about 1400 whales were harvested by Japanese and Korean whalers. The fishery dwindled as the whales ran out, and many authorities thought the population was exterminated. However, catch records for 67 whales taken from the Korean coast from 1948 to 1966 indicated that some western grays remained. From 1967 to 1975, a few were continuously caught. Sightings along the coast of Korea, Japan, China, and Russia after that were rare.

During the 1990s, a small number of gray whales were found feeding during summer and fall in the Okhotsk Sea, mostly along northeastern Sakhalin Island (in Russian waters north of Japan), emphasizing its importance as a feeding ground. The population size of western gray whales was estimated to be about 100 individuals in 1999 and less than 100 in 2001. The World Conservation Union listed this population as critically endangered in 2000. Some believe it is likely that the population is below a critical size sufficient for recovery and may soon become extinct; others suggest that it may be increasing slowly. There are no data from the population's southern range off China, North Korea, South Korea, or Japan, and research is needed. It is generally agreed that the western and eastern gray whales are discrete geographical populations. Recent genetic work has documented pronounced differences between them (implying negligible levels of gene flow) and indicates that the eastern and western gray whales can be genetically differentiated at the population level.

C. Eastern North Pacific Population
(or California-Chukchi)

1. Distribution and Migration From the end of May through September, most of the eastern North Pacific population is on its summer feeding grounds in the shallow, continental shelf waters of the Bering Sea and Chukchi Sea (between Alaska and Siberia), the Beaufort Sea (east to 130°W), and the east Siberian Sea (west to 178°30′E) (Fig. 1). The range reaches its northern limit at 69°N at the edge of the zone of close pack ice (to Wrangel Island in some years). Access to the vast feeding ground is controlled by the seasonal formation, disintegration, and drift of ice (for 5–6 months it is ice covered). Gray whales are widely dispersed throughout much of the region, but the major feeding areas where they occur in greatest ABUNDANCE are the northcentral and northwestern Bering Sea, as well as the western and southwestern Chukchi Sea. Although many of the feeding areas have not been studied, those that have are underlain by dense, infaunal amphipod communities. A highly preferred habitat is the Chirikov Basin (between St. Lawrence Island and Bering Strait). It contains one of the largest and most productive amphipod beds in the world and extends over 40,000 km^2. Apparently, whales do not forage in the coastal waters on the eastern side of the Bering and Chukchi Seas, which is consistent with the lack of benthic amphipod infauna in that portion of the continental shelf. As a rule, grays are distributed in shallow waters near shore and rarely go beyond 50 km offshore, although they also aggregate on shallow flats a great distance from shore (up to 180 km). The habitat utilized averages 38 to 40 m in depth, and from 1% to 7% ice cover, but can be as great as 30%. The grays are constantly moving; their DISTRIBUTION varies yearly, and even monthly, as a result of constant ranging between feeding areas. Their foraging areas also support the largest number of bottom-feeding marine mammals in the world, including walruses (*Odobenus rosmarus*), bearded seals (*Erignathus barbatus*), and sea otters (*Enhydra lutris*).

The departure of grays from the northern feeding grounds in late summer and fall is cued primarily by shortening photoperiods and ultimately necessitated by advancing ice formation over feeding areas as the Arctic summer draws to a close. Some turn southward as early as mid-August and begin the long migration extending 7500–10,000 km to the breeding grounds, depending on where they are on the feeding range. Starting in September, grays leave the Beaufort and east Siberian Seas and converge into the Chukchi Sea. In October and November, whales move south out of the Chukchi Sea into the Bering Sea. Then, whales travel southeast and exit the Bering Sea via Unimak Pass, Alaska (in the Aleutian Islands), the easternmost prominent corridor between the Bering Sea and the North Pacific Ocean. Some pass through as early as October, others as late as January, but 90% leave from mid-November to late December. Females in late pregnancy go first, followed by other adults and immature females, and then immature males.

Once through Unimak Pass, the whales travel along the coast of North America down to central California. The migration is spread out all along the coast of Canada and the United States. The main body of the population arrives in central California by mid-January and takes about 6 weeks to pass. Beyond Point Conception, California, the majority take a more offshore route across the southern California Bight, through the Channel Islands, and reencounter the coast in northern Baja California. When the last of the southward migrants reach central California in February, they begin to overlap with the first of the northward migrants returning to the feeding grounds.

From January to early March (through May for some cows and calves), most of the population is in the winter assembly area, which extends from about central California (Point Conception) southward along the west coast of the Baja California Peninsula and continues around Cape San Lucas to the southeastern shore of the Gulf of California off Sonora and Sinaloa, Mexico. Historically, a few continued on to Guadalupe Island, whereas others reached the Revillagigedo Islands. Although a few calves are born off California, most are born along the open coast and in the calving lagoons and bays of Baja California and mainland Mexico. The principal calving areas (with 85% of the calves) are Scammon's Lagoon (Laguna Ojo de Liebre), Black Warrior Lagoon (Laguna Guerrero Negro), San Ignacio Lagoon (Laguna San Ignacio), and the Magdalena Bay complex (from Boca de las Animas to Bahía Almejas), all on the outer coast of the Baja California Peninsula. A few calves are also born on the mainland coast of Mexico at Yavaros in Sonora, and Bahía Reforma in Sinaloa.

The breeding lagoons penetrate far into desert regions through narrow entrances marked by lines of whitewater over barrier sand bars. Except for mothers and calves, however, the vast majority of gray whales in Baja California are outside the lagoons and estuaries in Bahía Sebastián Vizcaíno and Bahía de Ballenas and along the coastline, milling, courting, and wandering along the coast. Courting whales in general do not remain in the lagoons for extended periods. Rather, they are constantly passing and repassing into and out of them, and roving to other areas of the winter assembly grounds, leading to a high turnover of courting whales and subadults in the lagoons. The activity of the grays continues unabated day and night. Cows with newborns seek the quiet, inner reaches of the lagoons early in the season, away from harassment by courting whales concentrated in the areas around the lagoon entrances and outside along the outer coast, where much rolling, splashing, and sexual play can be seen. However, cows with calves also move into the ocean (often at night) and then return during darkness in morning hours, and some visit other lagoons within a season. As the consorting adults start their north migration, the mothers and calves essentially abandon the inner lagoon nurseries and occupy the area near the lagoon entrances. Some cows return to the same lagoon in successive years to hear their young, whereas others rear calves in various lagoons in different years.

The spring migration north to the Arctic feeding grounds begins in mid-February. It retraces the route of the fall migration, but is not as concentrated or as fast. Newly pregnant females migrate first, returning soonest to the Arctic to feed in preparation for the high energetic cost of gestation and lactation. They are followed by anestrous females, adult males, and then immatures. Last to migrate are the mothers and calves; they remain in the breeding area 1–1.5 months longer than most grays while the calves strengthen and grow. The first journey to the Arctic is a time of particular danger for the calves, which are occasional targets of killer whales. Cows and calves tend to travel extremely close to shore (90% are within 200 m) and are mostly alone or in pairs. Northbound whales funnel into the Bering Sea through Unimak Pass from March through June.

The north migration culminates in the dispersal of gray whales throughout their Arctic feeding grounds, which is extended in time and closely related to the ice condition (spring melt). The earliest arrivals generally reach St. Lawrence Island by May as ice recedes north or when leads or polynyas (a large area of water in pack ice that remains open throughout the year) are extensive. The main core of the population usually arrives in the Bering Strait by the end of May, where they are distributed along the cracks of ice throughout areas free of pack ice. One part of the population moves southward along the Asiatic coast and another passes through the Bering Strait into the Chukchi Sea where the whales split off in two directions: east toward the Alaska Peninsula and west toward the Chukotka Peninsula. Another smaller route possibly runs toward the Asian coast, along the Aleutian and Commander Islands. By June, grays are common in the northern Bering Sea in ice-free years, and through the Bering Strait into the southern Chukchi Sea during summer and autumn, as well as into the northeastern Chukchi and Beaufort Seas. By August and September, the ice has retreated north an average of 480 km into the Chukchi Sea. Their eastern distribution in the Beaufort Sea is limited by pack ice, as is their western distribution in the Chukchi and east Siberian Seas.

The vast majority of gray whales go to the northern feeding grounds; however, a small but perhaps increasing number do not migrate the entire distance and spend the summer feeding along the coast from Baja California to British Columbia. These whales (called seasonal residents) join the southbound migrants again in early winter. Areas where they have been observed out of season in Mexico include Bahía San Quintin and Cabo San Lorenzo, on the Pacific coast of Baja California, and Bahía de Los Angeles in the Gulf of California.

2. Exploitation and Population Status Native peoples of North America and Siberia have taken gray whales from the eastern North Pacific population for thousands of years, and a few groups continue to hunt them today. The impact of aboriginal whaling was relatively slight, however, compared to the wholesale slaughter of this population by the first American and European commercial whalers to hunt them in the Pacific. In 1846, they discovered the winter breeding grounds of the gray whale, and commercial harvests began soon thereafter in the lagoons of Baja California, then along the migration route, and spread to the feeding grounds in the Bering Sea. From 1846 to 1874, it is estimated that a minimum of 11,390 grays (not including calves) were taken. From its inception, the relentless 19th century whaling, mainly by American whalers, devastated the population. The hunt in the breeding range was largely concentrated on the cows and calves that were easily killed in the crowded lagoons and bays. Because most of the cows carried fetuses, or would have been impregnated, or had calves that were killed or died of starvation, the reproductive capacity of the population was reduced greatly. By 1900, the once abundant population was thought to be nearly extinct, and whaling all but stopped due to lack of quarry. The attention of the whalers turned to other species, allowing the gray (perhaps a few thousand remained) a brief respite before the advent of modern whaling.

With the introduction of floating factory ships on the west coast of North America in 1905, the hunting of gray whales resumed. A few were taken off Baja California and California in 1919, but mostly between 1925 and 1929. About 48 were taken annually in the Bering Sea from 1933 to 1946. All together, at least 1153 were taken from the remnant population, mainly by Norwegian, Russian, Japanese, and United States vessels. Only fear of EXTINCTION led to their official protection in 1946, except for an aboriginal harvest of about 160 whales each year that have been taken legally by Siberian Eskimos, and also a few by Alaskan natives. Since receiving protection, and the end of research harvests of about 316 grays in the 1960s, the population has increased steadily (by 2.5% per year). Based on the most recent survey (in 1997–1998), the eastern North Pacific population was estimated to be 26,600, possibly exceeding the 1846 preexploitation abundance, which most experts place at between 15,000 and 24,000. There have been indications, however, that the population is approaching, or possibly exceeding, its carrying capacity and may have become food limited (large decreases in amphipod biomass have been linked to increased predator pressure from gray whales and to detrimental effects of global warming in the Arctic). If this is correct, we can expect the gray whale population to level off or even decline.

V. Conservation and Management

A. Legal Protection

Gray whales received partial protection from commercial whaling in 1931 under the Convention for the Regulation of Whaling (which was largely ineffectual). The major whaling nations, Japan and the former Soviet Union, were not signatories to this agreement. They continued to take grays until 1946, when they joined 15 other countries and ratified the International Convention for the Regulation of Whaling, which established the INTERNATIONAL WHALING COMMISSION (IWC). The IWC was intended to provide for the proper conservation of whale stocks and thus make possible the orderly development of the whaling industry. Although it failed in its primary mission, one of its first actions was to officially halt commercial whaling for gray whales in 1946, while allowing native subsistence harvests and scientific collections. Nevertheless, there were violations of the agreement by member nations of IWC, as well as pirate whaling (whaling that is practiced by fleets that acted beyond any national jurisdiction). In 2000, Russian scientists revealed that "literally at every sighting" this prohibited species was illegally killed by the former Soviet Union from 1961 to 1979, and whaling statistics were falsified.

Gray whales were listed as endangered under the U.S. Endangered Species Conservation Act in 1969. Further protection was given by the Marine Mammal Protection Act of 1972 and the U.S. Endangered Species Act of 1973. Under the protection afforded by these and other measures, the eastern population of gray whales recovered. In 1994, it was removed from the List of Endangered and Threatened Wildlife and Plants (under the U.S. Endangered Species Act) when the population numbered 21,000. The population was also downlisted in the World Conservation Union's "1996 IUCN Red List of

Threatened Animals," from "endangered" to "lower risk: conservation dependent." However, changes to the listing of the eastern North Pacific gray whale had no bearing on the status of the western North Pacific gray whale population, which is still critically endangered.

There is no allowable commercial take of any gray whales. The IWC quota for the years 1998–2002 of 140 eastern grays annually (with an overall total of 620 in five seasons) is in response to the catch requested by the Russian Federation for its native people. It also includes an annual quota of five whales requested by the United States to satisfy the Makah Indian tribe's tradition of whaling in Washington state. No grays have been allocated to Alaskan native hunters since 1991. Further protection for eastern gray whales was given by Mexico in 1972 when two of the principal breeding lagoons, Black Warrior Lagoon and Scammon's Lagoon, were declared the world's first whale sanctuaries. The same status was extended to San Ignacio Lagoon in 1979. All lie within the Vizcaíno Desert Biosphere Reserve, Mexico's largest refuge, and entrance into the lagoons is regulated. Currently, not only is it illegal to hunt gray whales, it is also illegal to harm, harass, or even cause behavioral changes without special permits.

B. Concerns

Recently there has been a major shift in the physical environment of the Arctic region with wide-ranging effects on the biota, which may have a deleterious impact on gray whales. Over the past 20 to 30 years, there has been a trend of decreasing sea ice concurrent with increased sea surface temperatures due to global warming. Primary productivity has decreased an estimated 30–40% since 1976. Major declines of marine mammal, fish, and bird populations have occurred in the Arctic's Bering Sea. Although the effects of climate warming on grays are unknown, there are indications that the depression in primary production may lead to reductions in the benthic prey communities on which they feed. Increased predation from the growing population of whales themselves also appears to be stressing the amphipod populations. The eastern North Pacific gray whales may be expanding their summer range in search of additional feeding grounds. Moreover, it is hypothesized that the increase in gray whale mortality in 1999 and 2000 included some whales that were starving. A substantial reduction in food resources, through anthropogenic or natural causes, could have long-term effects on the future health, growth, and stability of the gray whale population.

The region of the Okhotsk Sea around Shakalin Island holds large reserves of oil and gas and is currently being developed jointly by Russian, Japanese, and U.S. companies; oil drilling and production activities plus increased shipping and aircraft traffic may cause physical habitat damage or disturb or displace the highly endangered western Pacific population of gray whales on their only known feeding ground.

Gray whales are intimately related to the coastal habitats in which they have evolved, and it is the dynamic nature of coastal regions that has shaped their unique life history and behavior. It is also precisely their coastal habits that place them in direct conflict with humans. It is not enough to stop overharvesting the whales, we must also protect their critical habitat and allow them living space. They cannot avoid exposure to our intensive coastal development, POLLUTION, vessel traffic, military activities, noise, and industrial activities associated with increased exploration and development of continental shelf, oil, and gas resources over virtually their entire range. Additional concerns include disturbance from ecotourism along migration routes and within the calving grounds, entanglement in fishing gear (particularly gill nets), ship strikes, pollution from salt extraction facilities in Mexico's gray whale refuges, and commercial developments in the breeding area of Magdalena Bay, Mexico. In a world where the human population is expected to double in the next century, the pervasive effects of the population explosion will lead to additional regional and global environmental problems and further approbation of living space and resources that the gray whale requires to sustain itself.

Offshore Distances of Gray Whales Migrating Along the Oregon and Washington Coasts, 1990

Abstract

Aerial surveys were conducted during January and March, 1990, to determine the width of the gray whale (*Eschrichtius robustus*) southbound and northbound migration corridors along Oregon and Washington. Migrating gray whales occurred significantly farther offshore during the southbound migration compared to the northbound migration. Also, whales occurred significantly farther offshore Washington than Oregon during both migration periods, which we attribute to a portion the whales following a more direct offshore route between approximately the Columbia River mouth and central Vancouver Island rather than a longer nearshore route past Cape Flattery. When compared with previous studies, the migration corridor along the coasts of Oregon and Washington appears to be both seasonally and annually elastic, and in some locations expanding as far offshore as 43 km. These results question the feasibility of conducting accurate shore-based gray whale censuses along these coasts because of the high proportion of whales traveling beyond a shore-based observer's range of view. These results also suggest that the migration corridor is sufficiently wide, especially during the southbound migration, that it might overlap potential offshore oil development areas on the continental shelf.

Introduction

Nearly the entire population of approximately 21,000 (Breiwick et al. 1988) gray whales (*Eschrichtius robustus*) passes through the waters off Oregon and Washington twice yearly while migrating between winter calving lagoons in Mexico and summer feeding grounds in the Bering and Chukchi seas (Wolman 1985). The southbound migration generally peaks off Oregon and Washington during December and January with approximately 90% passing Yaquina Head, Oregon, between December 19 and January 23 (Herzing and Mate 1984). The first phase of the northbound migration peaks in mid-March, typically followed 7 to 9 weeks later by a second (cow/calf) phase (Herzing and Mate 1984).

Migrating gray whales generally travel close to shore, remaining within 3 km throughout most of the route (Hessing 1981, Braham 1984, Rugh 1984, Herzing and Mate 1984, Brueggeman et al. 1987, Breiwick et al. 1988). For instance, land-based observations by Herzing and Mate (1984) indicated that nearly all southbound and northbound (first phase) migrants passed within 5 km of Yaquina Head, Oregon, from 1978-1981. However, gray whales have been observed traveling through the Channel Islands 80-200 km from the southern California mainland (Rice 1965, Rice and Wolman 1971, Leatherwood 1974, Kent et al. 1980, Jones and Swartz 1987) following a more direct route past the California Bight. Also, Poole (1984) observed that the first phase of northbound migrators in California traveled a straight-line route past Estero Bay while the second cow/calf phase followed the longer coastal corridor inside the bay. Furthermore, in the 1960s, Wilke and Fiscus (1961) and Pike (1962) observed numerous gray whales migrating 8 to 28 km offshore of the Columbia River mouth and the Washington outer coast, and Pike (1962) reported a single sighting of 3 whales 37 km west of Cape Flattery.

In 1989-1990, we conducted aerial surveys for marine fauna (marine mammals, seabirds, and sea turtles) occurring within 185 km of the Oregon and Washington coasts as part of an impact assessment of potential offshore oil development. One objective of the study was to determine the breadth of the gray whale migration corridor along Oregon and Washington relative to the 1990 southbound and first wave of the northbound migration periods to identify where the corridor might overlap with potential oil development areas. This paper reports the results of this investigation.

Study Area and Methods

Aerial surveys were conducted during 3-12 January (southbound gray whale migration) and 11-16

March (first phase northbound), 1990, along 32 east-west oriented transect lines located between Cape Flattery, Washington, and the Oregon/California border. Spacing between transect lines varied to ensure coverage of areas where marine mammals and seabirds are known to concentrate (bays, river mouths, oceanic banks, etc.), but averaged approximately 22 km. Transect line lengths also varied with 75% of them extending from the coast to the 1,000-m isobath (50-75 km offshore) and 25% extending from the coast to 185 km offshore. This variation in line lengths were established to limit survey effort in typically less productive offshore waters.

Surveys were flown in a 300-series DeHavilland Twin Otter aircraft equipped with bubble windows providing forward and downward visibility. The marine mammal survey team consisted of two observers (one located on each side of the aircraft) and a data recorder. Surveys were flown at a 60-m altitude and a 185 km/hr ground speed.

Statistical comparisons between migration periods and between states (Oregon and Washington) were made using Student's t-test (Zar 1974). Centers and directions of migration corridors were approximated using linear regression (Neter and Wasserman 1974). Data were log-normal transformed before analysis.

Results

A total of 44 groups of 85 gray whales were observed during the January 1990 survey of the southbound migration and 68 groups of 124 whales during the March 1990 survey of the first wave of the northbound migration. Nearly 66% of the southbound migrating groups were >10 km from shore compared to 24% of the northbound groups (Figure 1). Gray whales occurred significantly ($t = 4.78$, $p < 0.0001$) farther from shore during the southward migration ($\bar{x} = 14.3$ km ± 8.2 SD) relative to the northward ($\bar{x} = 8.0$ km ± 3.9 SD).

Gray whales occurred significantly ($t = 3.10$, $p < 0.007$) farther offshore Washington ($\bar{x} = 18.5$ km ± 11.9 SD) than Oregon ($\bar{x} = 9.2$ km ± 4.2 SD) when data from both migration periods were combined. This difference was especially apparent during the southbound migration when Washington observations ($\bar{x} = 25.2$ km + 13.2 SD) were on average over 13 km farther offshore than Oregon observations ($\bar{x}$ = 11.9 km + 3.9 SD; $t = 2.81$, $p < 0.025$). Differences during the northbound migration period were less significant ($t = 2.21$, $p < 0.059$) although Washington sightings ($\bar{x} = 11.8$ km + 5.4 SD) still averaged over 4 km farther offshore than Oregon sightings ($\bar{x} = 7.5$ km + 3.4 SD). The farthest offshore distance during the southbound migration off Washington was 43 km (5 groups) and off Oregon 23 km (2 groups). During the northbound migration the farthest offshore sightings were 20 km off Washington (1 group) and 19 km off Oregon (1 group).

The linear regression analysis showed that the center of both the southbound ($r^2 = 0.0003$) and northbound ($r^2 = 0.033$) corridors did not change in respect to latitude off Oregon, while off Washington the distance whales traveled from shore increased dramatically with increasing latitude during both migration periods (southbound, $r^2 = 0.803$; northbound, $r^2 = 0.636$) (Figure 2).

All whales observed on full-effort (2 observers at full attention) transects migrating past Washington were >5 km offshore. Eight whales, however, were incidently observed migrating within 5 km of the Washington coast during transit flights. Although gray whales were generally found closer to shore along the Oregon coast, only 16% of these whales were observed within 5 km.

Discussion

Although gray whale migration patterns are relatively predictable with respect to timing and location, the extent of the migration corridor may change annually. Our observations off Oregon (only 16% of all whales passing within 5 km of shore) are in contrast with Herzing and Mate's (1984) shore-based observations of nearly all southbound and first phase northbound migrants passing within 5 km of Yaquina Head, Oregon, suggesting a change in the offshore distribution has occurred since their study ended in 1981. Past studies have also suggested that the width or location of the migration corridors may fluctuate over time. For instance, Hubbs (1959) and Rice and Wolman (1971) suggested that the few whales observed along traditional migration routes off California in the late 1800s and early 1900s (Townsend 1887, Andrews 1914, Howell and Huey 1930) was due to animals traveling farther offshore to avoid shore-based whaling pressure rather than an overall population decline.

That gray whales migrate within 5 km past Cape Flattery can not be refuted based on

observations by Pike (1962) and Hatler and Darling (1974). However, our sightings of whales traveling 5-43 km offshore of Washington coupled with observations by Wilke and Fiscus (1961) and Pike (1962) of whales traveling 9-37 km off Washington support the occurrence of either a single, very broad corridor or an alternate offshore route. We suggest that the some portion of the population take a more direct route to and from the central coast of Vancouver Island thereby avoiding the longer coastal route past Cape Flattery. Previous researchers in California have noted migrating whales following more direct routes past coastal indentations such as the California Bight (Rice 1965, Rice and Wolman 1971, Leatherwood 1974, Kent et al. 1980, Jones and Swartz 1987) and Estero Bay (Poole 1984). The Washington offshore route also allows whales to cross the deep (250-650 m) Juan de Fuca submarine canyon at its narrowest point (a pattern reported by Brueggeman et al. [1987] in the southeastern Gulf of Alaska), and the whales are able to travel in relatively shallow (100-150 m) water off the north coast of Washington as the continental shelf (water <200 m deep) here extends nearly 75 km from shore.

Our study also supports previous observations (Pike 1962, Braham 1984, Brueggeman et al. 1987) that the southbound migration in general occurs farther offshore than the northbound, and further suggests that the southbound migration corridor, in particular, could overlap potential offshore oil development areas.

REPORT ORGANIZATION AND ACKNOWLEDGEMENTS

This draft report, entitled Oregon and Washington Marine Mammal and Seabird Surveys, was prepared for the Minerals Management Service (MMS) under contract No. 14-12-0001-30426 by Ebasco Environmental and Ecological Consulting, Inc. The report is divided into three chapters addressing cetaceans, pinnipeds, and seabirds. Too little information was obtained on sea otters and sea turtles to prepare separate chapters, so information on these species was incorporated into the cetacean chapter. Each chapter is a "stand-alone" document" that includes an Abstract, Introduction, Methods and Materials, Results, Discussion, and Literature Cited section. This format was followed so that the chapters could be more easily modified for publication in the scientific journals. In addition, this format gives MMS the option of distributing the chapters as separate reports rather than one large volume.

We thank D. Lewis, D. Claridge, R. Rowlett, B. Troutman, M. Pierson, and D. Jaques for their assistance in the field. K. Short did a thorough job of compiling and analyzing the oceanographic data presented in this report. We are also grateful for the technical assistance provided by L. Russell, D. Volsen, D. Lehtinen, K. Winnick, C. Johnson-Dean, S. Gooljar, and, most especially, J. Vulk. T. Drummer, D. DeMaster, D. Palka, and A. York provided helpful advice on statistical analyses which was greatly appreciated. R. Lowe, P. Sekora, and U. Wilson of the U.S. Fish and Wildlife Service, and P. Crawford of the National Park Service were helpful in securing permits and coordinating logistics.

Empire Airways supplied the aircrafts for these surveys and their pilots ensured safe and successful flights. We are also grateful to E. Nunnally and W. Karp of the National Marine Fisheries Service for allowing us to piggyback on their Pacific whiting research cruise and to

the Captain and crew of the NOAA-Ship *Miller Freeman* for making our stay aboard a pleasant one.

Our study plan was reviewed by K. Burnham, D. Chapman, D. DeMaster, D. Hood, G. Hunt, L. Jones, P. Sekora, and J. Weins. Finally, we are most grateful for the support provided by the project COTR, G. Reetz, and his staff with the Minerals Management Service, Pacific OCS Region.

KEY WORDS: Oregon, Washington, marine mammals, seabirds, cetaceans, pinnipeds, sea turtles, sea otters, aerial survey, shipboard survey.

BACKGROUND: Information on the distribution, abundance, and habitat use patterns of marine mammals and seabirds off the coasts of Oregon and Washington was lacking. The study was intended to characterize the marine mammal and seabirds fauna of the Oregon and Washington coastal and offshore environments using aerial and shipboard survey techniques.

OBJECTIVES: (1) Review and analyze all available literature and databases to formulate hypotheses concerning marine mammal and seabird diversity, distribution, and abundance in the Oregon-Washington coastal and offshore areas; (2) To conduct field surveys over a 18-month period and test the developed hypotheses; (3) To prepare three reports (each addressing cetaceans, pinnipeds, and seabirds) showing the findings of the surveys and providing recommendations for future surveys.

DESCRIPTION: The information synthesis task was based the reviews of published and unpublished literature and the analysis of available databases from the North Pacific concerning the marine mammals and seabirds which inhabit the marine waters of Oregon and Washington. Hypotheses were developed from the information synthesis and tested by conducting aerial and shipboard surveys in the Oregon-Washington OCS. Field data were analyzed and conclusions drawn on the distribution, abundance, and habitat use patterns of Oregon and Washington marine mammals and seabirds.

SIGNIFICANT CONCLUSIONS: The cetacean faunal component was dominated by delphinids, especially Risso's and Pacific white-sided dolphins, which occurred primarily in slope and offshore waters. The nearshore waters were dominated by harbor porpoise and migrating gray whales, especially in the winter. The gray whale migration corridor and the distribution of harbor porpoises extended farther offshore than previously noted in the literature. Humpback whales use in the Oregon-Washington OCS was low and whales were photographically linked with the California feeding herd. Harbor seal and northern sea lion breeding populations appear stable or increasing and a northern elephant seal breeding haulout may become established in southern Oregon in the near future. The number of northern fur seals inhabiting the study area was estimated at between 1,200 animals in January and 7,000 in April. Seabirds were most densely concentrated in shelf waters and least so in offshore waters. Particularly high seabird use was recorded over the shelf-edge banks off central Oregon and the broad shelf area off northern Washington. Peak populations in Oregon and Washington reached into the millions of birds.

STUDY RESULTS: Aerial and shipboard surveys were conducted off the coasts of Oregon and Washington to determine the distribution, abundance, and habitat use patterns of cetaceans, pinnipeds, seabirds, sea otters, and sea turtles. Twelve surveys were conducted from a DeHavilland Twin Otter aircraft along 40,013 km of systematic trackline between April 1989 and September 1990. An additional aerial survey, targeting migrating gray whales, was conducted in May 1990 from a Cessna 337 aircraft along 2,555 km of systematic trackline. The shipboard survey was conducted from aboard the NOAA-Ship *Miller Freeman* during August 1989 from which 1,677 km of systematic effort was accomplished. Total survey effort accomplished, including systematic, coastal, and deadhead surveys, was 76,050 km. Additionally, over 10,000 aerial photographs were taken of seabird colonies and pinniped rookeries.

Fourteen species of cetaceans were observed during the study which included 381 *mysticetes* (6%) and 5,892 *odontocetes* (94%). Six species contributed 97% of the identified animals. Gray whales were found year-round in the study area, but were most common during the southbound (January) and first wave of the northbound (March) migrations. Eighty-seven percent of the migrants occurred >5 km from shore and 38% were >10 km from shore. Humpbacks first appeared off Oregon in May and Washington during July and were found in all depth zones (shelf, slope, and offshore), but most frequented the slope waters. Concentrations of these whales were found in Oregon along the southern edge of Heceta Bank and in Washington near Grays, Astoria, and Nitinat canyons. Humpbacks observed during June and September 1990 were photographed and matched with whales previously photographed in California and Mexico.

Risso's and Pacific white-sided dolphins, the most commonly observed cetaceans, were found year-round in the study area, but were most common during the spring and summer. Risso's dolphins were found almost exclusively in slope waters and none were observed offshore, while Pacific white-sides dolphins were found offshore in large groups during the spring. Seasonal changes in relative densities for both species indicated north-south movements between

California and the study area. Minimum population estimates (uncorrected for missed or submerged animals) for Risso's dolphins was about 7,700 for both spring and summer combined and for Pacific white-sided dolphins about 38,500 for spring only. Northern right whale dolphins were found in the study area during all seasons except winter. However, highest densities occurred in slope waters during the fall, especially during September 1990 when several large groups were observed off central Washington. Because data were clumped, population estimates were not calculated for northern right whale dolphins.

Harbor porpoise were found year-round in the study area with highest densities in the fall and winter, and lowest during the summer. Ninety-six percent of the harbor porpoise sightings occurred in shelf waters with 5-30% of the seasonal sightings occurring in waters 100-200 m deep. Our results show relatively high densities occurring from Cape Blanco to California and Hoh Head to the Columbia River. Minimum population estimates for the spring, summer, and fall seasons combined ranged between 3,858 animals for waters 0-100 m deep and 941 animals for waters 100-200 m deep. The pooled estimate for both depth classes was approximately 4,800 animals. Densities of Dall's porpoises were relatively consistent throughout the year. Dall's porpoise were also distributed across all three depth zones, although they did not inhabit waters <100 m deep. Distribution shifted seasonally from the outer shelf (100-200 m) in the summer and fall to offshore during the winter and spring. Seasonal densities were not significantly different and were pooled to provide a year-round minimum population estimate of 2,149 animals.

Five species of pinnipeds comprise the marine mammal fauna of Oregon and Washington. Pacific harbor seals used haulout sites clustered at about 50 general locations along the Oregon and Washington coasts. During the pupping season of 1990, 9,700 animals were counted in May and 7,700 animals in June; pups represented 13-19% of total numbers. At sea, 88% of harbor seal sightings were recorded over shelf waters (<200 m depth). Northern (Steller) sea lions have large rookeries off southern Oregon at the Rogue and Orford reefs; a few pups may also be born at Three Arch Rocks. In June 1990, a total of 3,400 animals were counted at the rookeries, including 745 pups. Distribution at sea was distinctly inshore with 89% of the sightings in shelf waters. In the summer, northern sea lions were predominantly in cold, upwelled waters off southern Oregon, over Heceta and Stonewall banks, and near the mouth of the Umpqua River. The greatest numbers of California sea lions occurred in the study area in the fall when migrating animals, mostly adult males, arrived from California. Fall counts ranged from 900 to 1,800 animals, with greatest numbers found at Shell Island off Cape Arago in southern Oregon. Northern elephant seals were seen on land only at Shell Island, which may be an incipient breeding colony; no pups were observed during our study. At sea, northern elephant seals were seen in approximately equal numbers in shelf, slope, and offshore waters. Northern fur seals were present off Oregon and Washington year-round, but found in substantial numbers only in January through May. They were 5-6 times more abundant in offshore waters than over the shelf or slope. Minimum estimates of the pelagic population increased from 1,200 animals in January to 7,000 in April. In January, 77% of the sightings were off the northern Washington coast, while in April, 77% of all sightings were off central and southern Oregon.

Forty-two species of seabirds were recorded in the Oregon-Washington OCS. Seabird populations were found to most densely concentrated over the continental shelf least so in offshore waters. During late spring through late summer, the shearwaters, storm-petrels, gulls, Common murres, and Cassin's Auklets numerically dominated the seabird fauna. All except the shearwaters nest in the study area. With fall migration, the importance of shearwaters and petrels declined, while the numbers of phalaropes, California Gulls, and fulmars increased. The latter, together with gulls, murres, auklets, and kittiwakes, constituted the major elements of the winter fauna. Although total population estimates have not been attempted in this study, there is no doubt that peak populations off Oregon and Washington reach into the millions of birds. Every area over the shelf harbored dense concentrations of birds during the year. However, a few stood out prominently. The major colony complexes were located in southern and northern Oregon and along the Olympic coast of Washington. Offshore of these sights, nesting birds foraged in dense aggregations within a 50-km radius. Petrels, shearwaters, and alcids heavily used the shelf-edge banks off central Oregon and northern Washington. The broad shelf area of northern Washington consistently harbored large populations of shearwaters, gulls, murres, and auklets.

INTRODUCTION

Until recently, few studies have been conducted to characterize cetacean populations off the Oregon and Washington coasts. Prior to 1989, the resource agencies' or scientific community's understanding of cetacean use off Oregon and Washington was based on sightings made during pelagic fur seal investigations (Fiscus and Niggol 1965), data collected ancillary to other activities (Wahl 1977), whaling records (Rice 1978), or collections of stranding data and anecdotal observations (Scheffer and Slipp 1948). Detailed studies have been conducted for only a few nearshore species such as gray whales (*Eschrichtius robustus*) (Sumich 1984, Herzing and Mate 1984) and harbor porpoises (*Phocoena phocoena*) (Barlow 1988, Barlow *et al.* 1988, Kajimura *in press*, Calambokidis *et al. in prep.*). Funding resources, or inducements to provide these resources, have simply not been available to adequately characterize cetacean populations, especially in offshore waters.

In the 1970s, the U.S. Department of the Interior, Minerals Management Service (MMS), supported a series of oceanographic and marine ecology programs in California, including studies of the cetacean populations (Dohl *et al.* 1978, 1983), to gather information for the management of marine fauna and habitat during the exploration and development of potential offshore oil and gas reserves. In the late 1980s, MMS expanded these programs to Oregon and Washington in anticipation of potential offshore development. The study we report here, which began in 1988, was a part of these programs and represents the first comprehensive survey of Oregon/Washington marine fauna using replicate, quantitative sampling. The purpose of this study was to document and describe the cetacean, pinniped, sea otter (*Enhydra lutris*), seabird, and sea turtle use of the study area. This chapter addresses the cetacean studies, which were aimed at characterizing the cetacean population and interpreting its spatial and temporal distribution in relation to the physical environment. The sea otter and sea turtle results are also summarized in this chapter because sightings were too few to warrant preparing separate chapters. Our approach was guided by a series of hypotheses directed toward species-specific distributional questions that were developed from a database synthesis report prepared at the beginning of this study (Brueggeman 1989). Hypotheses were developed only for those species where prior information was available; consequently, data analysis for some species was not hypothesis-directed.

This paper comprises several sections addressing aspects of our results. First, we discuss the numbers, distribution, and habitat relationships in a species accounts format. We also estimate encounter rates and abundance for those species observed frequently enough to produce meaningful results and investigate interspecific relationships of cetaceans. Finally, our results are discussed at a community level by looking at patterns of species diversity and associations, as well as locations of major concentration areas.

STUDY AREA

The study was conducted in the coastal and offshore waters of Oregon and Washington extending to 185 km offshore (Fig. 1). The orientation of the Oregon-

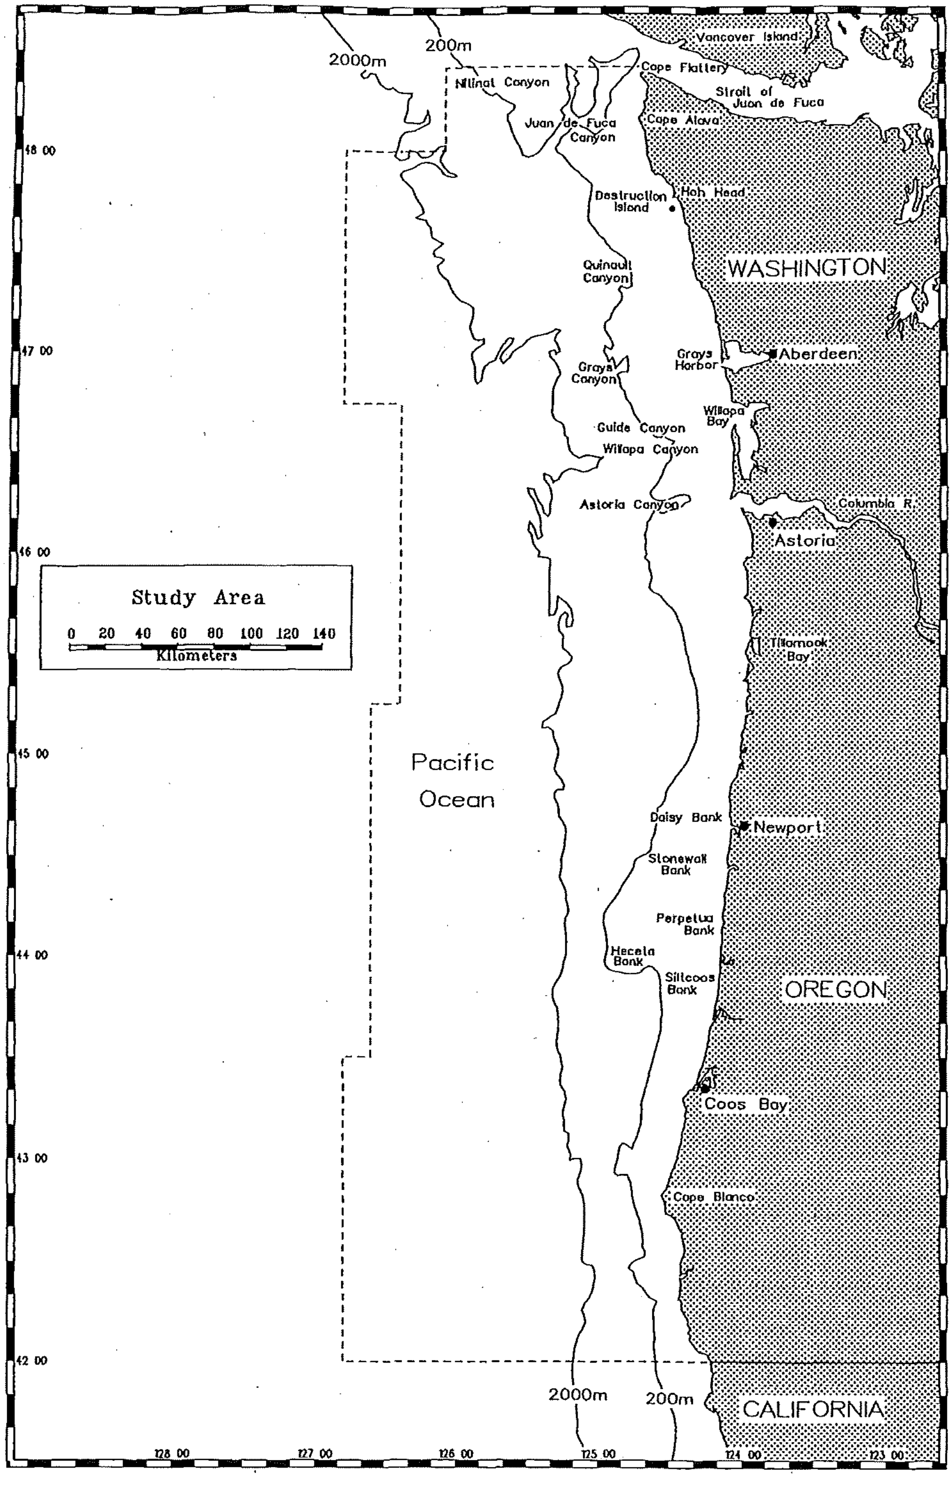

Fig. 1. Map of the study area showing place names and oceanographic features mentioned in the text.

Washington coastline is approximately north-south, unlike much of the California and British Columbia coasts. The continental shelf ranges in width from about 15 to 40 km, and exhibits topography that is relatively uniform compared to other coastal regions of North America. The shelf break occurs at approximately the 200-m isobath.

Although the shelf topography is relatively uniform, there are numerous geomorphologic features that influence the physical and biological processes. The continental shelf along Oregon is characterized by a series of oceanic banks, including Daisy, Stonewall, Perpetua, Heceta, and Siltcoos banks, and a major promontory, Cape Blanco. In contrast, the Washington shelf is furrowed by the Nitinat, Juan de Fuca, Quinault, Grays, Guide, Willapa, and Astoria submarine canyons. The 20- to 25-km-wide Strait of Juan de Fuca, separating Vancouver Island from mainland Washington, is a glacially excavated channel that is the primary avenue for vigorous estuarine exchange between the coastal ocean and the inland marine waters of Washington and British Columbia. The Columbia River discharges through a relatively narrow and deep river mouth that defines the coastal boundary between Washington and Oregon. Numerous small islands dot the coastal area of which Destruction Island off Washington is most prominent. Finally, two very large semi-enclosed bays, Grays Harbor and Willapa Bay, are on the southern Washington coast.

The physical oceanography of this area has been discussed in Landry and Hickey (1989) and shows that, compared to California, the shelf is relatively wide and tends to isolate the large-scale California Current and its infusion of nutrients from nearshore flows. Consequently, the nearshore biological productivity is primarily due to wind-driven coastal upwelling. The oceanography is also heavily influenced by freshwater infusion from the Columbia River, the largest river on the Pacific west coast. The Columbia River effluent amounts to approximately 60% of the freshwater entering the Pacific Ocean between San Francisco and the Strait of Juan de Fuca in winter, and more than 90% in spring, summer, and fall (Barnes *et al.* 1972). Coastal upwelling occurs most frequently in summer and fall, promoted by northerly and northwesterly winds. The upwelling season runs from April to October, with maximum intensity in July and August (Bakun 1973). Upwelling intensity is typically greatest along the southern Oregon coast (the Cape Blanco upwelling zone) and diminishes northward. However, it can occur anywhere along the Oregon-Washington coast under favorable winds.

Seasonal variations in the oceanography of the study area occur in response to solar heating and cooling, wind mixing, freshwater runoff, and coastal upwelling. During the 1989 to 1990 study, sea surface temperature (SST) analyses were conducted to identify pronounced or long-term anomalies in the physical environment that might constitute anomalous conditions for marine mammals. The database consisted of remotely sensed data (from aircraft and satellites) analyzed both by us and government agencies. SST characteristics for each year are summarized in Tables 1 and 2, which present values for waters off Oregon, Washington, and California. The SST data indicated that overall oceanography along the Oregon-Washington coast during 1989 to 1990 was normal. The SST anomaly patterns comprised an assortment of transitory positive and negative departures.

[a] N = northern half of California, S = southern half of California.

Although the magnitude of these anomalies occasionally reached ±2-3°C, such fluctuations were not persistent or widespread. During this 2-year period, there were no apparent consistent or recurrent anomalous features.

A more detailed description of the oceanography of the study area, including oceanographic characteristics during each survey period, is provided in Addendum A.

METHODS AND MATERIALS

SURVEY DESIGN AND PROCEDURES

Twelve aerial surveys, one aerial survey targeting gray whales, and one shipboard survey were conducted between April 1989 and September 1990. A photo-identification survey of humpback whales (*Megaptera novaeangliae*) was also conducted in June and September 1990 in conjunction with aerial surveys to study their movement patterns.

Aerial Surveys

Aerial surveys were conducted along 32 east-west oriented transect lines, termed systematic tracklines (Fig. 2). Transects were equally spaced every 22 km from a random starting point, except for a few transects that were placed to intersect submarine canyons, banks, the Columbia River, and bay mouths—areas where we expected that marine fauna might concentrate. The pattern remained fixed over the study period to enable "pairing" of the data when analyzing changes in animal distribution and density (or encounter rate) over time (Burnham *et al.* 1980). Transect line lengths varied with 75% of the transects extending from the coast to the 1,000-m isobath and 25% extending from the coast to 185 km offshore. This stratification allocated 60% of the survey effort to shelf and slope waters where marine mammals are typically most common and the remaining 40% to offshore waters where, presumably, cetacean diversity and/or density is lower. Surveys generally began with the most northern transect lines and finished with the most southern ones.

Upon completion of the east-west transects, the entire length of the study area was surveyed from south to north in one of three ways: coastal surveys flown 0.5 km off the coast (targeting summering gray whales, pinnipeds, and seabirds); sawtooth surveys conducted over the outer continental shelf (targeting harbor porpoises and migrating gray whales); and sawtooth surveys over the continental slope (targeting schooling delphinids) (Fig. 2).

Surveys were flown in a 300-series DeHavilland Twin Otter aircraft modified for viewing marine mammals. The survey team consisted of two observers and a recorder. One observer was located on each side of the forward part of the fuselage where each viewed through bubble windows. One observer rotated with the recorder every 1.5 hr to reduce visual fatigue. Marine mammal observers were occasionally backed-up by a seabird observer

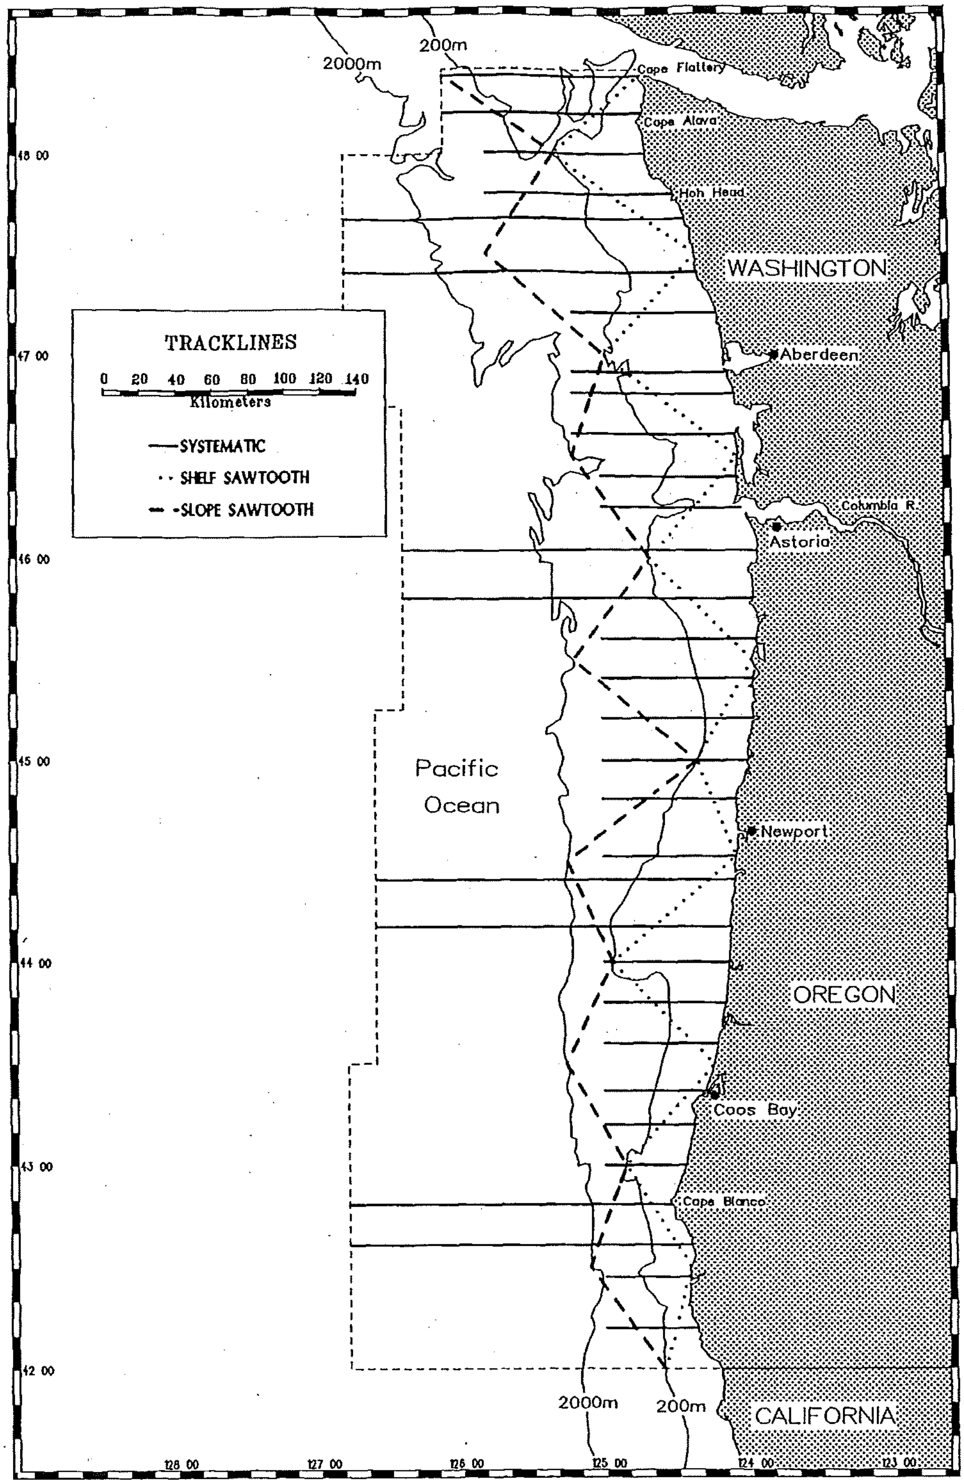

Fig. 2. Distribution pattern of systematic tracklines flown during aerial surveys.

seated in the rear of the aircraft. Seabird and marine mammals were concurrently surveyed from the aircraft. All marine mammal observers were experienced and had previously logged at least 800 hr of aerial survey effort. Surveys were flown at a 60-m altitude and a 185 km/hr ground speed. The low altitude permitted the simultaneous survey of seabirds and marine mammals. Surveys were terminated when sea states exceeded a Beaufort 4 (>30 km/hr wind speed) or visibility was below safe flying conditions. Previous research (Brueggeman *et al.* 1984, 1987; Au and Perryman 1985; Payne *et al.* 1986) has shown that cetacean detectibility from an aircraft is greatly reduced when sea states exceed a Beaufort 4.

An on-board Compaq Portable II computer was linked to the aircraft's Loran-C navigation system and radar altimeter, and to a Pyrometer PRT-5 radiation thermometer. The computer provided, both on-demand and at set intervals, a record of time, latitude, longitude, altitude, speed, bearing, and sea surface temperature. This information was automatically written at each entry to a hard drive, a floppy disk, and as a hard-copy printout. Using a data form, the recorder linked the computer records with sighting and weather information provided by the observers via an intercom system. For each marine mammal sighting, the observer related to the recorder the number of individuals, species, vertical angle (measured to the individual or center of group using a clinometer, and later used to calculate the perpendicular distance from the transect line), behavior, direction of travel, reaction to aircraft, and observer name and position. Weather information included Beaufort sea state, visibility, (Brueggeman *et al.* 1988) and glare, which was recorded at the beginning of each transect line and whenever conditions changed.

Gray Whale Aerial Survey

An additional aerial survey was conducted specifically for gray whales in May 1990 to better define the timing and distribution pattern of the cow/calf phase (Herzing and Mate 1984) of the spring migration. Two complete sawtooth surveys were conducted off the shelf and a single sawtooth survey within 9 km of shore. Observations were conducted from a Cessna 337 equipped with Loran-C navigation and flown at a 230-m altitude at 185 km/hr. Data collection procedures were identical to the other aerial surveys, except the data recorder, seated in the copilot seat, manually recorded all data onto a field form. Also, observations were made through large flat windows rather than bubble windows.

Vessel Survey

A vessel-based survey was conducted from the NOAA-Ship *Miller Freeman* in August 1989 to compare assessments of marine fauna distribution and abundance in shelf waters with the aerial platform. These surveys were conducted ancillary to a fishery study (NMFS, MF89-5).

Thirty-nine east-west transect lines, spaced 18.5 km apart and extending from the nearshore zone (55-m isobath) to just beyond the continental shelf edge (200-m isobath), were surveyed (Fig. 3). Observations were made from the flying bridge, 12 m above the

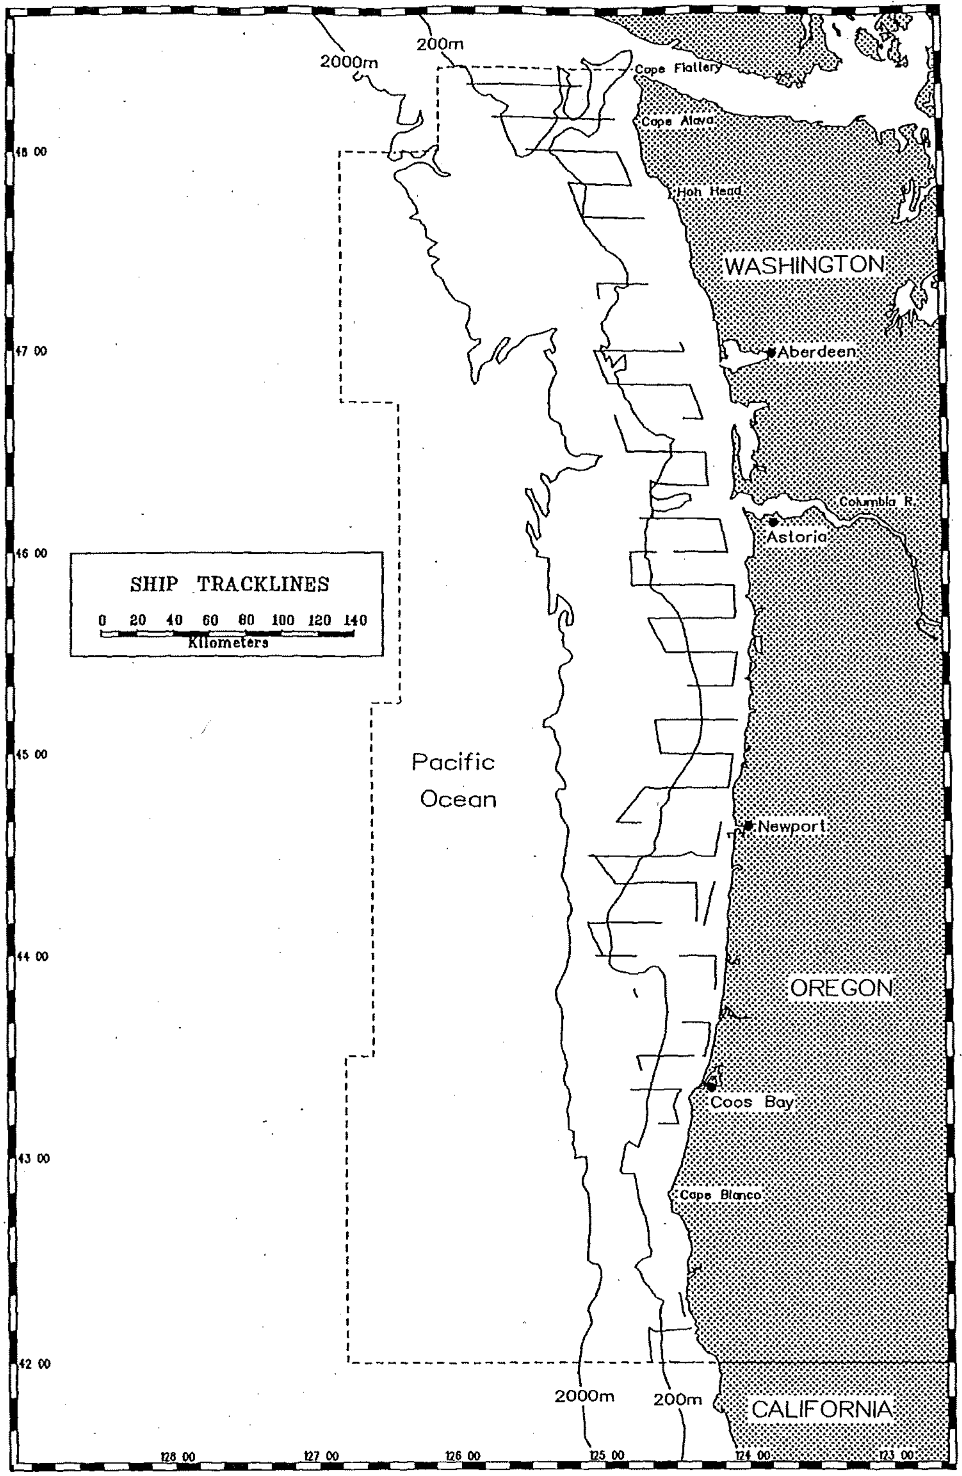

Fig. 3. Distribution pattern of systematic tracklines cruised during the shipboard surveys.

waterline. Surveys began off central California and ended off Vancouver Island, British Columbia; however, only data collected off Oregon and Washington are reported here. Data were recorded by the observer onto a field form, and position information was obtained from a Loran-C unit mounted on the flying bridge. One observer viewed an approximately 120° area centered at the ship's bow as the ship traveled along pre-established tracklines at 18 to 22 km/hr. The radial angle from the ship's bow (using a map compass) and the distance to an animal (using a horizon distance gauge with 230-m reticles) were measured for each sighting. The same sighting and environmental data recorded during the aerial surveys were recorded for the vessel survey, except where they were not relevant.

Photo-identification of Humpback Whales

During June and September 1990, a photo-identification survey was conducted to determine humpback whale movement patterns in the study area (and beyond) based on matching fluke photographs available from elsewhere in their range. Extensive catalogs of photographs have been developed for humpbacks that seasonally occur in the waters off Mexico, California, Hawaii, Alaska, British Columbia, Korea, and Japan. Humpback whale sightings made during June and September 1990 aerial surveys were provided to a vessel-based photographic crew directly by radio from the aircraft or by telephone after returning to an airfield. The vessel was a 6.7-m rigid-hull Novurania inflatable powered by a 200-hp outboard motor and equipped with Loran-C for navigating. Vessel range was limited for safety reasons to coastal waters within 75 km of shore and periods when surface winds were <11 km/hr. The photographic procedure followed the recommendations of Katona and Whitehead (1981), which involved photographing the fluke underside with a 35-mm camera equipped with a telephoto lens. The film was Ilford HP-5 pushed to 1600 ASA (Miles 1990). Film negatives were analyzed with a magnifying lupe, and the best photo of the fluke scars and pigmentation was selected to represent an individual whale. Photographic prints of animals were compared to fluke catalogs available from several sources to identify individual whales. Copies of prints were provided to the National Marine Mammal Laboratory (NMFS, Seattle, WA) for continuing analysis and archiving.

DATA ANALYSIS

The level of data analyses varied according to the survey type. Systematic, random, and sawtooth surveys were used to determine encounter rates, abundance, and habitat use patterns because both marine mammal observers were always on-duty (full-effort). Coastal surveys generally had only one marine mammal observer whose viewing conditions were inconsistent due to constantly changing altitudes and the presence of surf foam and direct sun glare. Marine mammal observers were generally not consistently viewing during deadhead (limited effort) transects but did make incidental sightings. Deadheads included flights flown between tracklines, during high-altitude transits to and from the survey area, during unacceptable survey conditions, and to confirm animal sightings. Because of inconsistency in viewing effort, coastal and deadhead survey observations were only used to describe cetacean distribution.

Encounter rates (number/1,000 km) were calculated for each species and compared by seasons, depth zone, and years to determine spatial and temporal changes in numbers. Encounter rates were calculated from all data collected on full-effort aerial surveys except under poor visibility conditions. The seasons used in the analysis were defined as spring (March to May), summer (June to August), fall (September to November), and winter (December to February). These "solar seasons" were selected to correspond to calendric periods used by Dohl *et al.* (1983) in order that comparisons could be made with their data. The depth zones corresponded to the continental shelf (0- to 200-m isobaths), slope (200- to 2,000-m isobaths) and offshore (>2,000-m isobath) regions. This stratification was used to define water-depth habitat associations by cetaceans.

Density and abundance were estimated for only those species (Risso's dolphin [*Grampus griseus*], Pacific white-sided dolphin [*Lagenorynchus obliquidens*], harbor porpoise, and Dall's porpoise [*Phocoenoides dalli*]) that had sample sizes sufficient to obtain reliable estimates. Density and abundance were estimated according to the line transect procedure (Burnham *et al.* 1980), except for harbor porpoises in which estimates were calculated using strip transect (Eberhardt *et al.* 1979). Line transect estimates were derived from program DISTANCE (Laake *et al.* 1991). The major steps involved in deriving the estimates are summarized below.

Density as derived from the line transect approach was calculated from the following expression:

$$1. \quad \hat{D}=\frac{nf(0)}{2L}$$

where n is the number of groups, L is the number of km of trackline observed under acceptable survey conditions, and $f(0)$ is the probability density function of the perpendicular distances, $f(x)$, evaluated at zero. Because dolphins and porpoises commonly occur in groups, it was more appropriate to treat the group, rather than the individual, as the observation. The $f(0)$ was calculated using the best-fitting estimator available in program DISTANCE (Fourier series, negative exponential, half-normal, Hazard). The tail of the sightability curve was truncated at the farthest perpendicular distances to reduce variability as recommended by Burnham *et al.* (1980). Variance of the density was calculated from the following equation:

$$2. \quad var(\hat{D})=\hat{D}^2[(cv(n))^2+(cv(f(0)))^2]$$

Where cv is the coefficient of variation of a given parameter.

A major assumption of the line transect procedure is that all animals on the trackline center are seen. To minimize violation of this assumption, bubble windows were used that provided downward visibility. However, the distortion in the bottom of the windows, speed and altitude of the aircraft, and physical difficulty in maintaining a downward head position made vigilance in observing the centerline difficult. The closest distance to the trackline that could be consistently covered, based on observer viewing angles, was 25 m. Consequently, the "centerline" was reset for each side of aircraft at 25 m, assuming a 50-m wide strip under the aircraft was not viewable. All perpendicular distance data were adjusted to account for the 25-m blindspot.

Density calculations only included data collected during full-effort surveys, by on-duty marine mammal observers, and in Beaufort sea state and visibility conditions when a given species could be effectively observed. Sighting rates were computed by species for each sea state and visibility condition. Sea state and visibility limitations were selected at the point the sighting rates began to substantially decline.

Abundance was estimated from the following formula:

$$3.\quad \hat{N}=\hat{D}A\bar{G}$$

where $\hat{N}$ is the abundance estimate, $\hat{D}$ the calculated density, A the area under consideration, and $\bar{G}$ the mean group size. The variance of mean group size was calculated using the equation:

$$4.\quad var(\bar{G})=\frac{\sum G_i^2-\frac{(\sum G_i)^2}{n}}{n(n-1)}$$

Finally, the variance of the abundance estimate ($\hat{N}$) was calculated by using:

$$5.\quad var(\hat{N})=A^2[\hat{D}^2 var(\bar{G})+\bar{G}^2 var(\hat{D})-var(\bar{G})var(\hat{D})]$$

with the coefficient of variation (*cv*) for the abundance estimate equalling:

$$6.\quad cv(\hat{N})=\frac{100\sqrt{var(\hat{N})}}{\hat{N}}$$

Abundance was estimated by depth zones where significant differences in animal densities occurred between depth zones, and then pooled into one value for the study area.

The line transect approach was used for estimating abundance of most cetaceans except harbor porpoises. Harbor porpoises at the surface were effectively counted within the 50-m seabird observation strip (combining both seabird observer and marine mammal observer sightings). Harbor porpoise abundance was calculated according to Method I of the strip transect procedure described by Estes and Gilbert (1978), with the variance of the estimated abundance calculated from Equation 5 above. This approach reduced the percentage of animals missed at the surface by the line-transect approach, which occurred because of the low survey altitude coupled with marine mammal observers spending significant time searching beyond the effective viewing distance (approximately 100 m) for harbor porpoise.

RESULTS

SURVEY EFFORT

Fourteen surveys were conducted in the study area between April 1989 and October 1990 (Table 3). Twelve aerial surveys were conducted across the entire study area, which included four surveys during spring, four during summer, three during fall, and one during winter. Replicate surveys were conducted in 1989 and 1990 for the May through September surveys. In addition, two surveys were conducted over the shelf, which included an aerial survey in the spring for gray whales and a vessel survey in summer. All surveys were generally scheduled to coincide with seasonal movement and use patterns of marine mammals and birds.

Survey effort in the study area totaled 76,050 km, which included 44,244 km of systematic, 27,925 km of deadhead, and 3,881 km of coastal survey effort (Table 3). Effort per survey averaged 5,850 km and ranged from 1,750 to 6,976 km. The 12 surveys represented 94% of the total effort compared to 4% for the gray whale survey and 2% for the vessel survey. Because of limited survey effort and coverage associated with the gray whale and vessel surveys, only data collected for the 12 aerial surveys along systematic tracklines was analyzed in detail.

A total of 40,012 km of full-effort survey was accomplished during the 12 aerial surveys with effort highest over the continental shelf (17,418 km), lowest offshore (7,350 km), and intermediate over the slope (15,244 km) (Table 4). Effort was also highest during the spring and summer survey periods (13,383 and 13,152 km, respectively), lowest during the winter (3,971 km), and intermediate during the fall (9,506 km).

SPECIES COMPOSITION AND TOTAL NUMBERS

Scheffer and Slipp (1948) and Mate (1981) listed 24 species of cetaceans off the Oregon and Washington coasts. We observed 14 species (two of which were identified only to genus) of cetaceans, which included 381 *mysticetes* (6%) and 5,892 *odontocetes* (94%) during all types of survey effort (Table 5). All species were observed in both states, except fin (*Balaenoptera physalus*) and Baird's beaked (*Berardius bairdii*) whales were observed only in Oregon, and a single *Kogia* was observed in Washington. Additionally, 208 cetaceans, mostly dolphins, were observed but not identified to the genus level. The most commonly observed species were Risso's dolphins (2,855), Pacific white-sided dolphins (1,377), northern right whale dolphins (*Lissodelphis borealis*) (661), harbor porpoises (559),

Table 3. Effort (km) accomplished during each of the 13 aerial and 1 shipboard survey periods by the various survey types in the Oregon/Washington study area, 1989-1990.

---

[a] Total survey effort for all survey types.

Dall's porpoises (341), and gray whales (282); these species represented 97% of the identified animals. Fewer than 70 animals were encountered for each of the remaining eight species. Four species that were observed (gray, humpback, fin, and sperm [*Physeter macrocephalus*] whale) are federally listed as endangered.

Twelve species known to occur off Oregon and Washington occasionally or historically were not identified in this study:

Blue whale (*Balaenoptera musculus*)
Sei whale (*Balaenoptera borealis*)
Northern right whale (*Eubalaena glacialis*)
Stejneger's beaked whale (*Mesoplodon stejnegeri*)
Hubb's beaked whale (*Mesoplodon carlhubbsi*)
Cuvier's beaked whale (*Ziphius cavirostris*)
Pygmy sperm whale (*Kogia breviceps*)
Beluhka whale (*Delphinapterus leucas*)
False killer whale (*Pseudorca crassidens*)
Short-finned pilot whale (*Globicephala macrorhynchus*)
Striped dolphin (*Stenella coeruleoalba*)
Common dolphin (*Delphinus delphis*)

Cetaceans of the genus *Mesoplodon* and *Kogia* were sighted during this survey, but were not identified to species, and a single Cuvier's beaked whale was found stranded in southern Oregon.

SPECIES ACCOUNTS

In the following species accounts we provide the numbers, distribution, and, where data are sufficient, encounter rates and abundance estimates of all species observed during this study.

Gray Whale

Nearly the entire population of 21,000 (Breiwick *et al.* 1988) Pacific gray whales passes through the waters off Oregon and Washington twice yearly as it migrates between breeding lagoons in Mexico and summer feeding grounds in the Bering and Chukchi seas (Wolman 1985). The southbound migration generally peaks off Oregon and Washington during late December/early January (B. Mate, Oregon State University, Personal Communication), while the first wave of the northbound migration peaks in mid-March typically followed 7 to 9 weeks later by the second cow/calf wave (Herzing and Mate 1984). An unknown percentage of gray whales (Brueggeman 1989) summer along the Oregon and Washington coasts (Sumich 1984, Calambokidis *et al.* 1987). Aerial survey periods during this study were partly established to coincide with the migration peaks.

There were 201 groups totaling 282 gray whales recorded in the study area (Table 5). Most were observed during the spring (169) and winter (85), with only a few animals sighted during fall (15) and summer (13). Twenty-nine percent of the whales were observed during the January 1990 survey of the southbound migration and 44% during the first wave of the northbound migration (March 1990). Only 5 whales were observed during a special survey of the second northbound wave during early May 1990. The timing of the 1990 cow/calf migration appeared to be atypical throughout the migration route (M. Dahlheim, NOAA, NMML, Seattle, Personal Communication). The remaining whales were observed between April and November. No calves were observed during migration, although a cow/calf pair was observed at the mouth of the Siuslaw River in July 1989. All gray whales were observed on the shelf (Fig. 4).

Point location studies indicate that migrating gray whales generally travel within 3 to 5 km of shore throughout most of their route (Hessing 1981, Braham 1984, Rugh 1984, Herzing and Mate 1984, Brueggeman *et al.* 1987, Breiwick *et al.* 1988). However, information from Rugh (1984) and Brueggeman *et al.* (1987) suggests that the width of the migration corridor may change as the width of the 0 to 40-m depth zone changes. This depth band is relatively narrow off Oregon (4-5 km) and wide off Washington (17-28 km), thus providing the opportunity to test the null hypothesis: *The width of the gray whale migration corridor does not change in concert with varying widths of certain depth zones.* Our results show that only 13% of all whales observed on full-effort transects off Oregon and Washington were found within 5 km of shore (Fig. 5). The migration corridor extended relatively far offshore with 38% of the sightings occurring >10 km from shore. The widest margin of the corridor occurred from approximately the Columbia River through Washington where the shelf (and 40-m isobath) extends farther offshore (Fig. 4). In fact, the mean distance gray whales occurred offshore Washington was 18.5 km (SD = 11.9 km) compared to 9.2 km (SD = 4.2 km) for Oregon. The differences are significant ($t = 3.10$, $p < 0.007$) indicating the migration corridor does change in concert with changes in the width of the shallower isobaths. All of the migrating whales observed on full-effort transects were >5 km offshore of Washington, which is similar to observations by Wilke and Fiscus (1961) and Pike (1962) where numerous gray whales occurred 8 to 28 km offshore of the Columbia River and Washington. Although gray whales were found closer inshore along the Oregon coast, only 16% of these whales were observed within 5 km, which contrasts with Herzing and Mate's (1984) shore-based observations that nearly all of the southbound and first wave of the northbound migrants passed Yaquina Head, Oregon, within 5 km.

Braham (1984) and Brueggeman *et al.* (1987) provided information that the southbound migration, at least in Alaska, occurred farther offshore than the northbound migration. In testing the null hypothesis: *The gray whale migration corridor width is constant relative to migration period*, we found gray whales to migrate farther offshore of Oregon and Washington during the southbound migration than during the first wave of the northbound. Nearly 66% of the southbound migrating groups were >10 km offshore compared to 24% of the northbound groups (Fig. 5). The mean distance offshore that gray whales occurred during the southbound migration was 14.3 km (SD = 8.2 km) compared to

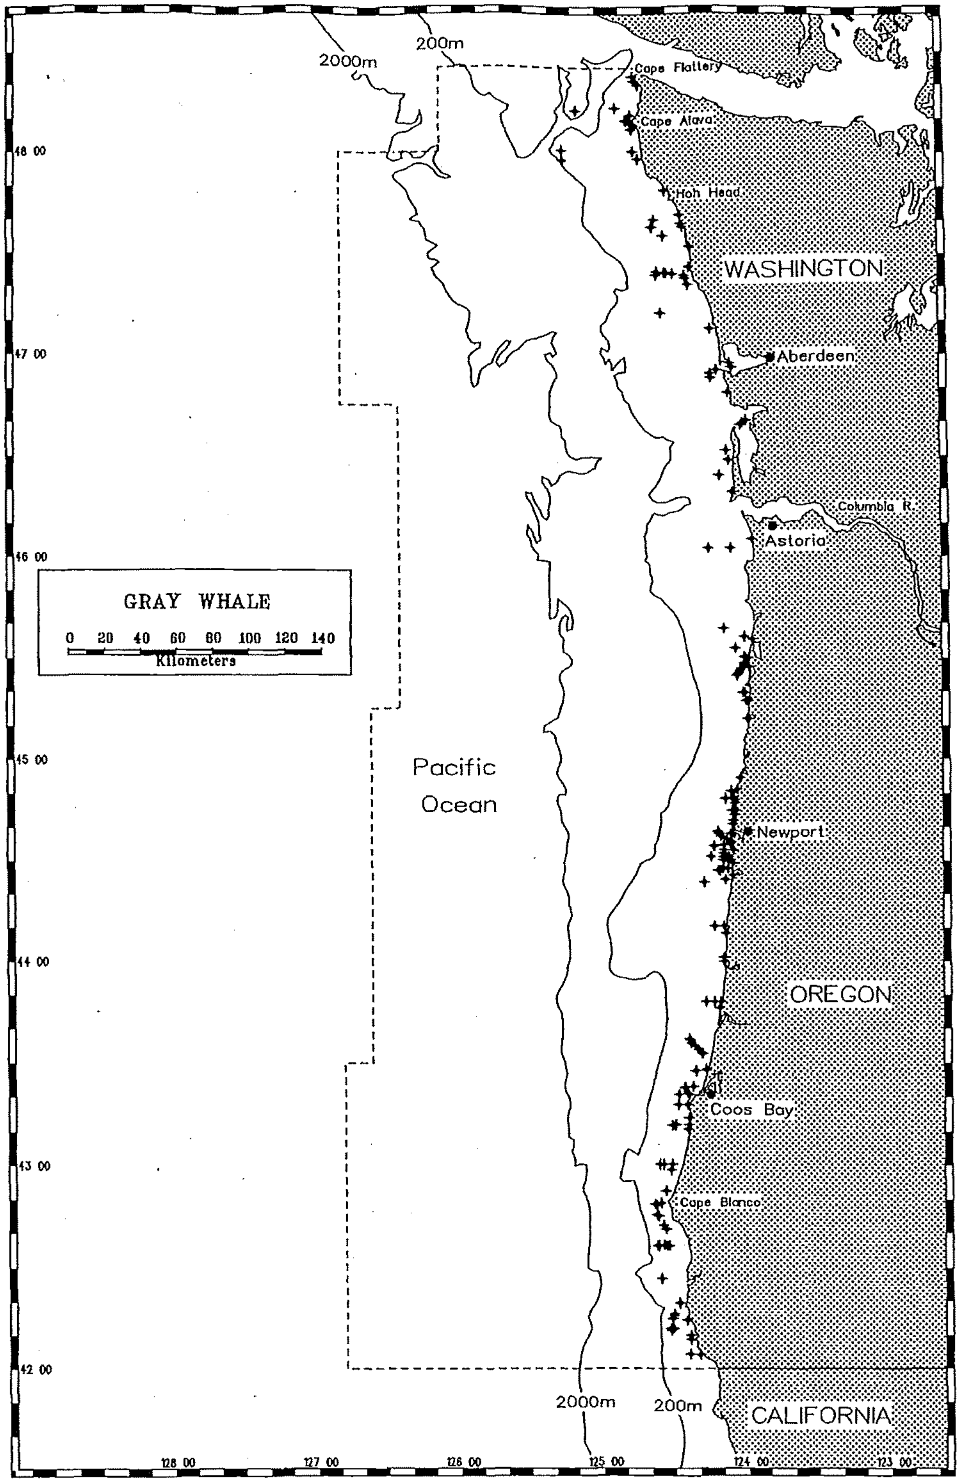

Fig. 4. Distribution plot of all gray whale sightings in the study area.

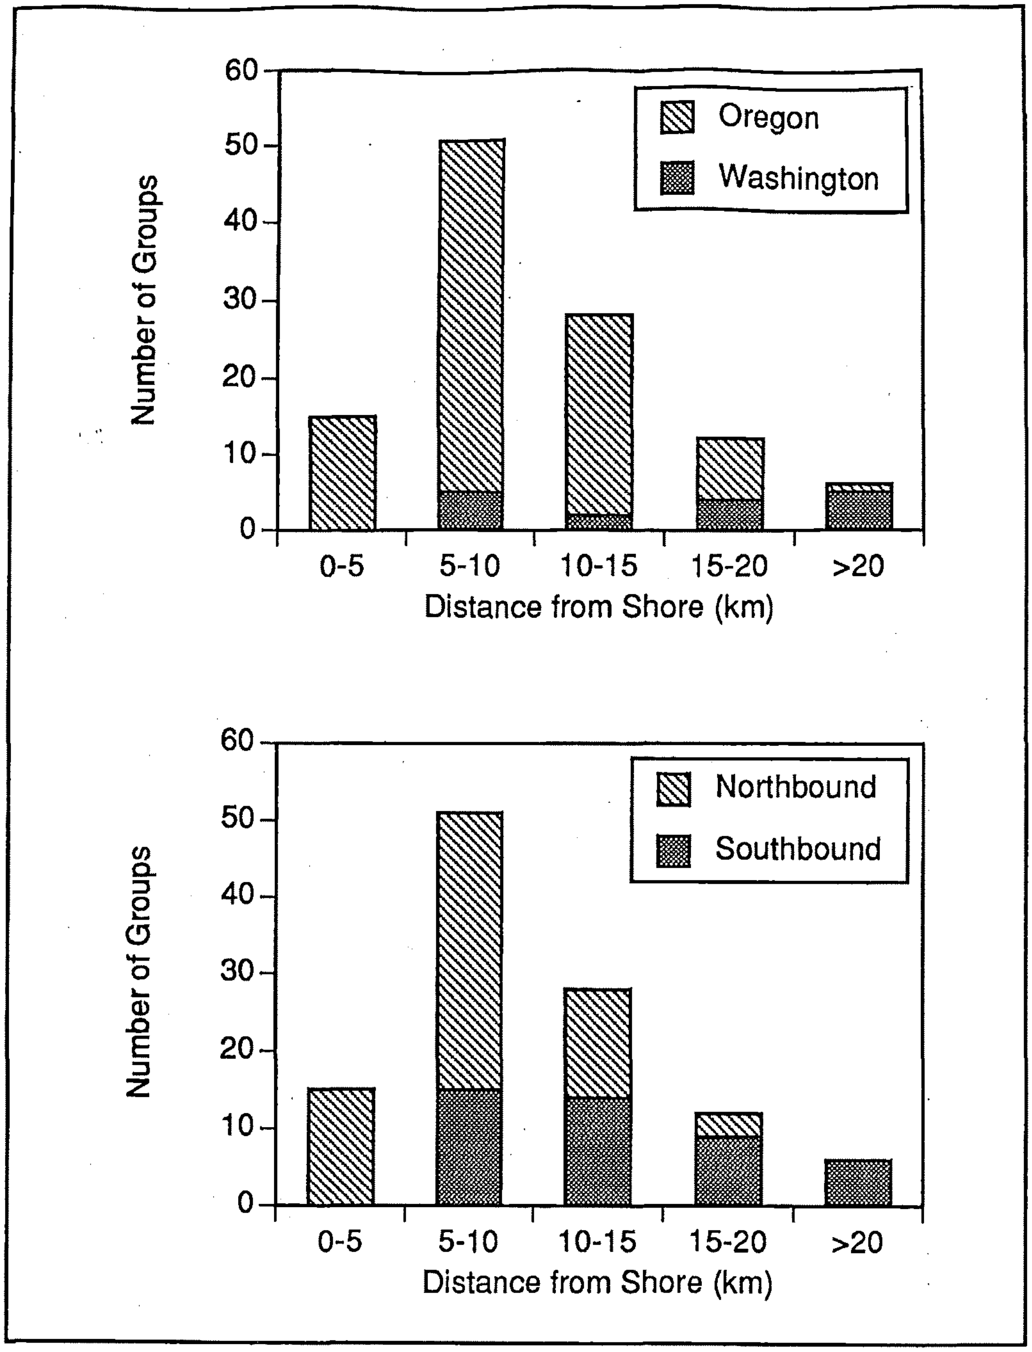

Fig. 5. Distance from shore of migrating gray whales comparing between states and the southbound and first wave of the northbound migrations.

8.0 km (SD = 3.9 km) for the northbound migration. The differences were significant ($t = 4.78$, $p < 0.0001$). The three farthest offshore sightings (>30 km) were southbound migrants (which included a group of three in the act of mating) that appeared to be taking a more direct route from Vancouver Island (a pattern reported by Rice and Wolman [1971] and Poole [1984] elsewhere) by crossing the Juan de Fuca submarine canyon at its most narrow point (a pattern reported by Brueggeman *et al.* [1987] in Alaska). Information reported by Pike (1962), Hatler and Darling (1974), and Hart (1977) suggests that the migration route between Washington and Vancouver Island is variable and wide with some animals crossing the strait to and from Cape Flattery while others follow a more direct offshore route.

Thirteen percent (26) of the sightings occurred during the non-migration period (mid-June to November) indicating a relatively strong presence of gray whales along the Oregon and Washington coasts during the summer and fall. Thirty-one percent of these sightings (over four surveys) were made in the vicinity of Yaquina Head (near Newport, Oregon), which falls within the stretch of Oregon coastline where Sumich (1984) found most of 1,200 sightings of summering gray whales. All our summer sightings, except one, occurred within bays or within 1 km of the coast, which roughly supports Sumich's (1984) observations that gray whales summering in the study area are nearly always within 0.5 km of the coast.

Humpback Whale

The North Pacific humpback whale population was severely depleted in this century by commercial whaling (Starks 1922; Scheffer and Slipp 1948; Pike and MacAskie 1969; Rice 1974, 1978; Tonnessen and Johnsen 1982; Reeves *et al.* 1985; Webb 1988). Approximately 28,000 humpbacks were killed in the North Pacific between 1905 and 1965, including almost 2,000 off Oregon and Washington (Rice 1978). Rice (1978) estimated that an original population of approximately 15,000 animals was reduced to approximately 850 by 1965. Present estimates for the North Pacific population vary between 1,200 and 2,100 (Baker *et al.* 1986, Darling and Morowitz 1986).

Major feeding aggregations of humpback whales occur in Alaska (Rice and Wolman 1982; Darling and Jurasz 1983; Baker *et al.* 1985, 1986; Reeves *et al.* 1985; vonZiegesar and Matkin 1985; Brueggeman *et al.* 1987, 1988) and California (Rice 1977; Calambokidis *et al.* 1988, 1989). Recent photo-identification studies have shown that California feeding aggregations winter off Mexico (Urban *et al.* 1987, Calambokidis *et al.* 1989, Balcomb *et al.* 1990) and most Alaska whales winter around the Hawaiian Islands (Darling and Jurasz 1983; Baker *et al.* 1985, 1986), although some slight interchange occurs between Hawaii and Mexico (Baker *et al.* 1986, Perry *et al.* 1988). DNA research by Baker *et al.* (1990) indicated a marked segregation of mitochondrial DNA halotypes between Alaska and California populations. Prior to this study, it was unknown whether Oregon and Washington humpbacks were associated with the California or Alaska feeding herds.

A total of 36 groups comprising 68 humpback whales was observed off Oregon and Washington between May and November (Table 5). No calves were encountered and the

Migration and Feeding of the Gray Whale (*Eschrichtius gibbosus*)[1]

By Gordon C. Pike

Fisheries Research Board of Canada
Biological Station, Nanaimo, B.C.

ABSTRACT

Observations of gray whales from the coasts of British Columbia, Washington, and Alaska are compared with published accounts in order to re-assess knowledge of migration and feeding of the American herd. Source of material is mainly from lighthouses and lightships.

The American herd of gray whales retains close contact with the shore during migration south of Alaska. Off Washington and British Columbia the northward migration begins in February, ends in May, and is at a peak during the first two weeks in April; the southward migration occurs in December and January, and is at a peak in late December. Northward migrants stop occasionally to rest or feed; southward migrants are travelling faster and appear not to stop to rest or feed during December and January. Gray whales seen off British Columbia, sometimes in inside protected waters, from June through October, probably remain in this area throughout the summer and fall months.

Available evidence suggests that gray whales retain contact with the coast while circumscribing the Gulf of Alaska, enter the Bering Sea through eastern passages of the Aleutian chain, and approach St. Lawrence Island by way of the shallow eastern part of the Bering Sea. Arriving off the coast of St. Lawrence Island in May and June the herd splits with some parts dispersing along the Koryak coast and some parts continuing northward as the ice retreats through Bering Strait. Gray whales feed in the waters of the Chukchi Sea along the Siberian and Alaskan coasts in July, August and September. Advance of the ice through Bering Strait in October initiates the southern migration for most of the herd. In summering areas, in northern latitudes, gray whales feed in shallow waters on benthic and near-benthic organisms, mostly amphipods.

There is no evidence to indicate that gray whales utilize ocean currents or follow the same routes as other baleen whales in their migrations. Visual contact with coastal landmarks appear to aid gray whales in successfully accomplishing the 5000-mile migration between summer feeding grounds in the Bering and Chukchi Seas and winter breeding grounds in Mexico.

Reconstruction of the migration from all available data shows that most of the American herd breeds and calves in January and February, migrates northward in March, April and May, feeds from June through October, and migrates southward in November and December.

INTRODUCTION

The gray whale (*Eschrichtius gibbosus*) is at present found only in the North Pacific Ocean and the adjacent Bering, Chukchi and Okhotsk Seas. It is represented by two herds. An American herd alternates between winter breeding grounds in the lagoons of Mexico and summer feeding grounds in the Bering and Chukchi Seas; an Asian herd alternates between winter breeding grounds along the south and west coasts of Korea and the Okhotsk Sea.

J. Fish. Res. Bd. Canada, **19**(5), 1962.
Printed in Canada.

Gray whales have been seriously reduced by excessive exploitation and, since 1937, their capture has been prohibited by international agreement. Consequently, the species has afforded neither opportunity nor an important practical need for careful biological study in recent years. Knowledge of the gray whale's migrations and distribution, however, are perhaps better known than that of any other stock of baleen whales, because of the species' predilection to shallow coastal waters for calving, migrating and feeding, and because of precision in the timing of its migrations.

This paper deals primarily with migrations of the American herd and secondarily with supplementary considerations of feeding and route-finding. Basic knowledge of the migrations, feeding areas and breeding areas of this herd was first described by Scammon (1874). Following a period of excessive exploitation during the last part of the 1800's the species was thought to be extinct on the American Coast. Its reappearance in recent years has led to renewed interest and several papers describing behaviour, migration, and population growth, have been published since 1954. Accumulated knowledge has not been sufficient to describe the entire migration route with certainty, however, and too few stomachs have been examined to confidently describe feeding habits of the species.

This paper describes observations of gray whales mostly during the northward migration along the coasts of Washington and British Columbia, and during their feeding period in the Bering and Chukchi Seas. These observations provide information which is used, in conjunction with published accounts, to re-assess the extent of knowledge on migration and feeding habits.

SOURCES OF INFORMATION AND ACKNOWLEDGMENTS

Observations are based chiefly upon the returns of log-book sight records from lightships and lighthouses along the coasts of Washington and British Columbia. Among these are included: Umatilla, Columbia River and Swiftsure Lightships; and Kains Island, Cape St. James, Langara, Amphitrite and Cape Beale Lighthouses (Fig. 1). The co-operation of personnel manning these light stations is gratefully acknowledged.

Dr Francis H. Fay, during the course of walrus studies in the vicinity of St. Lawrence Island, has kept notes on all whales observed. His permission to use these records and to examine and report on the stomach contents of two gray whales captured by the natives of this region is gratefully acknowledged. Mr T. H. Butler, Dr D. B. Quayle and Mr and Mrs Cyril J. Berkeley, of the Biological Station in Nanaimo, B.C., kindly identified the contents of these stomach samples.

Records of gray whales sighted by Department of Fisheries personnel, especially those from the C.G.S. *Laurier*, and by Mr W. F. Hausner of the tug *Neptune*, are greatefully acknowledged.

Supplementary observations by biologists and technicians aboard the M.V. *Pacific Ocean*, chartered for pelagic fur seal research from 1958 to 1961, are included.

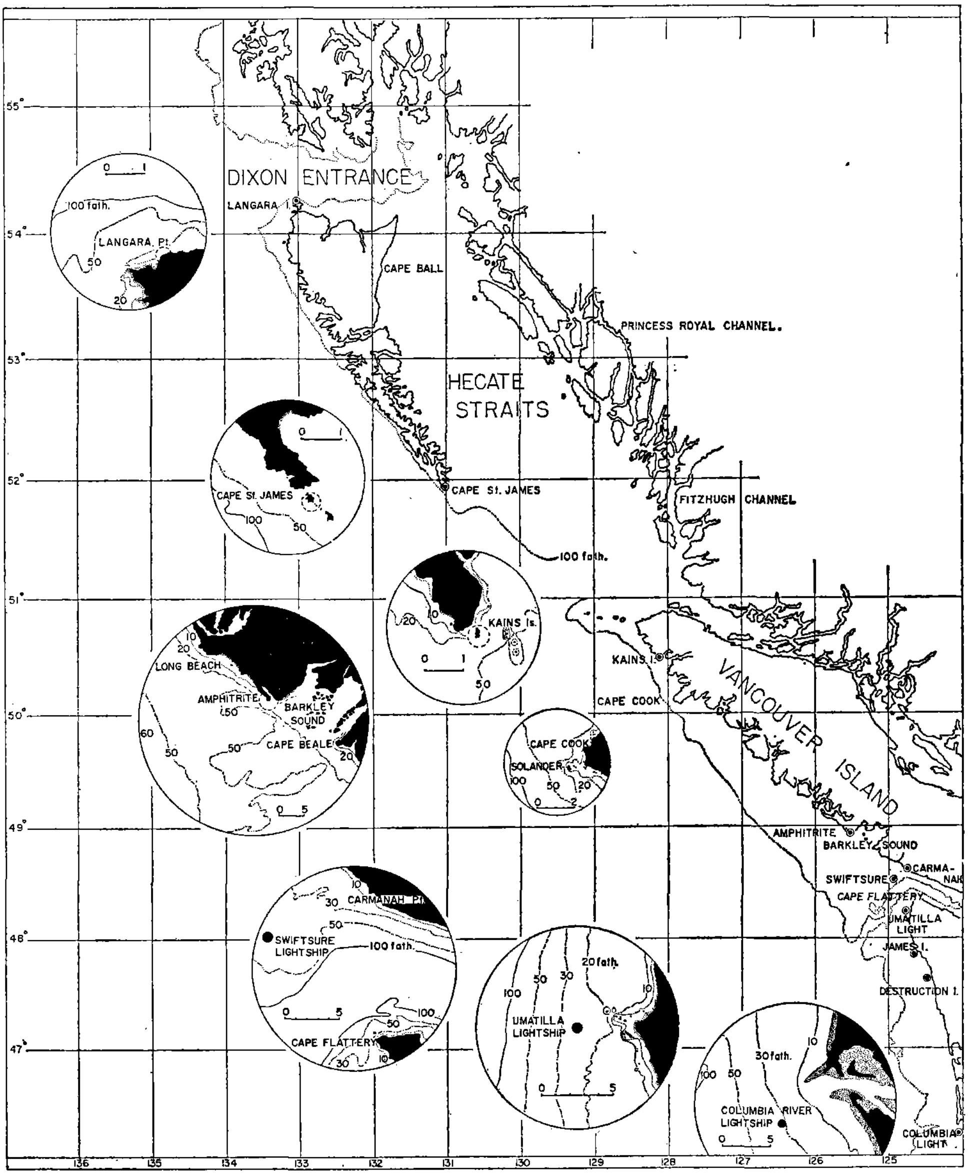

FIG. 1. Locations of gray whale observations along the coasts of Washington and British Columbia.

OBSERVATIONS OFF WASHINGTON

An estimated 500 to 1000 gray whales pass within sight of the Umatilla Lightship on their northward migration each year from March into May. This lightship is located 4½ miles[2] from shore near Latitude 48°10′N. Many whales pass by close to shore where their presence is difficult to detect against the surf breaking along the rocky coast and boiling over Umatilla reef. Many, however, pass by close to the lightship and sometimes remain in the vicinity for periods up to 4 hours. At these times their behaviour is variously described as "playing", "mating", "circling", "rolling" or "feeding". On several occasions the whales occupied their respite in rubbing themselves gainst the anchor chain.

In 1958 gray whales were seen from the Umatilla Lightship almost every day from March 16 to April 11; none was seen in May although sighting conditions were good. In 1959 gray whales were seen from this lightship almost every day from March 15 to May 14; the last northbound whale was seen on May 29. The peak of the migration at this latitude occurs during the first 2 weeks in April and is earlier in some years than in others. Few are seen at other times of the year. Six have been reported in December and 4 in January, mostly travelling southward.

Gray whales are seldom seen from the Columbia River Lightship during the northward migration. More are seen during the southward migration in December and January. Reports for these months include: 2 in late January, 1958; 2 in late January, 1959; 8 in early January, 1960; 5 in late December, 1960; and a school on January 11, 1960. Most northward migrants probably pass shoreward of this vessel which is stationed about 6 miles off. The *Pacific Ocean* encountered many gray whales 5 to 10 miles north of this lightship on March 12, 1958; at least 10 blows could be seen at any one time; all were within 6 miles of shore and most were close to the beach. During this same month, only 2 gray whales were reported from the Columbia River Lightship.

The *Pacific Ocean* conducted fur seal research off the coast of Washington in March, April and May, 1958 to 1960, inclusive. Waters up to 20 miles from shore were hunted intensively. Only once were gray whales seen more than 10 miles from shore; 2 adults and a calf were seen 20 miles off Cape Flattery on March 19, 1959. Gray whales were frequently encountered while the vessel lay at anchor or passed close to shore in transit to and from port; few were seen farther than 6 miles from shore; most appeared to be travelling within a mile of the coast where their presence was difficult to detect against the breaking surf. Important observations of gray whales from this vessel include: many between Gray's Harbor and Destruction Island from April 6 to 22, 1959; 20 to 30, 5 miles off Cape Flattery on March 27, 1958; and 50 between Destruction Island and Cape Flattery on March 27, 1960. While the vessel lay at anchor in shallow water off Raft River, Washington, whales could be heard blowing and splashing throughout the night of April 5–6, 1960.

The *Laurier* estimated 150 gray whales travelling close to shore between Destruction Island and Cape Flattery on April 1, 1958.

---

[2] Distances in this paper are given in nautical miles. 1 nautical mile = 1.855 km; 1 knot = 1 nautical mile per hour.

TABLE I. Observations of gray whales off Washington, 1958–60.

Location and vessel	Date	Remarks
	1958	
5–10 mi north of Columbia River; *Pacific Ocean*	Mar. 12	At least 10 blows seen at any one time; mostly northbound
5 mi off Cape Flattery; *Pacific Ocean*	Mar. 27	20–30 northbound gray whales
Destruction Island to Cape Flattery; *Laurier*	Apr. 1	150; mostly gray whales; close to shore; all northbound
Umatilla Lightship	Mar. 16–Apr. 11	Estimated 500–1000; all northbound; seen almost every day
Umatilla Lightship	May	Visibility good, but no whales seen
Umatilla Lightship	Dec. 10–31	6 whales, thought to be grays, southbound
	1959	
Umatilla Lightship	Jan. 18–19	4 gray whales; southbound
Umatilla Lightship	Mar. 15 29	Gray whales almost every day; all northbound; mostly from March 28 to April 12
Umatilla Lightship	Dec. 16–17	7 or more gray whales; southbound
Umatilla Lightship	Dec. 25–28	5 unidentified whales; probably grays; southbound
Columbia River Lightship	Jan. 21	2 gray whales; southbound
Gray's Harbor to Destruction Island; *Pacific Ocean*	Apr. 6–22	Many northbound gray whales
20 mi off Cape Flattery; *Pacific Ocean*	Mar. 19	3 gray whales: 2 adults, 1 calf
	1960	
Columbia River Lightship	Jan. 1–5	8 southbound gray whales
Columbia River Lightship	Jan. 11	School of southbound gray whales
Columbia River Lightship	June 30	1 southbound gray whale
Columbia River Lightship	Dec. 28–30	2 gray whales circling vessel
Destruction Island to Cape Flattery; *Pacific Ocean*	Mar. 27	50 gray whales en route; some feeding near Destruction Island
Near Destruction Island; *Pacific Ocean*	Apr. 5	Few northbound gray whales travelling both inside and outside Destruction Island
Mouth of Raft River (Lat. 49°20′N); *Pacific Ocean*	Apr. 5–6	Many gray whales blowing throughout night; very active in shallow water

OBSERVATIONS OFF BRITISH COLUMBIA

After leaving the Washington coast at Cape Flattery, gray whales cross the Strait of Juan de Fuca in a general northerly direction before changing course westerly to follow the west coast of Vancouver Island. Gray whales are frequently seen by coastal vessels close to shore between Carmanah Point and Barkley Sound, but few are seen from the Swiftsure Lightship located 8 miles off the coast.

Off Cape Beale, which is located at the lower entrance to Barkley Sound, gray whales sometimes stop to play or feed during the northward migration in March and April. After rounding Cape Beale some may enter the Sound for a short distance and have been seen rubbing themselves against the rocks along Folger Island. Most of the herd proceeds directly across the 15-mile mouth of the Sound towards Amphitrite Point, following closely along the outer edges of a group of rocks lying part way across; a few enter narrow channels between these rocks. Most of the northward migrating whales pass Amphitrite Point shoreward of a buoy which lies about 1 mile off the light. Some have been seen rubbing themselves against the lines which moor this buoy.

The lightkeeper at Amphitrite Point, former whaler, reports that almost 1000 gray whales pass northward within sight of the lighthouse each spring, mostly in March and April, but in some years beginning in February and in other years ending in May. He has never seen them travelling southward.

During the course of fur seal hunting in 1958, gray whales were seen at the mouth of Barkley Sound and along Long Beach almost every day from March 14 to April 30. Some were seen moving back and forth along Long Beach as though feeding and some were seen rubbing themselves against Long Beach Rocks and Florencia Island, both of which lie about 1½ miles off the sandy beach. No gray whales are seen more than 2 miles from shore in this locality although fishing activity and ship traffic are fairly heavy during the migratory period.

Whalers from the Coal Harbour whaling station, while passing in and out of Quatsino Sound, report that gray whales are seen following closely along the shoreline but are never encountered on the whaling grounds which extend from 10 to 100 miles offshore. While rounding Cape Cook, gray whales pass inside Solander Island, a rock located 1 mile off Cape Cook.

When crossing the mouth of Quatsino Sound, some gray whales enter the Sound for a short distance before regaining the shore near Kains Island Light. Northbound gray whales pass this lighthouse mostly during the second and third week in April at which time approximately 5 per day are seen, travelling close to shore at a rate of about 4 knots.

The scarcity of sightings of gray whales on the southward run along the west coast of Vancouver Island in winter is chiefly a result of poor weather which discourages coastwise shipping and makes observation difficult. Only three noteworthy reports of southward migrants along this coast have yet appeared. A whaling captain, Mr Einar Jensen, reports a school of gray whales travelling southward off Long Beach in January, 1953. Another whaling captain, Mr Harold Sampson, saw gray whales travelling southward off the west coast of Vancouver Island, December 15 to 20, 1955. Eighty gray whales, all travelling southward, were sighted from the Kains Island Lighthouse during a period of exceptionally good weather from December 15 to January 4, 1955–56. Up to 21 whales per day were seen on and near December 17. Some of these whales entered the Sound for a short distance or tarried briefly near the rocks.

The route taken by gray whales on leaving the north end of Vancouver Island is not known. The few observations available suggest that the whales may become temporarily confused in crossing this broad 120-mile stretch of water between Vancouver Island and the Queen Charlotte Islands. On April 7, 1958, 8 gray whales were sighted from the *Pacific Ocean* 10 miles east of the Cape St. James Light. Two gray whales were sighted from the *Laurier* 5 miles east of Cape Ball in northern Hecate Strait on April 23, 1958. The outer coast of Cape St. James is largely obscured from view from the lighthouse. Consequently, few gray whales are seen from this station. The few which have been sighted at the time of the northward migration in April appeared to be travelling southward along the Hecate Strait shoreline to re-enter the Pacific by way of a narrow channel which isolates the island on which the lighthouse is located.

Few gray whales are seen along the uninhabited west coast of the Queen Charlotte Islands during the northward migration. Some are seen from the Langara Island Lighthouse which is located near the northwest tip of the Islands. This lighthouse is, however, poorly located for observing gray whales, which may pass some distance offshore in commencing the crossing of Dixon Entrance. More are seen at times other than spring months, suggesting that some gray whales may linger in the vicinity of Langara Island throughout the summer and fall feeding season. Southbound gray whales are seen here from September through January, but mostly in December. During summer and fall months, the direction of travel is variable.

Two reports by reliable observers show that gray whales occasionally enter inland passages in British Columbia during summer months. The *Laurier* reports one gray whale in Princess Royal Sound on August 1, 1958, and one in Fitz Hugh Sound on August 2, 1958.

No gray whales are reported by research vessels operating offshore of Vancouver Island and the Queen Charlotte Islands and westward into the Gulf of Alaska, suggesting that the whales continue to hug the coast closely except when crossing major waterways such as Dixon Entrance and Queen Charlotte Sound.

TABLE II. Observations of gray whales off British Columbia, 1958–60.

Location and vessel	Date	Remarks
	1957	
Langara Light	Dec. 20–28	Several whales near shore, probably grays

(Table II continued)

Location and vessel	Date	Remarks
	1958	
Langara Light	Feb. 2–30	Several southbound gray whales
Langara Light	Mar. 25–30	10 northbound gray whales and several more blows; mostly April 20–26
Langara Light	June 18, Aug. 20, Sep. 4	3 eastbound gray whales
Langara Light	October	Several gray whales travelling in various directions
Langara Light	Nov. 24	8 blows near shore; 1 gray whale breached
Langara Light	Dec. 2–Jan. 18/59	50+ southbound gray whales
Kains Island Light	Mar. 11–Apr. 12	150+northbound whales; mostly grays
Cape St. James Light	Apr. 12–25	12 gray whales
10 mi east of Cape St. James; *Pacific Ocean*	Apr. 7	8 westbound gray whales
5 mi east of Cape Ball; *Laurier*	Apr. 23	2 gray whales
Princess Royal and Fitz Hugh Sounds	Aug. 1–2	2 gray whales
Off Barkley Sound and Long Beach; *Hillier Queen*	Mar. 14–Apr. 30	Northbound gray whales seen almost every day; mostly April 10–12
2 mi off Pachena Point; *Pacific Ocean*	Mar. 20	10 northbound gray whales
1–2 mi off Amphitrite Point; *Howay*	Apr. 11	12 gray whales feeding
Swiftsure Lightship	Apr. 4–12	28 northbound whales; probably grays
	1959	
Langara Light	May 18	3 eastbound gray whales
Langara Light	Sep. 9	6 southbound gray whales
Langara Light	October, November, December	Many southbound whales, mostly grays; in groups of 4–6
Sydney Inlet; *Pacific Ocean*	June 2	2 gray whales near mouth of inlet
Dixon Entrance	June 20	2 eastbound gray whales
Kains Island Light	Mar. 2–Apr. 1	27 northbound whales, probably grays
Swiftsure Lightship	Apr. 23	3 gray whales
	1960	
Estevan Point to Cape Cook; *Laurier*	Mar. 10–20 Apr. 26	10 gray whales 4 gray whales
Off Long Beach; coastal vessels	Mar. 15–30	Many gray whales
Off Cape Beale; *Atlin Post*	Apr. 3	12 northbound gray whales
Langara Light	Aug. 31	Several gray whales going northwest
Langara Light	September	Many gray whales seen
Langara Light	Sep. 10	6 southbound gray whales; 1 being attacked by killer whales
Langara Light	December	Many southbound gray whales
Langara Light	Jan. 3	Several southbound gray whales

OBSERVATIONS OFF ALASKA

Dr F. H. Fay (personal communication) has kindly supplied the following information on gray whales he has observed in the vicinity of St. Lawrence Island, Alaska. Gray whales, sometimes singly and sometimes in pairs consisting of a mother and a calf, were seen travelling and feeding close to the western shores of St. Lawrence Island from May 11 through July, 1952, from June 4 to July 26, 1953, and from May 11 to June 19, 1954. More recent records from Gambell on the west coast of St. Lawrence Island show that gray whales usually arrive in this area about the middle of May. Dr Fay records the following early arrivals at Gambell: May 17, 1956; May 18, 1957; May 11, 1958; May 20, 1959; and May 21, 1961. Most are seen near the beginning of June but some remain as late as November. Dr Fay records one seen near Northeast Cape, on the west coast, on November 14, 1957, a stranded carcass at Northeast Cape about October 24, 1959, and a fresh stranded carcass near Gambell about October 24, 1959. Most, but not all, gray whales pass along the western shore of St. Lawrence Island on the northward migration; some split off from the main herd and pass northward along the eastern shores of the Island.

Reports from the tug *Neptune* describe whales sighted while running between St. Lawrence Island and Point Barrow in 1958 and 1959. In July, 1959, a school of gray whales followed the vessel into a lagoon located south of Northeast Cape on St. Lawrence Island. During the last two weeks in July, 1958, 8 to 10 whales could be seen blowing at any one time in waters of 8 to 22 fathoms between the Diomedes Islands and St. Lawrence Island. Farther north, in waters of 10 to 20 fathoms, many gray whales were seen feeding 8 to 15 miles from shore between Cape Prince of Wales and Icy Cape. At this time in July, 1958, many unidentified whales were seen from an aircraft flying between St. Lawrence Island and Nome. In August, 1958, a gray whale was observed feeding in water 5 fathoms deep north of Cape Prince of Wales. As this whale surfaced close to the vessel, mud was seen washing from its back.

Mr Karl Kenyon (personal communication) reports that he saw no gray whales while he was hunting walrus at Little Diomede Island in the Bering Straits from May 11 to June 14, 1958. He reports also that he saw no gray whales from Amchitka, located near the western end of the Aleutian Chain, during a year's stay on this island.

A specimen of baleen from a gray whale was taken from the beach on St. Matthew Island on August 4, 1954 (courtesy of Dr Robert Rausch). Gray whales have not previously been recorded from this locality.

MIGRATION ROUTE

The route followed by gray whales in migration between winter breeding and calving grounds in and about the lagoons of Mexico and feeding grounds in the Bering and Chukchi Seas has been the subject of much recent controversy mainly because of insufficient data. Original observations of gray whales off Washington, British Columbia and Alaska presented in this paper are combined, by areas, with selected published records of gray whales from the west coast of North America in the following summary which attemps to define the route and timing of the migration.

MEXICO

Gray whales are concentrated for breeding and calving in coastal areas from San Diego to Cabo San Lucas and the southern end of the Gulf of California, mostly from early January to the end of February; a few stragglers have been seen offshore in the region of Guadalupe and Clarion Islands; some are still present along the Mexico coast in March and April (Gilmore, 1960b). At Magdelena Bay the height of the southward migration is January 22, but early whale catches were made from January 4 to February 16 (Risting, 1928).

CALIFORNIA AND OREGON

The northward spring migration past San Diego begins in mid-February, is at a peak in March and April, and tapers off in early May (Gilmore, 1960b). Five gray whales, one of which was captured, were seen near Crescent City on July 21, 1926 (Howell and Huey, 1930).

Southward migrants arrive along the coast of Oregon and northern California in October and November (Scammon, 1874). Twelve to 15 were seen off southern Oregon in September, 1947 (Gilmore, 1960b).

The southward migration past San Diego occurs from December 25 to February 10, with stragglers passing 3 weeks earlier or later; late southbound migrants overlap early northbound migrants in late February (Gilmore, 1960a).

WASHINGTON AND BRITISH COLUMBIA

The northward spring migration in this locality begins usually in March, is at a peak from mid-March to mid-April, and ends in May.

Stragglers are occasionally seen at various coastal points from the Columbia River mouth to Dixon Entrance and in protected waters of British Columbia during the summer months.

Gray whales are occasionally seen near Dixon Entrance travelling in various directions during fall months; some of these are probably early southward migrants but most appear to linger here throughout the summer and fall.

During periods of good weather in winter many southward migrants pass close to shore in December and January, mostly in late December.

SOUTHEAST ALASKA AND KODIAK ISLAND

There are few records of gray whales from the Gulf of Alaska. One was taken by whalers operating from Baranov Island in southeast Alaska, 3 were taken by whalers off Kodiak, 2 of them in May, 1928 (Gilmore, 1960a). Eight were seen travelling westward along the south coast of Kodiak Island on May 11, 1957 (Wilke and Fiscus, 1961).

ALEUTIAN ISLANDS

No gray whales are seen by Japanese whalers operating north and south of the Aleutian Islands in spring and summer (Ichihara, 1958). The whaling station located at Akutan on Unimak Island recorded no gray whales taken (Kellogg, 1931). A dozen or so were seen passing through Unimak Pass in early June (Turner, 1886) and one was seen in the northern part of Unimak Pass on May 29, 1957 (Ichihara, 1958). No gray whales pass Amchitka in the western Aleutians (Mr Karl Kenyon, personal communication).

Bering Sea from Alaska Peninsula to St. Lawrence Island

There are no sight records of gray whales from this region although whalers are active in offshore waters north of the Aleutian Islands throughout late spring, summer, and early fall months. Only once, in July, 1958, have gray whales been seen from the Pribilof Islands (Gilmore, 1960a).

St. Lawrence Island to Bering Strait

Gray whales are well known to residents of St. Lawrence Island where they first appear each year in May (Dr F. H. Fay, personal communication).

Several recent reports show that gray whales, travelling and feeding, are abundant in this area during the summer months. One hundred seventy-two were counted off the northwest coast of the Island on August 2, 1955 (Ichihara, 1958). A school entered a lagoon on the east coast of the Island in July, 1959 (p. 823). Approximately 150 were seen off the east coast of the Island and a scattered few northward to Bering Strait in August, 1958 (Nasu, 1960). Many whales, possibly grays, were seen between the Island and Nome in late July, 1958 (p. 823).

Some gray whales are still found in Bering Strait in October (Nikulin, 1946). Strandings on St. Lawrence Island, mostly along the east coast, occur during fall months as late as November.

Chukchi Sea

The Chukchi Sea is closed by ice throughout the spring months and does not open until late June and early July (Maher, 1960). Gray whales are abundant near the arctic Alaska coast during summer months. Many (200+) were seen feeding in Kotzebue Sound on August 10 to 20, 1959, and 20 were seen scattered and moving southward north of Cape Prince of Wales on August 24, 1959 (Wilke and Fiscus, 1961). Eskimos see gray whales migrating northward past Cape Thompson during the first half of July each year (Fay, MS, 1961a). Many whales, some of which were definitely grays, were seen feeding off Kotzebue Sound in July, 1958 (p. 823).

Maher (1961) provides the following information: 9 gray whales were taken by Eskimos between Wainright and Point Barrow from July 18 to September 13, 1954 to 1959; 50 to 100, travelling southward, were seen from the beach at Wainwright on August 9 to 10, 1953; a few were seen passing Cape Sabine on August 3 to 5, 1959; gray whales are scarce at Point Barrow; gray whales are present near Point Barrow until mid-September, but some may begin moving southward in early August.

Gray whales are also abundant near the northern Siberian coast during early summer until ice restricts their movements. Seventy-eight were seen from a Japanese oceanographic vessel off the Siberian coast on July 27, 1958 (Nasu, 1960). Fifty-eight were taken by Japanese whalers off the Siberian coast in August, 1940 (Mizue, 1951).

KORYAK COAST

Gray whales arrive off this coast in May and early June; they no longer range southward to Kamchatka (Sleptsov, 1955). Thirty-one gray whales were taken by the "Vega" expedition between Cape Olyutorskii and Cape Navarin from July 27 to August 19, 1925 (Risting, 1928). A few were seen off the Gulf of Anadyr in August, 1958 (Nasu, 1960).

Two major gaps remain in our knowledge of the route followed by this population of gray whales. Knowledge of the route between British Columbia and feeding grounds in the Bering Sea during both northward and southward migrations remains speculative. Available evidence as to the most probable route taken will be discussed later.

Northward migrants pass San Diego from February (when others are still moving southward) into May, but mostly in March and April. The literature contains no information on the exact dates during which peak numbers pass by this point going north. Near Cape Flattery, some 1200 miles north, peak numbers pass during the first two weeks in April. The peak of the northward migration past San Diego is, therefore, probably within the first two weeks of March, assuming a rate of travel of 35 to 50 miles per day or 1.5 to 2.0 knots. From San Diego the whales appear to head directly across the Santa Catalina bight and are several miles from shore when passing La Jolla (Gilmore, 1960b). Farther north they travel close to shore, skirting headlands and usually cutting directly across the mouths of large bays.

The re-appearance of gray whales on the southward run off San Diego begins in early December and ends in late February; most whales pass during the middle two weeks in January (Gilmore, 1960b), at which time they are travelling in a narrow stream, little more than a mile wide, at an average rate of 4.6 knots, and seem to converge on the kelp beds off La Jolla (Wyrick, 1954). Similarly, at San Simeon, located on a coastal bight, pregnant females appear closer to shore during the "down" season as they seek bays and lagoons to bring forth their young (Townsend, 1886). Scammon (1874) states that they appear off the coast of Oregon and northern California during October and November and that both males and females keep near to shore during the southward passage. Observations off northern British Columbia show that, although gray whales appear during the fall months, the main herd of southward migrants does not pass until December and January, with maximum numbers passing in December. Off the north end of Vancouver Island they pass in greatest numbers near the end of December and off Washington in early January. The southward run from British Columbia to San Diego appears to take from 2 to 4 weeks at an average rate of about 50 to 100 miles per day or 2 to 4 knots.

The southward migrants proceeding towards the breeding grounds are more concentrated, pass by over a shorter period of time, and travel at a faster rate, than the northward migrants proceeding towards the feeding grounds (Fig. 2).

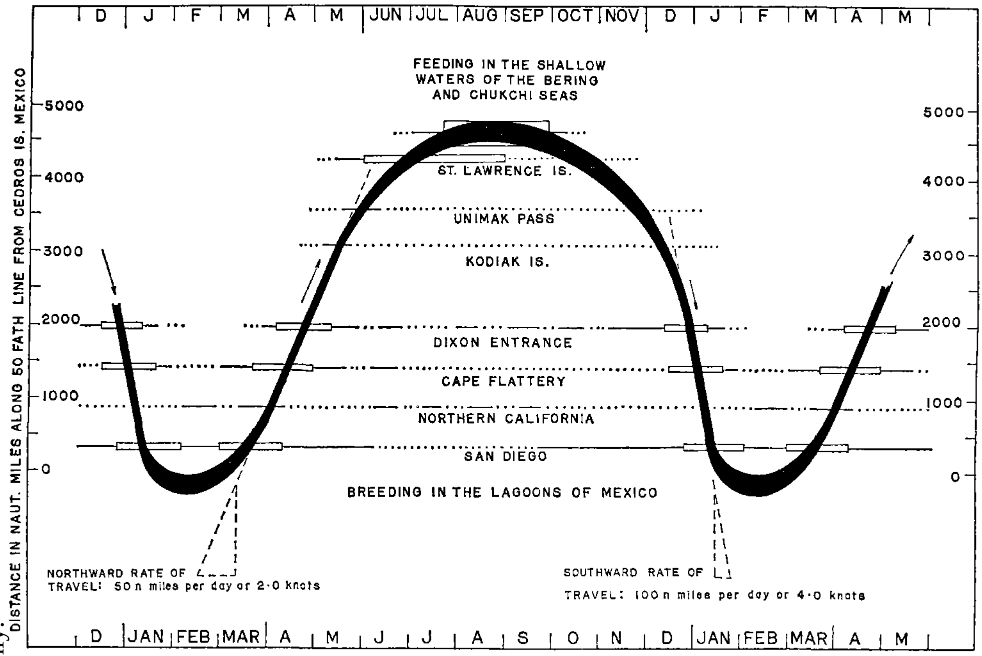

FIG. 2. Diagram summarizing the seasonal distribution of the American herd of gray whales. Relative abundance is indicated horizontally across the graph as follows: *open rectangles*—numerous; *solid line*—few records; *dotted line*—probable occurrence.

The route from Dixon Entrance to the Bering Sea is unknown except for a few observations of westbound whales from the south coast of Kodiak Island in May (Wilke and Fiscus, 1961) and north of Unimak Pass in late May and early June (Ichihara, 1958; Turner, 1886). None have been reported by oceanographic and fisheries research vessels operating offshore in the Gulf of Alaska and none have been reported by Japanese whalers operating north and south of the Aleutian Islands. The *Baikal Maru* operated from 48° to 54°N and 159° to 173°W from May 20 to October 3, 1953, and saw no gray whales (Sakiura and Ozaki, 1953). We consider that this evidence, although negative, is important in showing that gray whales do not cross the Gulf of Alaska on leaving British Columbia, but continue to follow the coastline northward and westward towards Unimak Pass. The coastal route is approximately 200 miles greater than a direct route across the Gulf, and would, therefore, not greatly prolong the journey.

Japanese whalers operating in the Bering Sea concentrate their hunting in areas which lie to the west of a line joining Unimak Pass and St. Lawrence Island, in waters outside the 50-metre contour (Fig. 3). Whaling is conducted from June to September, but no gray whales are seen. Gray whales have only once been reported from the Pribilof Islands, which also lie to the west of this line. Fiscus saw 3 or 4 gray whales off St. Paul Island on July 2, 1958 (Gilmore, 1960a). Gray whales have never been reported from the Aleutian Islands west of Unimak Pass. We consider that this evidence strongly favours a route which crosses the Bering Sea in its eastern part over the Alaskan continental shelf rather than in the western part as suggested by Gilmore (1955, 1960a, 1960b) At St. Lawrence Island gray whales first appear off the east coast in May, following the retreat of the pack ice. Whaling statistics show that they appear along the Koryak coast first in July (Risting, 1928) although the area is ice-free in June. The earlier arrival of gray whales off St. Lawrence Island suggests that the route followed is by way of the eastern rather than the western Bering Sea.

Fay (MS, 1961a), records 13 strandings of gray whales on St. Lawrence Island, where the species is occasionally hunted by the Eskimos, from 1955 to 1959. Most of these occurred in July and August; the latest stranding was in October. About two-thirds of the stranded whales were young animals less than 30 feet (9.2 m) in length, and 2 had been injured by killer whales. Three gray whales, each carrying crude harpoons of a type used by the natives of Cape Chaplin, stranded on St. Lawrence Island in September, 1961.

Three strandings on the Alaska mainland in 1959 are recorded by Fay (MS, 1961a). One stranded on September 4 at Scammon Bay, south of Norton Sound, where Eskimos report the species to be rare. Two stranded in August near Cape Thompson, 125 miles northwest of Kotzebue, where Eskimos report gray whales migrating northward during the first half of July each year.

A map showing the distribution of the American herd of gray whales is presented in Fig. 3. Arrows indicating the route past St. Lawrence Island represent probable routes taken by the main herd. Some whales pass northward along the east coast of the Island and, no doubt, some also pass southward along the west side.

The northward migration in June and July is impeded by the retreating pack ice which, in most years, provides a lead past the west coast of St. Lawrence Island in early June and through Bering Strait in July. Maher (1960) shows the approximate mean limits of the pack ice at about 300 miles north of Bering Straits in the Chukchi Sea in August and September. Ice re-appears in the Gulf of Anadyr and closes Bering Strait in October. It then moves rapidly southward until December when it completely closes the northern part of the Bering Sea from Cape Navarin to Nunivak Island.

Leads past St. Lawrence Island are closed in December or January. Assuming a rate of travel of 50 to 100 miles per day (2 to 4 knots) gray whales would cover the 2000-mile distance between St. Lawrence Island and Dixon Entrance via Unimak Pass in 3 to 6 weeks. Most gray whales pass northern British Columbia in December, which suggests, on the basis of the foregoing assumptions, that most of the herd leaves the Bering Sea early in November. A few southward migrants (which had probably left the Bering Sea in September and October) are seen off northern British Columbia in October and November.

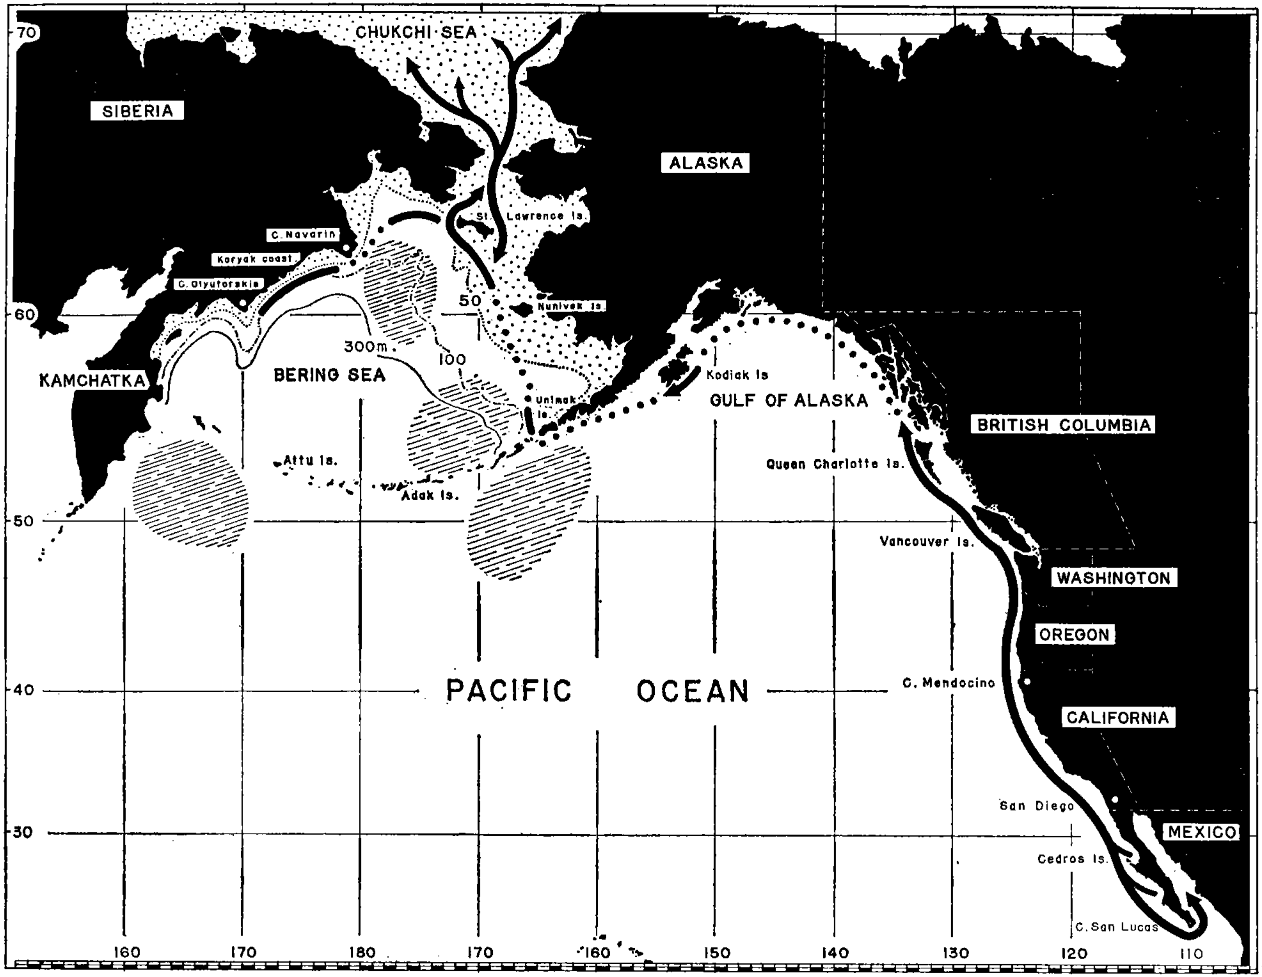

FIG. 3. Map showing the distribution of the American herd of gray whales. Solid lines: known routes; broken lines: probable routes; hatched areas: commercial whaling areas where gray whales are not seen.

TABLE III. Distances from Cedros Island, Mexico, along the migration route of gray whales.

Location	Distance in nautical miles	
	Point to point	Cumulative
Cedros Island	0	. . .
San Diego	300	300
Point Conception	240	540
Cape Mendocino	420	960
Cape Flattery	500	1460
Cape Scott	200	1660
Cape St. James	120	1780
Langara Island	180	1960
Unimak Pass	1600[a] (coastal)	3560
St. Lawrence Island	700[b] (direct)	4260
Koryak Coast, Siberian Coast or Point Barrow	400–600	4660–4860

[a]Direct distance across the Gulf of Alaska is approximately 1400 miles.

[b]Approximate distance along Aleutian Islands to St. Lawrence Island is 2000 miles via Attu and 1400 miles via Adak.

FEEDING

A sample from the stomach contents of 2 small gray whales taken near Gambell, west coast of St. Lawrence Island, were as follows:

(1) Taken June 9, 1954; sample size about 200 cc
Amphipods: several *Ampelisca macrocephala*; one *Anonyx nugax*
Polychaetes: several tubes of *Pectinaria* (sp.)
Gastropods: one moon-snail, family Photidae
Other: some sand and silt

(2) Taken May 29, 1958; sample size about 1 litre
Amphipods: about 90%; mostly *Ampelisca eschrichti*, few *Anonyx nugax*
Ascidians: remains of 2 compound, branched and globular ascidians
Decapods: 2 intact spider crabs, *Chionoecetes bairdi* and *Hyas coarctatus*
Lamellibranchs: remains of 3 small bivalves; one 7-mm shell of *Liocyma*, probably *L. fluctuosa*
Polychaetes: 2 pieces of shells from *Pectinaria*
Cumacea: remains of 1 unidentified specimen
Gastropods: a 9-mm shell of *Volutina*; part of an operculum
Other: some sand and a few bits of wood

Tomilin (1954) earlier described gray whales in arctic regions as feeding upon near-benthic amphipods and true benthic organisms, including polychaetes, hydroid polyps, the mollusc *Buccinum*, and others, in some cases mixed with tiny pebbles and silt.

Feeding behaviour of gray whales in shallow waters has been described by several authors. Scammon (1874) describes gray whales surfacing with head and lips besmeared with mud from soft bottoms. Wilke and Fiscus (1961) describe gray whales feeding in August in the Chukchi Sea, in waters of about 24 fathoms, making muddy blotches in the water as they surfaced, apparently having expelled the mud through the baleen. Tomilin (1954) describes the baleen plates of the gray whale according to the animal's ability to dig up and probably even plough up the silty benthic ground. Reports of the tug *Neptune* describe gray whales surfacing with mud washing from their backs as they fed in water 5 fathoms (9 m) deep north of Cape Prince of Wales in August. Seabirds have been seen following feeding gray whales and settling into the muddy spots where the whales had surfaced (Wilke and Fiscus, 1961).

Fay (MS, 1961a) describes the waters about St. Lawrence Island as an important summer feeding ground. Here gray whales feed usually in waters of 15 fathoms (27 m) or less and within 300 yards (270 m) of shore, creating muddy patches in the water as they surface. Photographs taken by Dr Fay show them feeding in the surf within 50 feet (15 m) of the beach (Fig. 4).

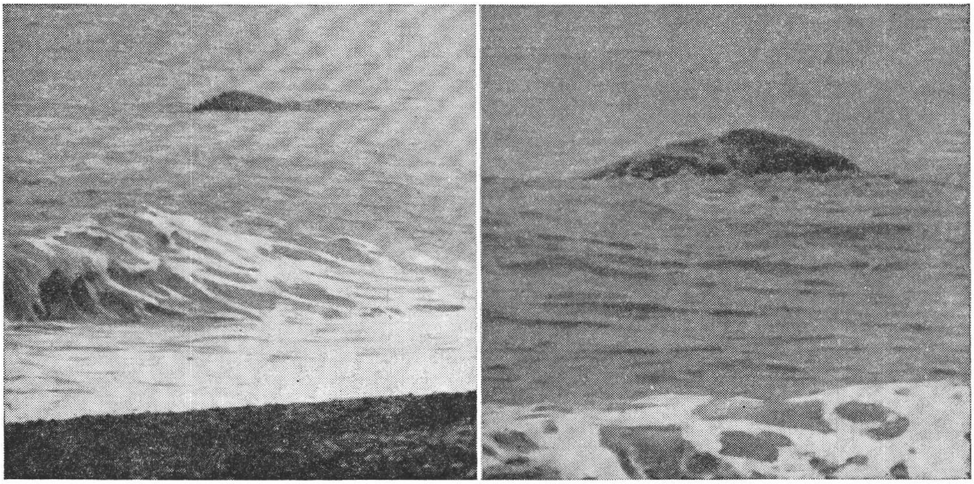

FIG. 4. Gray whales feeding close to shore off St. Lawrence Island, Alaska. (Photo by Dr F. H. Fay.)

Outside its arctic habitat, gray whales appear to feed little (Andrews, 1914; Townsend, 1886; Scammon, 1874). Scammon (1874) observed that stomachs of gray whales caught in the breeding lagoons were usually empty although some contained "sedge" or "sea-moss". He also describes mussels found in the mouths and among the baleen, but does not state the locality in which this occurred. Matthews (1932) describes sei, humpback and gray whales feeding on schools of the anomuran decapod *Pleuronocodes planipes* in Magdelena Bay, in 1926. Dr Carl L. Hubbs (personal communication) relates local testimony that "several barrels of sardines" were found in the stomach of a gray whale stranded near the north end of San Ignacio Lagoon in Mexico. Mizue (1951) reports that the anomuran decapod *Nephrops thomsoni* was found in the stomachs of 2 gray whales caught in the northern waters of the Yellow Sea in May 1922.

Two reports suggest that gray whales injest plant material incidentally during bottom forages while on migration. Andrews (1914) examined a number of stomachs of gray whales during the southward migration off North Korea and found only dark green water with bits of kelp, seaweed and a light gelatinous material he thought might be jelly-fish. The present author examined the stomachs of 10 gray whales taken under special permit by whale catchers off the west coast of Vancouver Island, near the mouth of Quatsino Sound, in April, 1953, during the northward migration. These stomachs contained a green liquid within which was suspended bits of plant material; the intestines contained variable quantities of thick mucous coloured from a dark cream to a yellow-green. Although these stomachs contained no animal material, the cream-coloured intestinal contents suggest animal material in an advanced stage of digestion and that the whales had probably been feeding. Mizue (1951) reports only green-coloured gastric juice in the stomachs of gray whales taken during the southward migration off Korea.

Observations off Washington and British Columbia during the northward migration in March and April show that gray whales occasionally tarry to feed en route. Behaviour which is described as feeding has been reported from several localities along the coast of Washington and Vancouver Island, but mostly from the Umatilla Lightship and along Long Beach. The depth of water at Umatilla is 20 to 25 fathoms (37–46 m) over a sandy bottom; the depth where whales feed along Long Beach is 5 to 10 fathoms (9–18 m) over a sandy bottom. The overall rate of progress north of San Diego appears to be slower during the northward run, probably as a result of frequent interruptions in the migration as the whales slow down or stop for the purpose of resting or feeding.

Dr Carl L. Hubbs (personal communication) cites instances of gray whales near La Jolla stopping sometimes for more than an hour, circling tightly, and otherwise behaving as though feeding, while most whales carry on without hestitation; in one specific instance gray whales behaved in this manner on the occasion of the spawning of squid off La Jolla, on January 21, 1954.

Howell and Huey (1930) report that a male gray whale, 39 feet or 11.9 m long, in company with 4 others, was taken by whale catchers off northern California in July, 1926. This whale had within its mouth and among its baleen a quantity of *Euphausia pacifica*.

DISCUSSION

Original observations described in this paper, when combined with recent publications on the species, show that gray whales follow the coastline closely when migrating between the breeding lagoons of Mexico and the northern part of British Columbia, and that they stop on occasion to rest and to feed. The northward migration is more protracted in time, proceeding at a slower rate than the southward migration. Information on the migration route north of British Columbia is scanty. Lack of offshore sightings in the Gulf of Alaska, combined with a few sightings along the coast, however, suggest that northward migrants continue to hug the coastline while circumscribing this area. Similar evidence along the Aleutian Chain and in the Bering Sea suggests that during the northward run, gray whales pass through Unimak Pass and/or Isanotski Strait and proceed directly towards the west coast of St. Lawrence Island. Off the west coast of St. Lawrence Island gray whales begin to disperse as they search for food. Some disperse westwards to feed off the Koryak coast and the Gulf of Anadyr; some proceed northward past St. Lawrence Island following the retreat of the ice through Bering Strait in July. The migration route splits again north of Bering Strait with some whales following the Siberian coast in a northwesterly direction and some continuing northward across the mouth of Kotzebue Sound to follow the Alaska coast northwesterly towards Point Barrow.

Open ice-free water permits feeding in the Chukchi Sea during July, August and September. From August to September, with the encroachment of ice through Bering Strait, gray whales proceed southward usually, past the east coast of St. Lawrence Island. They are next seen, travelling close to shore, along the coast of British Columbia, mostly in December and January. Some, probably those which fail to complete the migration to its limits in the Bering and Chukchi Seas, are present along the northern British Columbia coast as early as September, others spend the summer between northern California and southeastern Alaska.

The scarcity of reports of gray whales from whalers and from research vessels operating in oceanic regions off British Columbia, in the Gulf of Alaska, north and south of the Aleutian Islands, off Kamchatka, and over deep waters of the central and western parts of the Bering Sea is, in my opinion, convincing evidence that gray whales avoid these areas during migration and feeding. The absence of reports of gray whales in coastal regions such as Unimak Pass and the southeastern coast of Alaska, however, is not convincing evidence that gray whales avoid these localities. Experience has shown that gray whales travelling close to shore are difficult to see against the breaking surf by vessels which must keep well off shore along treacherous storm-lashed and rock-strewn coasts.

Existing knowledge of ocean currents and of whale migrations fails to support the theory (Gilmore, 1955, 1960a, 1960b) that gray whales follow ocean currents. Previous attempts to relate oceanic migrations of other whale species to ocean currents have been unsuccessful (Harmer, 1931; Townsend, 1935; Dawbin, 1956). With few exceptions, gray whales, wherever observed, have been travelling close to shore where large oceanic water masses lose their identity under the influence of topographical irregularities in the coastline, freshwater run-off, and climatic aberrations caused by proximity to land. One of several inconsistencies in Gimore's theory that gray whales are assisted in their migration by ocean currents is that the coastal Davidson Current flows northward along the North American coast to at least 48°N Latitude in November, December and January (Sverdrup *et al.*, 1946) at a time when migrating gray whales are travelling southward. Another inconsistency is that there is no appreciable surface current northward of the Strait of Juan de Fuca to Dixon Entrance in summer (Favorite, 1961) as gray whales migrate northward. The effects of local run-off, which can be traced several hundred miles offshore along the coasts of British Columbia and Washington (Favorite, 1961), show no evidence of deflecting gray whales in their migration.

In seeking environmental conditions associated with the distribution of gray whales, it would be more appropriate to consider the coastal climate and topography rather than the oceanic climate. A continuous temperate faunistic province stretches along the west coast of North America from the middle of lower California, along the coastal arch to the Aleutian Islands, and continues uninterrupted in the eastern Bering Sea as far north as the Bering Strait (Ekman, 1953). The Aleutian Trench and the basin of the western Bering Sea constitute faunistic barriers. Coastal waters of the Asian parts of the Bering Sea, the sea around Kamchatka, and the Okhotsk Sea are distinctly Arctic. The American side of the Bering Sea is, however, warmed by northward-flowing temperate water which is seldom less than 6°C even in July and August. Bottom topography of the Bering Sea features a wide continental shelf in its eastern parts. The 50-metre contour continues through Unimak Pass to outline a narrow band along the north side of the Alaska Peninsula, curving into Bristol Bay and continuing in a northwest direction to the west coast of St. Lawrence Island. Bering Strait and the Chukchi Sea are mostly less than 30 m in depth.

Ichihara (1958) admits doubt as to the true migration route of the gray whale in the Bering Sea, but draws inferences from the migrations of other baleen whales in this area as learned from marking experiments. There is, however, little reason to expect gray whales, which are known to hug the coastline closely during a large part of their migration, to conform to migration routes used by other whale species which are oceanic in their distribution; nor should we expect them to select feeding areas used by other whales. Hardy and Gunther (1935) and Nemoto (1959) have shown that oceanic species of baleen whales concentrate in feeding areas as an indirect result of the search for preferred foods. Euphausians are a preferred food of fin and humpback whales whose feeding apparatus is adapted to skimming these as they swarm near the surface, usually off the edge of the continental shelf or in areas of convergences. Only one euphausiid, *Thysanoessa raschii*, is abundantly distributed in cold shallow waters of the Gulf of Anadyr and the northern Bering, Chukchi and Okhotsk Seas. Fin and humpback whales may feed directly or indirectly on this species in shallow waters in the northern parts of the Bering Sea (Nemoto, 1959) where they are sometimes associated with gray whales, but mostly these whales concentrate along the edges of the shelf in deeper waters. The gray whale, however, is adapted to feeding on benthic or near-benthic organisms (Tomilin, 1954) which abound in cold shallow seas. It would neither be expected to distribute itself in the same manner as those whales which feed on epipelagic plankton, nor does evidence from stomachs and feeding behaviour indicate that it does.

There is no evidence available to show that gray whales ever cross broad expanses of ocean or stray far from land. Throughout the feeding migration south of the Bering Sea, they travel in a general northwesterly direction, keeping exposed ocean coasts of all major land masses, including large islands such as Vancouver Island, the Queen Charlotte Islands and Kodiak Island on the right side. When passing small islands such as Solander Island, where an unobstructed view of open ocean appears beyond, they pass on the inside; when passing large islands where an unobstructed view of open ocean does not appear, they pass on the seaward side.

The combination of senses providing clues to the migration route is not certain. Circumstantial evidence suggests that gray whales supplement their directional sense by means of visual clues provided by coastal landmarks. In this regard, Gilmore (1960a) remarks on the gray whale's habit of periodically thrusting its head out of the water, while subsequent movements suggest re-orientation, and on page 417 of his paper he illustrates this behaviour with the caption "gray whale spying out a boat". Scammon (1874, p. 32) illustrates similar behaviour of gray whales in the Arctic ice. While blowing, the gray whale barely exposes the eyes.

The distance (d) in nautical miles at which landmarks of various heights (h) in feet may be seen from the sea surface is described by the formula:

$$d = 1.2\sqrt{h}$$

According to this formula, landmarks 100, 500, 1000, 2000, 4000 and 8000 feet high are visible from approximate distances of 10, 25, 35, 50, 75 and 100 nautical miles, respectively (1 foot = 0.305 m). Although it is not certain that baleen whales in general and gray whales in particular are anatomically equipped to see great distances in air (some authorities generalize that the Mysticetes lack the power of accommodation and are myopic in aerial vision), their behaviour in following the coastline, except when by-passing wide openings in the coastline, suggests that they are utilizing landmarks for orientation. High mountains fringing the west coast of North America provide an almost continuous path for gray whales should they utilize these for directing their coastal courses between breeding and feeding areas. Specific mention has been made of one locality where gray whales appear temporarily to deviate from their route. This is the mouth of Queen Charlotte Sound, a gap of 120 miles between Cape Scott and Cape St. James. Mountains near the southern end of Queen Charlotte Islands range to heights of from 1500 to 2000 feet (460–610 m) and could not be seen from the sea surface at distances greater than 40 to 50 miles. Northbound whales appear to continue on a northwesterly course after leaving Vancouver Island; later, probably when within sight of these mountains, they appear to re-orientate in the direction of Cape St. James. Some may continue northward through Hecate Strait. Future studies in Queen Charlotte Sound are planned in order to learn how gray whales orient themselves in the absence of visible landmarks.

Navigational aids used by gray whales need not be completely innate since calves accompany their mothers on their first northward migration, and are thereby provided with the opportunity to learn the route.

SUMMARY AND CONCLUSIONS

The northward migration of gray whales along the coasts of Washington and British Columbia begins in February, ends in May, and is at a peak during the first two weeks in April. At the peak of the migration, gray whales are seen almost every day at several points between the Columbia River and Dixon Entrance, travelling close to shore except when by-passing wide indentations in the coastline at which time they travel from headland to headland. None are seen offshore. Occasional stops are made for resting and feeding.

Few southbound migrants are seen off Washington and British Columbia because of reduced visibility in winter months. The southward migration begins in late September and October, ends in late January, and is at a peak in late December. Gray whales continue to hug the coast on the southward run, but appear to be travelling at a faster rate and seldom stop to rest or feed.

Gray whales sometimes occur along the coast and in protected waters of British Columbia from June through September. At this time the direction of travel is not constant; these whales are probably summer residents in the area and are not migrating.

On their feeding grounds in the Bering and Chukchi Seas, gray whales feed on benthic and near-benthic organisms, mostly amphipods. They are, consequently, distributed over the shallow continental shelf in northern regions rather than in offshore oceanic areas where commercial species of baleen whales distribute themselves in search of favoured epipelagic plankton. When dispersing to feed, gray whales first appear off the west coast of St. Lawrence Island in May. The herd splits up in this region with part travelling westward towards the Koryak coast and part continuing northward through Bering Strait. The herd splits again in the Chukchi Sea with part travelling westward along the Siberian coast and part travelling northward along the Alaskan coast. Encroachment of the ice through Bering Strait in October probably initiates the southward migration which is directed mainly along the eastern side of St. Lawrence Island.

Available evidence suggests that northward migrants travel a coastal route until they reach the western tip of the Aleutian Peninsula where they enter the Bering Sea and continue northward within the 50-metre contour which outlines a broad pathway in the eastern Bering Sea. It is unlikely that they follow ocean currents, since throughout known parts of the migration they travel close to shore where ocean currents lose their identity under the influence of coastal configurations.

FOREWORD

WHALES long remained among the world's least known mammals because their large size and oceanic habitat make them difficult to observe and collect. Individual whales cannot be observed repeatedly, therefore knowledge of most aspects of their life history must be deduced from data provided by examining large series of specimens. In the early decades of this century the expansion of the modern whaling industry with its efficient catcher boats and its mechanized shore stations and floating factory ships finally provided biologists the opportunity to undertake large-scale studies of whales. Concern for the future of whale stocks provided an incentive for government support of whale research. As a result, we have now learned more about the biology of the rorquals and the sperm whale than of most other species of wild mammals. Gray whale populations, however, had been depleted before this opportunity for research arose. Although field observations had provided a fairly detailed picture of the distribution, migration, and behavior of the gray whale, many important aspects of the species' biology—such as age and growth, reproduction, parasites, pathology, and population dynamics—remained virtually unknown.

Under the protection afforded by the 1946 International Convention for the Regulation of Whaling, the California gray whale stock has increased so much that a resumption of commercial exploitation has been considered. As the dearth of basic data on the biology of the species would handicap any efforts at rational regulation of the harvest, the Bureau of Commercial Fisheries in 1959 initiated a research program that included collecting small series of gray whales under Special Scientific Permits. Beginning in 1966, the number of animals taken annually was increased upon recommendation of the Scientific Committee of the International Whaling Commission, which has reviewed the work each year and provided much encouragement and advice. The data now available reveal the basic features of the ecology of the gray whale and provide a foundation for further studies on its population dynamics.

This study would not have been possible without the cooperation of the Del Monte Fishing Company and the Golden Gate Fishing Company of Richmond, California. John Caito and Charles Caito of Del Monte, and Robert Casebeer of Golden Gate placed the facilities and crews of their whaling stations and catcher boats at our disposal for collecting and examining specimens. Kenneth C. Balcomb III, James Ekberg, Bernard Lenheim, and Toshio Kasuya (Ocean Research Institute, University of Tokyo), assisted in the examination of whales at the whaling stations. Margaret Anderson, Lawrence Dickson, Susan D'Vincent, Ekberg, James Houk, Hiroshi Kajimura, Lenheim, Donald Ramsey, Jeffrey Rochin, James Rote, Catherine Short, and Robert Strawn manned the counting stations. Lenheim, Ramsey, and Ancel M. Johnson conducted the transect cruises of the catcher-boat *Allen Cody*. Balcomb, Kasuya, Thomas J. McIntyre, Masaharu Nishiwaki (Ocean Research Institute), Daniel Lluch B., and Joaquin Arvizu M. (both with the Instituto Nacional de Investigaciones Biologico Pesqueras, Mexico) assisted in the whale-marking cruises. Ford Wilke, Johnson, and Lenheim assisted in the aerial surveys. Francis H. Fay, Arctic Health Research Laboratory, U. S. Public Health Service, provided a sample of the stomach contents of a gray whale killed near St. Lawrence Island, Alaska. Earl L. Bousfield, National Museum of Canada, identified the amphipods, provided information on the habits of benthic invertebrates, and made suggestions concerning the feeding behavior of gray whales. The following individuals identified other stomach contents or parasites: Martin W. Johnson and Margaret D. Knight, Scripps Institution of Oceanography (crab larvae); Josephine F. L. Hart, British Columbia Provincial Museum (cumaceans); Frank Bernard (ascidians and holothurians) and Cyril Berkeley (polychaetes and salps), Pacific Biological Station, Fisheries Research Board of Canada; Yuk-maan Leung and John L. Mohr, University of Southern California (cyamids); Kenneth M. Neiland, Alaska Department of Fish and Game (acanthocephalans and campulid trematodes); Robert L. Rausch, Arctic Health Research Laboratory (cestodes and notocotylid trematodes); John T. Davey, Commonwealth Bureau of Helminthology (nematodes). Daniel F. Cowan, Michigan State University, examined a pathological liver specimen. The late Gordon C. Pike, Arctic Biological Station, Fisheries Research Board of Canada, made the baleen tracings and allowed us to see his unpublished manuscript on gray whales taken off British Columbia. Unless otherwise noted, individuals mentioned above are present or former employees of the Marine Mammal Biological Laboratory, Bureau of Commercial Fisheries.

CONTENTS

INTRODUCTION

IN February each year, pod after pod of gray whales departs from the tropical mangrove-fringed lagoons bordering Bahia Magdalena, from Laguna Ojo de Liebre in the heart of the Vizcaino Desert, and from other lagoons on the west coast of Baja California. Swimming slowly but steadily, they move northward along the coast; four months later the same whales may be surfacing and blowing among the ice floes of the Chukchi Sea. This migration is the longest performed by any mammal.

The gray whale, *Eschrichtius robustus* (Lilljeborg, 1861), is unique in other ways. It is the sole member of the family Eschrichtiidae and the most primitive surviving baleen whale. In structure it is remarkably similar to the extinct cetotheres, which were ancestral to all living baleen whales. The gray whale became extinct in the North Atlantic only a few centuries ago and is now a relict species confined to neritic waters of the North Pacific Ocean and adjacent waters of the Arctic Ocean (Fig. 1).

Because gray whales swim slowly and congregate in near-shore waters, they were easy prey to whalers. By the turn of the century, the species was almost extinct. Since 1946, the eastern Pacific stock has increased under the legal protection afforded by the International Convention for the Regulation of Whaling to the point that commercial utilization may again be advocated.

Gray whales are the only large whales that can regularly be observed in large numbers from shore. Their annual passage along the coast of California is one of the world's outstanding wildlife spectacles. Public interest in gray whales is increasing, and they have become an important tourist attraction in southern California. More than a million people visit Cabrillo National Monument on Point Loma, San Diego, each year to watch the migrating whales, and several sport-fishing companies in San Diego and San Pedro profitably operate "whale watching" cruises (Rice, 1961).

The abundance and accessibility of gray whales in their calving lagoons and along the coast is also attracting a growing number of experimental biologists, and there is cause for concern that, especially on the calving grounds, repeated harassment of gray whales

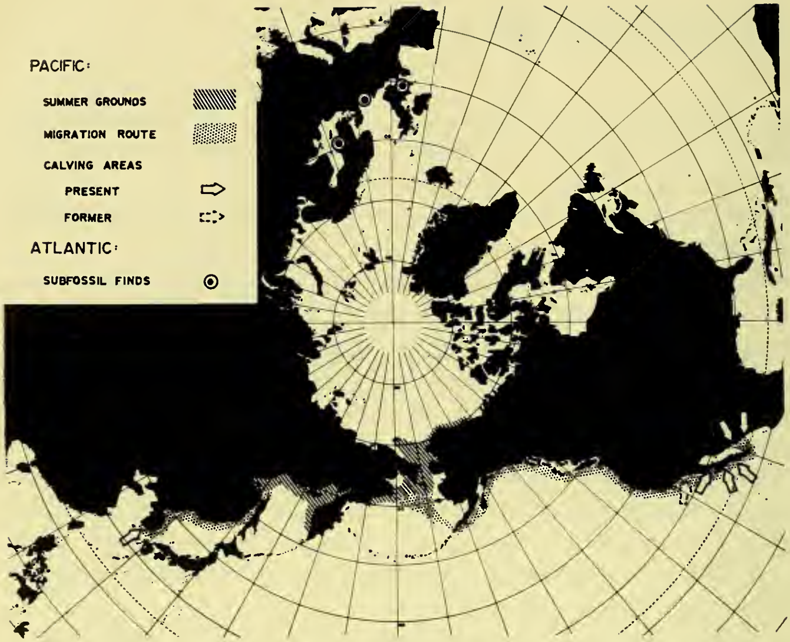

FIG. 1. Distribution of the gray whale. A few gray whales spend the summer in the migration area, especially along the coast of Washington and Oregon.

by investigators using small boats or aircraft in attempts to implant telemetering and tracking devices or drug darts may deleteriously affect reproduction (Schevill *et al.*, 1967; American Society of Mammalogists, 1967). Another threat to the survival of the gray whale is increasing industrial development and boat and ship traffic in the remaining calving lagoons (Marx, 1966). The species has long since been driven from San Diego Bay.

The gray whale is clearly an important species from the standpoint of basic scientific interest, esthetic appeal, and economic significance. If commercial exploitation is resumed it should be limited to the sustainable yield so that the scientific and esthetic values of the population may be preserved. A wise management program must be based on a sound knowledge of the biology of the species.

Beginning with Scammon's (1874) classic account, the gray whale has been the subject of many field observations (for example, Gilmore, 1960*a*, 1960*b*; Hubbs, 1959; Hubbs and Hubbs, 1967; Pike, 1962*a*). As a result, certain facets of its life history and ecology, such as distribution, migrations, and behavior, are better known than for other baleen whales.

Only five biologists have had the opportunity to examine series of gray whales. Andrews (1914) studied 23 specimens taken during southward migration and brought into the shore station at Ulsan, Korea, in January and February 1912. In his monograph he presented a historical review of earlier research on the species. Zenkovich (1934*a*, 1934*b*, 1937*a*, 1937*b*, 1937*c*) examined 104 gray whales aboard the Soviet floating factory *Aleut* during the summers of 1933 through 1936. Tomilin (1937) examined 54 specimens aboard the *Aleut* in August and September 1934. Unfortunately, neither Andrews, Zenkovich, nor Tomilin recorded reproductive information other than measurements of fetuses and condition of mammary glands. Pike (1962*a* and unpublished data) examined 10 northward migrating gray whales killed under a special scientific permit and brought into the shore station at Coal Harbour, British Columbia, during the first week of April 1953. Zimushko (1969*a*, 1969*b*) reported on 63 gray whales collected off the Chukotsky Peninsula in the summer and autumn of 1965 and 1966.

Few other original data based upon examination of dead gray whales have been published. Gilmore (1960*a*) and Eberhardt and Norris (1964) examined a number of dead calves at Laguna Ojo de Liebre, Baja California, and Maher (1960) reported on several whales killed by Eskimos at Barrow, Alaska.

Statistical data from commercial catches of gray whales in Baja California and in the Bering Sea were analyzed by Risting (1928). Unfortunately, his data are unreliable, because body lengths were estimated rather than measured (see Mackintosh and Wheeler, 1929, p. 273), and therefore the conclusions concerning fetal growth and size at sexual maturity are not valid. Mizue (1951) presented statistical data from gray whale catches in Korea.

The Bureau of Commercial Fisheries began a program of research on the species in 1952 under the leadership of Raymond M. Gilmore. During the first five years, the work consisted of field observations and censuses designed primarily to determine the extent of the calving grounds and to document fluctuations in population size (Gilmore, 1960*a*, 1960*b*).

In 1958, responsibility for whale research was transferred to the Marine Mammal Biological Laboratory in Seattle, Washington, under the direction of the senior author. Beginning in 1959, small series of gray whales have been periodically collected to obtain basic data on all aspects of the life history and ecology of the species. Particular emphasis has been given to reproduction, growth, age, and population structure. As collections and observations had to be made incidentally to studies on rorquals and sperm whales, they have been mostly confined to the periods when the gray whales were on migration along the coast of California. This report presents the results of the study from 1959 through February 1970.

NOMENCLATURE

THERE has long been a controversy over the correct scientific name of the gray whale. *Eschrichtius robustus* (Lilljeborg, 1861) is used here for the extinct Atlantic and the living Pacific populations of gray whales following Cederlund (1939). As the data and conclusions of this author have been mostly ignored by subsequent workers, none of whom has contributed new evidence to refute his conclusions, it seems desirable to briefly review the nomenclature of the gray whale.

The generic name *Eschrichtius* Gray (1864) is now used by virtually all taxonomists. There are three available species-group names (Hershkovitz, 1966) that require consideration. These are, in order of priority: (1) *Balaena gibbosa* Erxleben (1777), based on the New England "scrag whale" described by Dudley (1725); (2) *Balaenoptera robusta* Lilljeborg (1861), based on subfossil skeletal remains from Gräsö, Sweden; and (3) *Agaphelus glaucus* Cope (1868), based on gray whales from the coast of California. Two questions must be resolved: (1) which of the first two names should be used for the Atlantic population, and (2) is the Pacific population taxonomically distinct from the Atlantic population?

The applicability of Erxleben's name *gibbosa* to the gray whale depends upon the identity of Dudley's "scrag whale." Dudley's (1725) brief description reads as follows: "The Scrag Whale is near a-kin to the Fin-back, but, instead of a Fin upon his Back, the Ridge of the Afterpart of his Back is scragged with half a Dozen Knobs or Nuckles; he is nearest the right Whale in Figure and for Quantity of Oil; his Bone is white, but won't split." The lack of a dorsal fin, knobs on the back, and white baleen are diagnostic of the gray whale. It seems improbable that Dudley's description of the scrag whale is inaccurate because all other large whales described by him are readily recognizable. On the other hand, there are minor discrepancies between Dudley's description of the scrag whale and the gray whale. For one thing, the oil yield is too high; Scammon (1874) stated that right whales yielded an average of 60 barrels, but that gray whales produced only 20 with a maximum of 60 or 70. For another, the number of knobs on the back is too few; gray whales have nine to 14 knobs behind the dorsal hump, although the posterior knobs are weakly defined. These discrepancies might seem minor were it not for the fact that no other account of early whaling gives any indication of the occurrence of *Eschrichtius* in the North Atlantic (True, 1904) and the fact that the term "scrag" or "scragg" was applied to different kinds of whales, particularly small, lean, right whales (Allen, 1916; Eschricht and Reinhardt, 1866). As the identity of Dudley's scrag whale can never be unequivocally determined, we agree with Cederlund (1939) and Schevill (1952) that Lilljeborg's specific name should be used for the Atlantic gray whales.

The question of the taxonomic relationship of the Pacific and Atlantic gray whale stocks has been investigated by van Deinse and Junge (1937) and Cederlund (1939), who compared the subfossil skeletal material from the Atlantic with skeletons and published data and photographs of Pacific gray whales. These authors found no consistent differences between the Atlantic and Pacific specimens and concluded that these populations were conspecific.

FIELD AND LABORATORY PROCEDURES

Collection of Specimens

A total of 316 gray whales was examined. These were collected by the whale catcher boats of the Del Monte and the Golden Gate Fishing Companies, Richmond, California, under special scientific permits issued to the Marine Mammal Biological Laboratory. The whales were taken along the coast of central California between Half Moon Bay (37°30′ N lat.) and Point Reyes (38°00′ N lat.).

The collections were scheduled to provide representative samples for the periods of the southward (December to January) and northward (February to April) migrations. The total sample included 180 southbound migrants (85 males, 95 females) and 136 northbound migrants (81 males, 55 females). Dates of collection, numbers of specimens (in parentheses), and persons who made the examinations and measurements are as follows: 23 to 26 February 1959 (two) Rice; 27 to 30 March 1962 (four) Rice; 14 to 25 March 1964 (20) Rice; 22 to 29 March 1966 (26) Rice, Wolman, Balcomb; 14 December 1966 to 19 January 1967 (95) Rice, Wolman, Ekberg, Kasuya; 21 February to 9 March 1967 (30) Wolman, Ekberg; 14 to 25 January 1968 (35) Rice, Wolman; 26 February to 11 March 1968 (24) Wolman, Lenheim; 2 to 11 April 1968 (seven) Rice, Wolman; 20 December 1968 to 9 January 1969 (50) Rice, Lenheim; 2 to 16 March 1969 (23) Wolman, Lenheim.

Whales were delivered to the shore stations of the Del Monte and Golden Gate Fishing Companies at Point San Pablo, Richmond, California, where the following data were recorded.

Measurements and Counts.—Twenty-two standard external body measurements of the first 177 whales collected were made with a steel tape graduated in centimeters. A preliminary analysis revealed that many of these measurements were redundant, imprecise, or useless. Consequently, only nine measurements were made on the last 139 specimens. These were: total length (straight line from tip of snout to notch of flukes); head length (from tip of snout to occipital condyles); tail length (from notch of flukes to anus); maximum girth of body (determined by measuring from the mid-dorsal line to the mid-ventral line on the side of the whale that was uppermost as the animal lay on the flensing deck and multiplying by two); span of flukes; breadth of flukes (from notch to nearest point on leading edge); anterior length of flipper; posterior length of flipper; and maximum width of flipper. Sixteen skulls and one complete skeleton were collected for cranial measurements. Throat grooves, baleen plates, and knobs on the dorsal ridge of the caudal peduncle were counted on most specimens.

BODY WEIGHTS.—Weights of six whales were determined by summing the weight of the meat produced after it had been packaged in 50-pound (22.7 kilogram) bags and the weights of the blubber, viscera, and bones, which were determined by weighing each truckload of raw material on commercial truck scales. One near-term fetus was weighed in pieces.

ECTOPARASITES AND EPIZOITES.—Abundance, position, and sizes of ectoparasites and epizoites on the body surface and baleen plates were recorded, and a series of each species was collected for identification.

SCARS.—The nature and position of any scars and wounds were noted.

BLUBBER THICKNESS.—Thickness of the blubber was measured (to the nearest half centimeter) at a mid-lateral point on the body opposite the dorsal hump.

MAMMARY GLANDS.—Development of the mammary glands and presence or absence of secretory activity was noted. Maximum thickness of the glands, as determined by inspection, was measured to the nearest half centimeter. A small portion of mammary gland tissue was fixed in 10 per cent formalin or FAA (10 parts formalin, 30 parts isopropanol, 5 parts acetic acid, 55 parts water), sectioned at 10 microns, and stained with hematoxylin and eosin. The development of glandular tissue subsequently was determined by projecting a randomly selected section about one-quarter of a square centimeter onto a sheet of paper on which 100 dots were arranged in a regular 10 by 10 grid; the number of dots falling within glandular areas was used as an index of the proportion of glandular tissue.

OVARIES.—The ovaries of each female were collected and fixed in 10 per cent formalin. The preserved ovaries were weighed to the nearest hundredth of a kilogram and serially sectioned at half a centimeter on a mechanical meat slicer. Each corpus luteum and corpus albicans revealed through sectioning was measured, to the nearest millimeter, across its greatest diameter and across its maximum diameter at right angles to the greatest diameter; and the two measurements were averaged. The maximum diameter of the largest Graafian follicle also was measured to the nearest millimeter.

UTERUS.—The diameter of each uterine horn at approximately the middle was measured to the nearest half a centimeter. A sample of the uterine wall was fixed in 10 per cent formalin or FAA, sectioned at 10 microns, and stained with hematoxylin and eosin for histological study. In specimens in which a corpus luteum or recently ovulated follicle was present in either ovary, but there was no obvious indication of pregnancy, the entire uterus was removed from the carcass, each uterine horn slit open along its entire length, and the surface of the endometrium carefully searched. Embryos and small fetuses were preserved in 10 per cent formalin and their length (crown to tip of tail, with body straightened) and sex recorded. Standard body measurements were made on near-term fetuses and the sex was noted.

TESTES.—Each testis was weighed to the nearest tenth of a kilogram at the whaling station. A small sample (1 to 2 cubic centimeters) of the largest testis of each whale was taken for microscopic examination from the middle of the gonad about halfway between the surface and center and fixed in FAA, 10 per cent formalin, or Bouin's solution. Specimens were sectioned at seven microns and stained with hematoxylin and eosin. Mean diameter of the seminiferous tubules was calculated from measurements with an ocular micrometer of the greatest diameter and maximum diameter at right angles to the greatest diameter of 20 tubules cut in cross section. The presence or absence of fluid in the epididymides and deferent ducts was noted.

PENIS.—The length of the extruded penis from the base on the ventral surface to the tip and the circumference at the base were measured to the nearest centimeter. These measurements could not be made on some males, especially immature individuals, because the penis was not completely extruded.

STOMACH CONTENTS.—The quantity of any food remains in the stomach was estimated and a sample preserved for identification.

ENDOPARASITES.—The stomach, intestine, liver, kidneys, lungs, peribullary sinuses, and blubber were examined for endoparasites. The intestine was slit open at three or more randomly selected points, and in the years 1967, 1968, and 1969 the rectum also was opened for inspection. The tips of the liver lobes were examined for evidence of cirrhosis and were sliced to reveal the bile ducts. The kidneys were slit to expose the main urinary duct.

VERTEBRAL EPIPHYSES.—The degree of fusion of the epiphyses of the anterior thoracic vertebrae to their centra was determined by chopping into the ends of the vertebrae with a hatchet to a depth of several centimeters.

EAR PLUGS.—An attempt was made to collect at least one ear plug from each whale. In a few animals, however, the plug was so soft that it could not be successfully removed. Ear plugs were preserved in 10 per cent formalin. They were bisected longitudinally and gently polished on a whetstone, so that the growth layers could be counted.

BALEEN PLATES.—Several of the longest baleen plates were collected from each whale. Variations in thickness of the plates were recorded graphically by means of an apparatus similar to that used by Ruud (1940).

Field Observations

Observations on living gray whales were made from coastal lookout points, chartered whale catcher boats, and light aircraft.

Coastal Stations.—During the southward migration in 1967–68, 1968–69, and 1969–70, coastal lookout stations were established to count migrating whales. One was on Point Loma at San Diego, California (32°40′ N lat.), 130 meters above sea level (Rice, 1961) and is the site where previous counts were made (Gilmore, 1960*a*, 1960*b*; Rice, 1961). This station was manned for 52 days (27 December to 16 February) in 1967–68 and for 57 days (20 December to 14 February) in 1968–69. The second station was 2 km. S Yankee Point, Monterey Co., California (36°29′ N lat.), 23 meters above sea level and about 100 meters back from the shoreline. This was near the site where a partial count of migrating gray whales was made in 1966–67 (Adams, 1968). We manned this station for 49 days (18 December to 4 February) in 1967–68, 60 days (10 December to 7 February) in 1968–69, and 64 days (8 December to 9 February) in 1969–70.

Observations were made continuously from 0700 to 1700 hours (essentially sunrise to sunset) each day. At each station, two observers each worked a 5-hour shift; morning and afternoon shifts were alternated between the two observers. The number of whales, time of passage, estimated distance from shore, and direction of travel were recorded for each group sighted. Wind direction and force, cloud cover, precipitation, and fog were logged throughout the day.

Vessels.—Between 25 January and 9 February 1968, we ran a series of transect cruises between Point Loma and a position west of Tanner and Cortez Banks. A similar transect was run off Yankee Point on 18 January 1968. While the vessel was underway, a constant watch for gray whales and other marine mammals was maintained on the bridge. All whales sighted were approached closely enough to ensure positive identification and the number of whales in each pod, the direction of travel, and the position and time of sighting recorded.

Observations on gray whales also were made during many cruises conducted for marking rorquals (Balaenopteridae) and sperm whales (*Physeter catodon*). The area covered included the waters along the coast from Point Reyes, California (38° N lat.), south to Isla Clarion off Colima, Mexico (18° N lat.). The cruises, totaling 15 months, were made mostly between December and April from 1962 to 1969. The calving grounds in Laguna Ojo de Liebre, Laguna Guerrero Negro, Laguna San Ignacio, and Bahia Magdalena, Baja California, were briefly visited. Gray whales were sighted on 304 occasions, and a total of 1045 individuals was recorded.

Aircraft.—On 25 and 26 March 1969, an aerial survey was made in both directions along the entire coast beween San Francisco, California (38° N lat.), and Cape Flattery, Washington (48° N lat.). Two aircraft (a Cessna 177 and a Cessna 185) were used, each with two observers in addition to the pilot. The flight path was 0.3 to 2.0 kilometers offshore at an average altitude of 230 meters and air speed of 200 kilometers per hour. When pods of whales were sighted they were often circled at a lower altitude. Data were recorded on a tape recorder. Sighting conditions were optimum, with calm seas and clear skies, throughout the period of the survey.

SEASONAL MIGRATORY CYCLE

Gray whales now occur only in the North Pacific Ocean and adjacent waters of the Arctic Ocean. The species also existed in the North Atlantic until a few centuries ago. There are presently two geographically isolated stocks (Fig. 1): an eastern Pacific stock, which migrates between Baja California and the Bering and Chukchi seas, and a western Pacific stock, which migrates between South Korea and the Okhotsk Sea. These may be designated the California stock and the Korean stock, respectively, on the basis of their breeding grounds.

California Stock

Summer Grounds.—From late May through October, gray whales occupy the shallow waters of the northern and western Bering Sea, the Chukchi Sea, and the western Beaufort Sea. They are common along the Koryak coast of Siberia from Cape Navarin to Glubokoi Inlet (Berzin and Rovnin, 1966). Farther to the southwest they are rare; a few have been seen as far as Kronotskiy Bay on the Kamchatka Peninsula (Tomilin, 1957) and the Kommandorskiye Islands (Barabash-Nikiforov, 1938; Grebnitskii, 1902). In the Gulf of Anadyr, these whales are abundant along the southwest shore from Cape Navarin to Tymna Lagoon; they have not been seen in the northwestern part of the gulf from the Anadyr Estuary to Cape Kresta (Berzin and Rovnin, 1966). Gray whales are also common along the northeastern shore of the Gulf of Anadyr, from Cape Retkon to Cape Chaplino (Berzin and Rovnin, 1966), around St. Lawrence Island (Ichihara, 1958), around the shores of the Chukotskiy Peninsula as far northwest as Cape Serdtse Kamen' (Nikulin, 1946), in Kotzebue Sound (Wilke and Fiscus, 1961), and in the Chukchi Sea (north as far as 69° N lat.—Nasu, 1960). A few go westward along the coast as far as Tynkurginpil'gyn Lagoon (Berzin and Rovnin, 1966), and northwestward through the pack ice as far as Wrangel Island (Sleptsov, 1955).

Along the Arctic coast of Alaska they are found regularly from Cape Thompson (Pike, 1962*a*) east to Point Barrow, and a few have been reported by Eskimos along the shores of the Beaufort Sea as far east as Barter Island (Maher, 1960). To the southeast, there are few records of gray whales. One was found stranded at Scammon Bay, south of the Yukon Delta, in September (Fay, *in* Pike, 1962*a*). There is only one published record of gray whales from the Pribilof Islands (Gilmore, 1960*b*), but several were seen around St. George Island in the summers of 1965 and 1968 by C. H. Fiscus, A. M. Johnson, and V. B. Scheffer (personal communication). Gray whale remains have been found on St. Matthew Island (Pike, 1962*a*), and C. H. Fiscus (personal communication) saw four gray whales in Sarichef Strait between St. Matthew Island and Hall Island on 3 August 1960.

Not all gray whales migrate to the Arctic in the summer. A few remain scattered along the west coast of North America. Pike and MacAskie (1969) reported several near Langara, Queen Charlotte Islands, British Columbia, in late August and early September of 1959 and 1960, and a young male stranded near Ucluelet, Vancouver Island, on 16 August 1966. Some were seen near Lapush, Washington, in June and July 1961 by C. Munsen (personal communication) and in July 1967 by the junior author. A few were seen near Kalaloch, Washington, in July 1968, by A. M. Johnson (personal communication). Fiscus (personal communication) saw one near Cannon Beach, Oregon, in July 1969. Gilmore (1960*a*) reported that a few regularly spend the summer in the vicinity of St. George Reef and Pelican Bay in northern California and southern Oregon. Whalers working off San Francisco occasionally see gray whales during the summer. L. Newton (personal communication), captain of the catcher boat "Lynnann," saw a few near the Farallon Islands, California, throughout the summer of 1964; they remained until late September or early October. K. C. Balcomb saw a small gray whale in Bahia Magdalena, Baja California, on 11 June 1965, during one of our whale marking cruises aboard the catcher boat "Sioux City."

The northern boundary of the known summer range of the gray whale corresponds closely with the southern edge of the zone of close pack ice during the period 1 to 15 September (U. S. Navy Hydrographic Office, 1958). Close pack ice may limit their movements. Scammon (1874) and Sleptsov (1955) have reported seeing gray whales in broken pack ice. Gray whales do not arrive at Point Hope or at Barrow, Alaska, until most of the ice has gone out, long after the bowhead whales have arrived. As few observers experienced in identifying whales enter the close pack ice in ships or fly over it in the summer, the extent to which gray whales penetrate the pack ice is unknown. In the western Bering Sea, gray whales are confined to coastal waters, their seaward range being delimited by the edge of the Continental Shelf. They have never been found in the deep waters of the southwestern Bering Sea. Their feeding habits (see section on food and feeding) apparently restrict them to shallow water. Although most of the eastern Bering Sea is shallow, the scarcity of gray whales there is ✓ believed to be the result of a low biomass of benthos, 55 grams per square meter, compared with 200 to 900 grams per square meter in the northwestern region (Berzin and Rovnin, 1966; Neiman, 1963).

Migrations.—Pike (1962*a*) summarized all published information on the migration route of the California population and presented significant new data. There are few observations on southward-migrating whales in the northern part of their range. From October through January, they probably move down the eastern side of the Bering Sea, go through Unimak Pass, and then follow the coast to Baja California. A few go around Cabo San Lucas and cross to the eastern side of the Gulf of California. From late February to June, the northward migration of males and females without calves, which is much better documented, follows the reverse route.

Our observations during whale marking cruises off California and Baja California show that the majority of gray whales migrate within a few kilometers of shore when passing points, headlands, and sectors of coastline where the Continental Shelf is narrow and ✓ there are no off-lying islands. Many tend to take the most direct route, however, when crossing bights and indentations of the coastline. For example, many southbound whales, after passing Point Conception (34°27′ N lat.), head southeast through the Channel Islands, passing as much as 200 kilometers offshore from the mainland of southern California (Rice, 1965). Some gray whales make a similar offshore passage from about Punta Baja (29°57′ N lat.)

to Isla Cedros (28°22′ N lat.), Baja California, thus avoiding the long journey around the shores of Bahia Sebastian Vizcaino. Quantitative data on offshore migration are presented in the chapter on populations.

The route taken by females with calves during the spring migration is unknown. During this study, the catcher-boat crews saw only one female with a calf—near Point Reyes on 15 March 1969. From 1959 through 1967, we collected no gray whales later than 30 March, and during that time we thought females with calves moved north later in the season. Therefore, in 1968 we hunted gray whales until 25 April, 14 days after the last whale was taken, and had one boat searching exclusively for females with calves from 2 to 25 April. Each year from 1956 through 1968, the regular sperm whaling season opened on 1 April and the baleen whaling season opened on 1 May (1956–59) or 16 April (1960–68). During these years, the whalers never saw a gray whale accompanied by a calf. Shore-based whalers working from San Simeon, California, in the 1880's likewise told Townsend (1887) that they never encountered females with calves.

On whale marking cruises in 1965, 1966, 1967, and 1969, we traveled north during late February, March, and early April, by which time most females with calves had already left the calving lagoons. We put in at many points along the coast between Cabo San Lucas (23° N lat.), Baja California, and San Francisco (38° N lat.), California, but never encountered a female accompanied by a calf, although we saw many northward-migrating gray whales. During the transect cruises, we saw two females with calves on 10 February 1968 (at 32°48′ N and 118°08′ W, heading west-northwest ✓ near San Clemente Island). During the aerial surveys between San Francisco, California, and Cape Flattery, Washington, on 25 and 26 March 1969, no females with calves were identified among 816 gray whales sighted. Morejohn (1968) reported a female with a calf at Moss Landing, northeast of Monterey, California, on 2 May 1967.

Gray whales observed on migration are usually swimming steadily and continuously in a constant direction on a course ✓ parallel to the shore. They surface regularly about every 3 to 5 minutes to blow three to five times. When out of sight of land, they usually travel in a straight line. General observations indicate that the usual swimming speed is about 7 to 9 kilometers per hour (4 to 5 knots). Wyrick (1954) followed four separate gray whales migrating south past San Diego, California, for a total of more than 5 hours; their average speed was 8.5 kilometers per hour (4.6 knots). Cummings *et al.* (1968) tracked nine lone whales (some in daytime, others at night), over distances less than 1.7 kilometers and found the average speed to be 10.2 kilometers per hour (5.5 knots).

There was no consistent hourly variation in the number of gray whales migrating south past the counting stations, contrary to the opinion of Ramsey (1968). This lack of variation indicates that gray whales, on the average, maintain a constant speed throughout daylight hours.

There are few observations to show how fast gray whales travel at night. Unlike sperm whales, baleen whales are rarely, if ever, seen resting at the surface. Since they must rise to the surface regularly every few minutes to breathe, they must continue to swim at least slowly during hours of darkness. In polar regions during the summer when daylight is continuous, baleen whales appear to remain active continuously.

Cummings *et al.* (1968) used an array of hydrophones mounted on the sea bottom off San Diego to track migrating gray whales. They reported the following: "Gray whales were soniferous day and night. One hundred twenty-four signals were recorded from at least 61 whales between 1800 and 0600 h, compared with 107 signals recorded from at least 157 whales between 0600 and 1800 h. All whales seen or heard at night apparently were migrating southward, and there was no evidence of the popular notion that gray whales characteristically stopped migrating at night to rest or to sleep."

The average speed of gray whales along their entire migration route, calculated from dates of peak passage at various points along the coast, is about 185 kilometers per day, or 7.7 kilometers per hour, on the southward migration and half as fast on the northward migration (Pike, 1962*a*). If their average speed during the 10 hours of daylight is 8.5 kilometers per hour, they cover 85 kilometers; to travel the remaining 100 kilometers during the 14

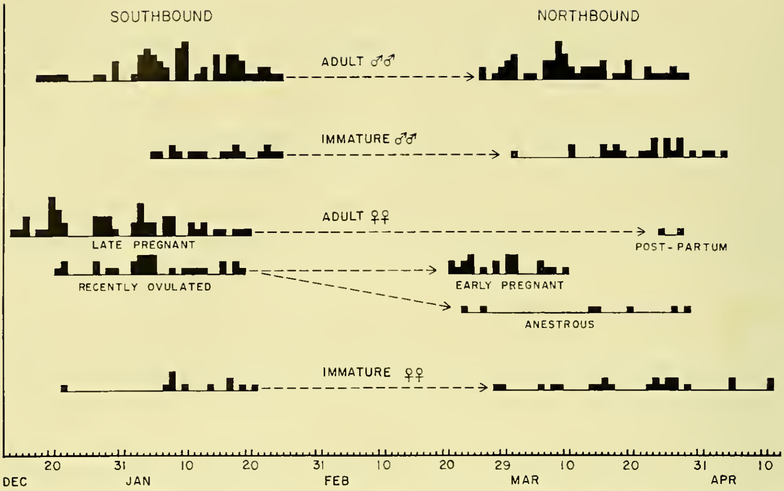

FIG. 2. Collection dates of gray whales, according to sex, age, and reproductive status. Each square represents one animal.

hours of darkness, they must average 7.1 kilometers per hour, or 92 per cent of their speed during daylight.

During migration, there is a partial temporal segregation of gray whales according to sex, age, and reproductive status. This is evident from Fig. 2 in which the collection date of each whale is plotted according to sex, maturity, and reproductive status. These data cannot be regarded as strictly representative, however, because the collecting effort was not the same throughout the season. It must be kept in mind also that the gunners doubtless tended to select the larger animals, even though we imposed no size limitations. This tends to bias the sample in favor of mature animals and females, especially those in late pregnancy. The mean and extreme dates of passage for each class (Table 1), however, should be fairly reliable.

In general, in both the southward and the northward migration, females migrate earlier than males and adults migrate earlier than sexually immature animals. The vanguard of the southward migration from mid-December to the first of January is composed predominantly of females carrying near-term fetuses. The late-pregnant females are followed by adult females that have recently

TABLE 1

MEAN PASSAGE DATES OF MIGRATING GRAY WHALES OFF CENTRAL CALIFORNIA (38° N LAT.) CLASSIFIED ACCORDING TO SEX, AGE, AND REPRODUCTIVE STATUS.

Category	Mean passage date		Days elapsed
	Southbound	Northbound	
Late pregnant (southbound); postpartum females (northbound)	31 December	26 March	85
Recently ovulated (southbound); early pregnant females (northbound)	5 January	28 February	54
Recently ovulated (southbound); metestrous and anestrous females (northbound)	5 January	14 March	68
Immature females	11 January	21 March	69
Adult males	9 January	12 March	62
Immature males	15 January	23 March	67

ovulated but have no macroscopically visible conceptus in the uterus; most of these females presumably weaned a calf a few months previously. The number of females in this class that were collected was fewer than expected. This probably resulted from gunner selection, although there also is a possibility that such females travel farther offshore. Next to pass are the immature females and, at about the same time, the adult males. Last to pass are the immature males.

During the northward migration, the first to pass are the newly pregnant females, which comprised the recently ovulated class of the preceding southward migration. Most of them pass within a limited period of about 15 days. We took them only between 21 February and 7 March in 1967, and between 26 February and 10 March in 1968. None was taken in 1969, when collecting did not commence until 2 March. The peak passage of adult males occurs more than 2 weeks later than that of the pregnant females. Adult males are followed by a few anestrous females that have failed to conceive. Immature whales of both sexes are the last to pass. Only two postpartum females were collected, both in late March. Neither was lactating; obviously their calves were stillborn or were lost shortly after birth.

Migrating gray whales travel singly or in pods of up to 16 individuals. In the course of the southward migration past Cali-

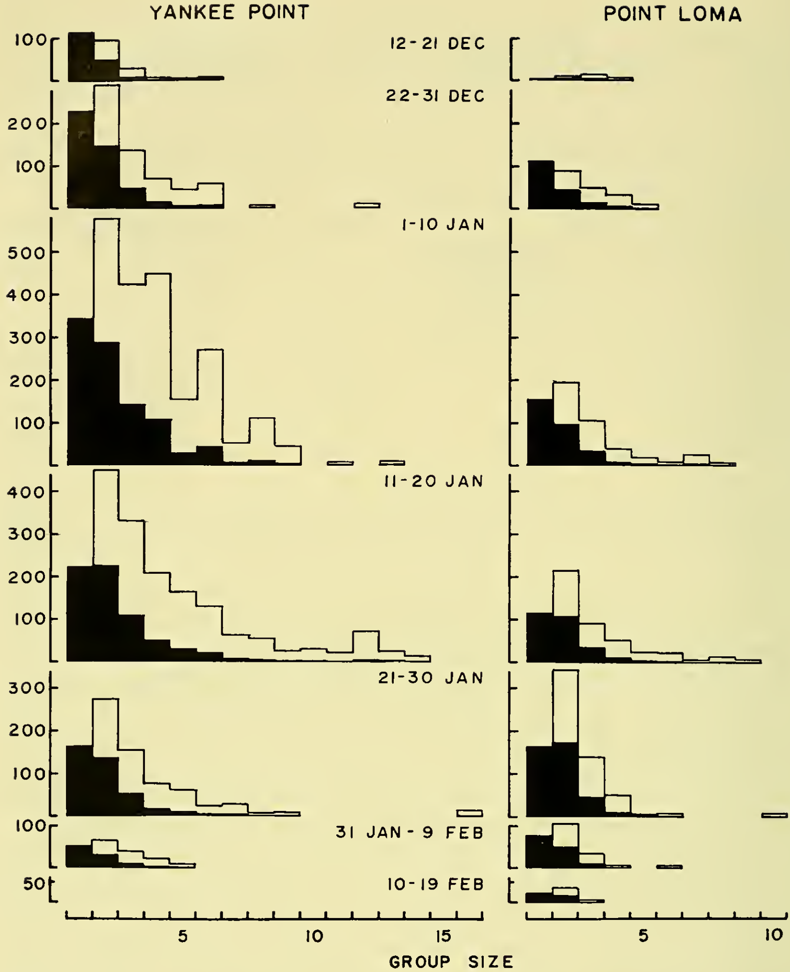

Fig. 3. Frequency distribution of group size of gray whales passing Yankee Point and Point Loma, by 10-day periods, during the southward migrations of 1967–68 and 1968–69. Solid bars indicate the number of groups, open bars the number of whales.

fornia, there are marked changes in the sizes of the groups (Fig. 3). During the early part of the migration, single whales (presumably mostly females carrying near-term fetuses) predominate, and almost no whales are in groups of more than six. During the remainder of the migration, groups of two predominate. Most of the larger groups pass in the middle of the season, and towards the end of the season no groups contain more than five whales.

Winter Grounds.—In January and February most gray whales of the eastern Pacific population are in warm temperate or tropical waters on the west coast of Baja California and the southern Gulf of California. Our southernmost sighting was at Punta Mita, Bahia de Banderas, Jalisco (20°45′ N, 105°34′ W) on 17 February 1965. Gilmore (1960*a*) reported alleged sightings of gray whales at Isla Guadalupe and at Isla Clarion; we have seen none there nor anywhere else far off the coast of Mexico.

Most calves, as far as is known, are born in certain shallow lagoons. The six known calving areas, charted in detail by Gilmore (1960*a*), are as follows: *California and west coast of Baja California*—San Diego Bay (no longer occupied), Laguna Ojo de Liebre ("Scammon's Lagoon") and the adjacent Laguna Guerrero Negro, Laguna San Ignacio, and Bahia Magdalena and adjacent waters (including Bahia Almejas, Canal San Carlos, Estero Soledad, Estero Santo Domingo, Estero Las Animas); *eastern shore of Gulf of California*—open coast south of Yavaros, Sonora (see Gilmore *et al.*, 1967), and Bahia Reforma, Sinaloa.

Korean Stock

There is little information on the distribution of the Korean stock. No gray whales have been reported in recent years in either the Okhotsk Sea or the Sea of Japan, according to (personal communications) V. A. Arseniev and M. V. Ivashin of the All-Union Research Institute for Marine Fisheries and Oceanography, Moscow; H. Omura of the Whales Research Institute, Tokyo; and M. Nishiwaki of the Ocean Research Institute, Tokyo.

Summer Grounds.—Gray whales occupy, or at least formerly occupied, the northern Okhotsk Sea. They penetrated as far north as Penzhinskaya Bay (Krasheninnikov, 1755), and ranged southward as far as Akademii and Sakhalinskiy gulfs on the west (Sleptsov, 1955), and the mouth of the Kikhchik River on the east (Ditmar, 1890).

Migrations.—The migration route of the Korean stock of gray whales lay along the mainland coast of eastern Asia from Tatarskiy Strait to South Korea. Southbound whales passed Ulsan, South Korea, from late November to late January, and northbound whales passed there from the middle of March to the middle of May (Andrews, 1914). All the whales apparently passed through Tatarskiy Strait, as none was ever seen in La Perouse Strait between northern Hokkaido and southern Sakhalin (Mizue, 1951).

Winter Grounds.—The channels, inlets, and bays along the southern coast of South Korea are believed to have been the winter calving grounds of the western Pacific gray whales. According to Andrews (1914): "In November and December, when the females are taken, almost every individual will be found to be carrying young nearly ready for birth. As these would necessarily be delivered within two or three weeks after passing Ulsan, the birth must occur in the bays among the numerous islands at the extreme southern end of the peninsula. Indeed Captain H. G. Melsom, who has hunted gray whales for 15 years along the Korea coast, has often observed them in this vicinity, but because of the abundance of other and more valuable species, they are not killed at this time by the Japanese."

Atlantic Stocks

Subfossil gray whale bones have been found at five localities along the coast of northwestern Europe: Pentuan, Cornwall, and Torquay, Devonshire, England, on the English Channel; IJmuiden and Wieringermeer Polder in the Netherlands; and on the Island of Gräsö, Sweden, in the northern Baltic (van Deinse and Junge, 1937). The most recent bones are those from IJmuiden, which date from about A.D. 500. There are no historical records of gray whales in the eastern North Atlantic. The summer grounds of the eastern Atlantic gray whales probably were in the Baltic Sea, where *Ampelisca macrocephala* (the predominant food of the California stock in the Bering Sea) is abundant (Kanneworff, 1965). Their winter grounds were perhaps along the Atlantic or Mediterranean coasts of southwestern Europe or northwestern Africa.

Discussion and Conclusions

In their annual migrations between summer feeding grounds in Arctic waters and winter breeding grounds in subtropical waters, gray whales may travel more than 18,000 kilometers each year, a distance exceeding that traveled by any other baleen whale. This extensive migration, spanning 50 degrees of latitude, exposes them to a broad range of environmental conditions. Sea surface temperatures on the summer grounds range from about 8° centigrade down to 0° or slighly less in the pack ice. On the winter grounds, temperatures range from about 18° centigrade at the latitude of Laguna Ojo de Liebre to 22° off Cabo San Lucas. In midsummer most gray whales experience more than 22 hours of light each day, and those north of the Arctic Circle experience continuous daylight for several weeks. As the whales migrate southward, they are subjected to a rapidly decreasing photoperiod, which reaches a minimum of less than 8 hours in early December. Day length increases slowly during the remainder of the southward migration and while the whales are on the winter grounds, and then increases rapidly as the animals move north in the spring. The variable photoperiods to which the species is exposed may be an important proximate factor in regulating gonadal development.

There is no evidence to suggest that gray whales slow down at night while migrating southward. The length of their migration route, and their relatively slow swimming speed, makes it necessary for them to travel almost continuously at night as well as day.

The reasons for this long migration become apparent when the food habits of the gray whale are considered. In summer, the species requires areas of shallow water with an abundant benthos. In the North Pacific, large areas with such conditions are found only in parts of the Bering Sea and adjacent waters of the Arctic Ocean, and in the northern Okhotsk Sea. For almost half the year, the ice cover on these summer grounds cuts off the whales' major food supply and forces them to migrate.

Because they cannot feed much during the winter, it is necessary that they seek warmer waters to minimize energy requirements, particularly for the newborn calves. During the winter, the eastern North Pacific from California north is cold (less than 15° centigrade) and is subject to frequent storms with northwest winds that cause heavy surf along the coast. The lagoons of Baja California are the nearest areas of warm, shallow, protected waters suitable for calving.

Females ready to bear a calf arrive on the winter grounds earlier and spend more time there than females that have recently mated. Apparently, calves must remain in warm protected waters until they have grown sufficiently to face the rigors of the long northward migration. The movements of females with calves after they leave the breeding lagoons are unknown. Unlike the other members of the population, they must travel farther offshore.

Pregnant females apparently are the first to arrive on the summer feeding grounds and spend more time there than lactating females. This is also true of fin whales, *Balaenoptera physalus* (Mackintosh, 1965), and humpback whales, *Megaptera novaeangliae* (Dawbin, 1966), and is no doubt related to the need of pregnant females to acquire more fat reserves (see discussion beyond of seasonal changes in nutritive condition).

FOOD AND FEEDING

Stomach Contents

SUMMER.—Few data are available on the stomach contents of gray whales killed on the summer grounds. Zenkovich (1934*a*, 1934*b*, 1937*c*) and Tomilin (1937) examined 104 and 54 stomachs, respectively, of whales taken in the Bering and Chukchi Seas from August to October. They did not publish quantitative data, but reported finding mostly gammaridean amphipods, of which were listed the following forms: Family Ampeliscidae—*Ampelisca macrocephala*; family Aoridae—*Lembos arcticus*; family Lysianassidae—*Anonyx nugax* and an unidentified species; family Haustoriidae—*Pontoporeia femorata*; family Eusiridae—*Eusirus* sp.; family Atylidae—*Atylus* sp.; family Gammaridae—unidentified species.

Ampelisca macrocephala predominated in the stomachs of whales killed in the Chukchi Sea and northern Bering Sea, whereas a species of Atylidae, apparently *Atylus carinatus,* predominated in those from along the coast between Natal'inskiy Bay and Cape Navarin. In addition to amphipods, several stomachs contained a few bottom-dwelling isopods, mysids (*Mysis oculata*), mollusks (*Buccinum* sp.), polychaetes (*Travisia forbesi*), and hydroids (Sertulariidae).

Pike (1962*a*) examined samples of the stomach contents of two gray whales killed by Eskimos off St. Lawrence Island in May and June. He found mostly the amphipods *Ampelisca macrocephala* and *A. eschrichti,* and a few *Anonyx nugax*; other items recorded were decapod crustaceans (including *Chionoecetes bairdi, Hyas coarcticus,* and *Liocyma fluctuosa*), cumaceans, polychaete (*Pectinaria* sp.) tubes, gastropods, and ascidians.

We examined a sample (collected by F. H. Fay) of the stomach contents of an immature female gray whale killed by Eskimos about 9 kilometers southwest of the village of Gambell, St. Lawrence Island, Alaska, in water about 30 meters deep. The sample of about 1 liter was a composite of random samples from several parts of the total contents of the stomach. More than 95 per cent of the sample consisted of gammaridean amphipods, ranging from less than 6 to more than 25 millimeters in length. A few other invertebrates were present. Following is a complete list of the species identified. Classification of amphipods at the level of family and genus follows Barnard (1969). The numbers of each species of amphipod identified are given in parentheses, but they do not necessarily represent the proportion of each species in the total sample.

- CLASS CRUSTACEA
  - Order AMPHIPODA
    - Family Lysianassidae
      - *Anonyx* sp. (16)
      - *Hippomedon ?minusculus* (1)
      - *Hippomedon* cf. *abyssi* (4)
      - *Orchomene minuta* (12)
    - Family Phoxocephalidae
      - *Paraphoxus ?milleri* (3)
    - Family Ampeliscidae
      - *Ampelisca macrocephala* (*ca.* 85)
      - *Ampelisca* sp. (fragments)
    - Family Pleustidae
      - *Pleustes* sp. (2)
    - Family Oedicerotidae
      - *Acanthostepheia malmgreni* (6)
    - Family Atylidae
      - *Atylus bruggeni* (1)
    - Family Isaeidae
      - *Protomedeia grandimana* (1)
    - Family Ischyroceridae
      - *Ischyrocerus latipes* (1)
    - Family Podoceridae
      - *Dulichia* cf. *knipowitschi* (1)
  - Order CUMACEA
    - *Diastylis bidentata*

- CLASS POLYCHAETA
  - Unidentified tube

- CLASS HOLOTHUROIDEA
  - Unidentified holothurian

- CLASS TUNICATA
  - Order ASCIDIACEA
    - ? *Phallusia* sp.
  - Order THALIACEA
    - ? Salps (attached to polychaete tube)

All of the organisms found in the stomachs of gray whales killed on the Arctic summer grounds are typically infaunal benthic species, that is, they burrow or live buried in the bottom sediments. *Ampelisca macrocephala*, the species most commonly eaten, is a large amphipod about 25 millimeters long. A study of its life history has been published by Kanneworff (1965). In the Bering and Chukchi Seas, *A. macrocephala* occurs mainly on sandy bottoms at depths of 5 to 300 meters (Gur'yanova, 1955).

Most of the amphipods in our sample were adult females, which are rarely found above the substratum during the day, although they form an appreciable part of the planktonic population at night; males alone tend to be pelagic during the day (E. L. Bousfield, personal communication).

In addition to food items, there was a considerable amount of fine gray sand or silt mixed with the stomach contents of the whale from St. Lawrence Island that we examined. Such extraneous material has also been recorded by other authors. Pike (1962*a*) found sand, silt, and bits of wood in the two samples he examined, and Zenkovich (1937*a*) found quantities of pebbles, as much as "2–3 pails," in many stomachs. Tomilin (1937) also reported finding silt, pebbles, and a large cobblestone, in addition to kelp leaves.

In northern California, Howell and Huey (1930) found a quantity of *Euphausia pacifica* in the baleen of a gray whale killed on 21 July 1926; they did not examine the stomach. This euphausiid is the chief food of rorquals in the waters off California.

The occasional infestation of gray whales with parasites that probably require fishes as intermediate hosts (see discussion of parasites in a later chapter) suggests that they sometimes eat fish.

DURING MIGRATION.—Our data confirm the reports by other authors (Andrews, 1914; Pike, 1962*a*; Scammon, 1874) that the stomachs of migrating gray whales are almost invariably empty. Stomachs of all 180 southbound migrants and those of 134 of the 136 northbound migrants examined contained no traces of food, and the intestines contained only small amounts of a thick greenish fluid, apparently bile and mucosal secretions. One of the two specimens containing food was an anestrous female taken on 20 March 1964. Its stomach contained about 20 liters of the zoea stage larvae of the littoral crab *Pachycheles rudis* (Anomura, Porcellanidae) and a few brachyuran zoeae, probably of the genus *Fabia* (Brachyura, Pinnotheridae). The other animal was an immature female taken on 11 April 1968. Its stomach contained about 50 liters of the zoea stage larvae of a pinnotherid crab, probably the same species found in the preceding specimen, and a few scattered porcellanid zoeae, which were in too poor condition to identify further.

Migrating whales sometimes have gravel and other miscellaneous items in their stomachs. We found almost a kilogram of gravel in the stomach of one southbound, recently-ovulated female; mixed with the gravel were numerous ascidian tunics, fragments of hydroid stems and polychaete worm tubes, a few gastropod opercula, one pelecypod shell, and two tiny fragments of waterlogged wood. A late pregnant female had several liters of hydroid stems and a few polychaete tubes in her stomach, but no gravel or sand. The stomachs of two immature males collected during the northward migration each contained about 10 kilograms of gravel. The stomach of an early pregnant female contained about 100 kilograms of gravel in which were a few polychaete tubes, hydroid stems, and a small bit of waterlogged wood. A northbound immature female contained about 50 kilograms of sand and silt. The stomachs of several other animals contained traces of sand and gravel. Andrews (1914) found pebbles in the stomachs of two southbound migrants taken off Korea. Gravel and sand are probably ingested accidentally while the whale is feeding.

WINTER.—Scammon (1874) appears to have been the only person to examine the stomachs of animals taken in the calving lagoons. He examined "several" and found no food—only a small quantity of vegetable matter that was no doubt accidentally ingested.

According to Matthews (1932), Norwegian whalers found gray whales feeding on the "red crab," *Pleuroncodes planipes* (Anomura, Galatheidae), at Bahia Magdalena, Baja California, in 1926. He did not indicate whether this was ascertained by actual examination of stomachs. The red crab exists in both a benthic and pelagic phase (Boyd, 1967) and at times is extremely abundant off the western coast of central and southern Baja California. We found red crabs so abundant in Bahia Magdalena on the night of 6 February 1965 that they formed a continuous, tightly packed layer on the surface, evidently attracted by the lights of our anchored vessel. On 1 March 1967, we passed through many dense shoals of these crabs, each a few meters wide and up to half a kilometer long or longer, just inside the 180-meter isobath about 45 km. SW Punta Abreojos. However, we never saw gray whales that appeared to be feeding on red crabs. *Pleuroncodes* apparently does not occur in Laguna Ojo de Liebre. According to Matthews (1932), Norwegian whalers noticed that the blubber oil obtained from "sei" whales (*Balaenoptera borealis* or *B. edeni*) on the Mexican coast was yellowish; he suggested that this was due to their feeding on *Pleuroncodes.* We have found that the blubber of gray whales is often yellow or orange during both the southward and northward migrations. A similar variation in blubber color was noted by Andrews (1914) in northbound Korean whales and by Zenkovich (1934*a*) in summer-taken specimens from the Bering Sea.

There is only one report on the stomach contents of gray whales on or near the wintering grounds in the western Pacific (Mizue, 1951). Two individuals killed in the northern waters of the Yellow Sea in May 1922 contained *Nephrops thomsoni,* a small benthic anomuran decapod similar to *Pleuroncodes.* These whales were taken unusually late in the spring and probably somewhat outside the normal range.

Seasonal Changes in Nutritive Condition

During southward migration, gray whales are fat, whereas during northward migration they are much thinner. Quantitative information on nutritive condition is provided by body weight, blubber thickness, and oil yield.

BODY WEIGHT.—We calculated and compared body weights of gray whales on southward and northward migrations, and attempted to estimate metabolic rate to determine if the difference between the two periods is sufficient to account for energy requirements in winter.

Weights and lengths of nine gray whales are given in Table 2. To calculate weights of other whales that could not be weighed, we used the formula $W = aLG^2$, where W = weight in kilograms, L = length in meters, and G = maximum girth in meters. The

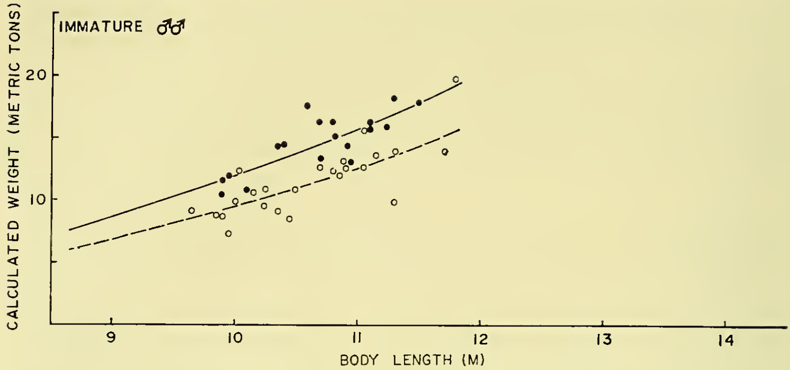

FIG. 4. Comparison of calculated weights of immature male gray whales during the southward and northward migrations. Solid circles and unbroken line indicate southbound migrants; open circles and broken line indicate northbound migrants.

value of *a* was derived from the seven gray whales of known weight, length, and girth (Table 2); this ranged from 32 to 44. The limited data suggest that *a* and body length are not correlated. This lack of correlation is not unexpected, as there is virtually no change

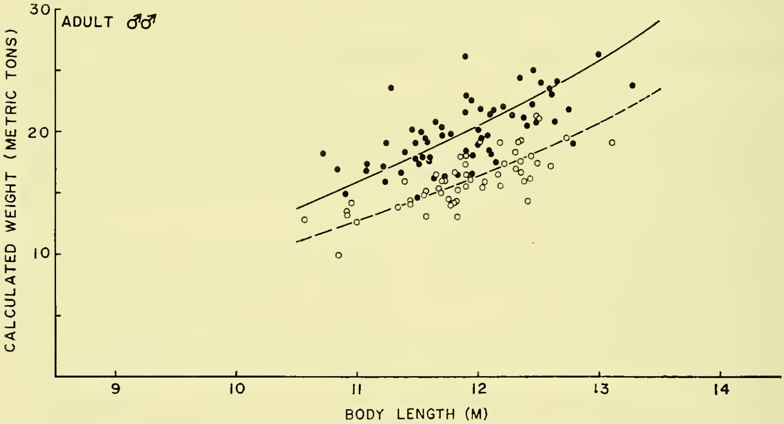

FIG. 5. Comparison of calculated weights of adult male gray whales during the southward and northward migrations. Solid circles and unbroken line represent southbound migrants; open circles and broken line represent northbound migrants.

TABLE 2

WEIGHTS AND MEASUREMENTS OF NINE GRAY WHALES. UNLESS OTHERWISE NOTED SPECIMENS WERE COLLECTED IN PRESENT STUDY.

Sex	Age	Date	Body length (meters)	Girth (meters)	Weight[1]		Value of *a*[5]
					Kilograms	Pounds	
♀	Fetus	20 January 1968	4.75	2.15	(409)	901	41

in body proportions with increasing length. We have used the mean value of 38. Estimates of percentage weight loss are independent of the value of *a* used.

The calculated weights of all whales (except for seven for which there were no comparable girth measurements) classified according to sex, age, and reproductive status, are plotted against body length in Figs. 4 to 8. Each class of southbound migrants is compared with the corresponding class of northbound migrants. Within each class, weight was closely correlated with length to the third power (in other words, there was no change in relative girth with increase in length), so we calculated mean weight-length curves for each class with the equation $W = bL^3$. The value of b was calculated from the formula

$$b = \frac{\Sigma (G/L)^2}{N} a.$$

The mean absolute weights of whales of any given length during their southward and northward migrations may thus be compared. Their relative weights are simply a function of G^2.

The total weight loss of gray whales between the southward and northward migrations varied from 11 to 29 per cent and was correlated with elapsed time (Table 3). Weight loss per day varied from 0.21 to 0.37 per cent. Weight lost by postpartum females is, of course, not entirely attributable to metabolism. The fetus and fetal membranes and fluids probably account for about 2000 kilograms. The nutritive condition and energy requirements of pregnant and postpartum females are discussed beyond.

To determine if the observed weight loss is sufficient to account for energy requirements during the 54 to 85 days elapsing between the southward and northward migrations past San Francisco, it was necessary to estimate the metabolic rate. For simplicity, we have estimated the metabolic rate of a near-average gray whale weighing 20 metric tons on the basis of oxygen consumption and have assumed that the number of kilocalories per day per kilogram of body weight expended is the same for all whales regardless of body length. This assumption is open to question, but more data are required before more refined estimates of metabolic rate can be made.

No data are available on the lung volume of gray whales. As the relative size and shape of the lungs are similar to those of fin whales, we have used Scholander's (1940) measurements of 800, 1500, and 2000 liters for the lung capacity of three fin whales 15.2, 20.7, and 22.0 meters long, respectively, as a basis for estimating a value for the gray whale. His estimates of the body weights of these whales were too high, so we used Ash's (1952) formula to recalculate the weights as 20, 49, and 58 metric tons, respectively. The mean lung capacity in liters is thus equal to 3.5 per cent of the body weight in kilograms. A 20-ton whale would, therefore, have a lung capacity of 20,000 by 0.035, or 700 liters. The volume

[1] See text for explanation.

of tidal air may be estimated at 80 per cent, as Irving *et al.* (1941) found in *Tursiops truncatus,* giving an estimate of 560 liters per breath. Oxygen utilization may be estimated at 10 per cent of tidal volume, based on *Tursiops* (Irving *et al.*, 1941), giving an estimate of 56 liters of oxygen per breath. As a gray whale breathes about once a minute, it uses an estimated 80,640 liters of oxygen per day, or 0.17 cubic centimeters per gram per hour. Since 1.99 liters of oxygen are required to oxidize 1 gram of fat (Bishop, 1950), 80,640 liters is sufficient to oxidize 41 kilograms or 0.20 per cent of the animal's body weight per day.

Oxidation of 1 gram of fat produces 9.54 kilocalories (Bishop, 1950), so the whale will produce about 3.8 by 10^5 kilocalories per day or 19 kilocalories per kilogram per day. This estimate of the metabolic rate is lower, on the basis of kilocalories per kilogram of body weight, than that of smaller mammals, but lies above Benedict's (1938) "mouse-to-elephant" curve. His curve gives a value of 70 times $20{,}000^{0.75}$, or about 1.2 times 10^5 kilocalories per day for a 20-ton animal. It should be noted, however, that our estimate cannot be considered a basal rate, because it is based on the respiration rate of an actively swimming animal. In some other mammals, the energy expended over a 24-hour period ranges between 1.3 and 4.0 times the basal rate, and for animals performing a moderate amount of work the average is approximately three times the basal rate (Brody, 1945). On this basis, the metabolic rates of large whales do not appear to be far above the "mouse-to-elephant" curve (see Kanwisher and Sundnes, 1966).

Blubber Thickness.—The thickness of the blubber has long been about the only measurement that has been used as an indicator of the nutritive condition of large whales (Slijper, 1954). Blubber thickness of gray whales was not correlated with body length, so we have used absolute measurements in our analysis. All sex and age classes of gray whales showed a slight decrease in blubber thickness between the southward and northward migration (Table 4), but this decrease was not statistically significant ($P > .05$) for any class.

Blubber thickness is less sensitive than girth as an indicator of the nutritive condition of gray whales. The reduction of girth reduces body surface area, and thus tends to make the blubber

TABLE 4

Comparisons of Blubber Thickness of Gray Whales During Migration Periods.

Age, sex, and reproductive status	Number	Blubber thickness (cm)	
		Mean ± SE	Range
Immature males			
Southward	17	12.8 ± 0.3	10.5–15.0
Northward	25	12.6 ± 0.3	9.5–16.0
Adult males			
Southward	66	13.5 ± 0.2	9.5–17.5
Northward	44	12.8 ± 0.2	10.5–16.0
Immature females			
Southward	11	14.4 ± 0.4	12.5–16.5
Northward	23	12.8 ± 0.4	8.0–17.0
Adult females			
Southward (recently ovulated)	27	15.7 ± 0.4	10.5–20.0
Northward (early pregnant)	22	15.2 ± 0.4	10.0–18.5
Northward (anestrous)	8	13.3 ± 1.1	9.5–19.0
Southward (late pregnant)	53	15.7 ± 0.2	12.5–19.0
Northward (postpartum)	2	14.5	10.0–19.0

thicker. It was apparent to us while examining the viscera of southbound and northbound migrants that weight loss is due more to utilization of body fat than to utilization of blubber.

Oil Yield.—The oil yield of the carcass is probably the most reliable indicator of nutritive condition, but such data are not available for individual gray whales. The mean estimated body weight and mean yields of oil, meal, and meat from southbound whales were two and one-half to three times those of northbound animals (Table 5). The southbound sample consisted mostly of adult females carrying near-term fetuses; the northbound sample consisted mostly of males, and included many immature animals. The cubic mean length of the southbound whales was 12.62 meters, whereas that of the northbound animals was 11.23 meters. Quantities of each product were also affected by the relative amount of meat salvaged from each carcass. The remainder of each carcass was rendered for oil and meal. The difference between calculated body weight and total weight of oil, meal, and meat may be attributed to water loss during rendering of the oil and drying of the meal. Inasmuch as the samples are heterogeneous as regards

TABLE 5

MEAN WEIGHTS OF OIL, MEAL, AND MEAT PRODUCED FROM GRAY WHALES TAKEN IN SOUTHWARD AND NORTHWARD MIGRATIONS. MEAN CALCULATED BODY WEIGHT OF 26 SOUTHBOUND WHALES WAS 31,662 KILOGRAMS AND THAT OF THE 26 NORTHBOUND WHALES WAS 12,861 KILOGRAMS.

	Southward migration		Northward migration	
Products	Kilograms	Per cent	Kilograms	Per cent
Oil	7,559	39.6	2,496	38.1
Meal	6,834	35.8	2,520	38.5
Meat	4,689	24.6	1,533	23.4
Total	19,082	100.0	6,549	100.0

sex, age, and reproductive status, they are not directly comparable, but they do show the great difference in body weight between southbound and northbound migrants. The ratio of oil to meal also indicates a moderate decrease in relative oil yield between the southward and northward migrations.

Discussion and Conclusions

The predominance of gammaridean amphipods, especially *Ampelisca macrocephala,* among stomach contents indicates that gray whales, unlike other baleen whales, are primarily, if not exclusively, bottom feeders. The poor representation of polychaete worms and mollusks, which are usually dominant in the infauna, suggests that gray whales are selective feeders. Perhaps they stir up the bottom sediments with their snouts, then filter the turbid water immediately above the bottom from which the heavier mollusks have settled out. The worms presumably retreat deep into their tubes and burrows, whereas the amphipods, freely swimming, are trapped in the baleen plates. The occurrence of sand, silt, and gravel in the stomachs provides further evidence that gray whales feed on the bottom. In the Chukchi Sea, several observers (Pike, 1962*a*; Scammon, 1874; Wilke and Fiscus, 1961) have reported seeing gray whales, presumably feeding, surfacing with muddy snouts. Greater wear of the baleen on the right side suggests that gray whales swim on their right side while feeding (Kasuya and Rice, 1970). Fin whales (Gunther, 1949), Bryde's whales, *Balaenoptera edeni* (Rice, field notes), and humpback whales (Andrews, 1909) swim on their sides when feeding near the surface. Swimming on their side permits whales to turn more easily in the horizontal plane.

While migrating, gray whales apparently rarely attempt to feed, at least along the southern sector of their migration route. What little evidence is available also indicates that gray whales seldom, if ever, feed while on the winter grounds. A calculated weight loss of 0.21 to 0.37 per cent of body weight per day between the southward and northward migration past San Francisco exceeds the hypothetical value of 0.20 per cent per day based upon their estimated metabolic requirements. Thus, there is no reason to assume that gray whales must feed while on the winter grounds. This conclusion may not apply to females with calves, however, as we have no data for them.

AGE AND GROWTH

Age Determination

No gray whales of known age have been studied. Age must be deduced from indirect evidence and by analogy with other species of baleen whales. Jonsgård (1969) reviewed methods of determining the ages of cetaceans. Three criteria appeared promising for determination of age in gray whales. These are the number of growth layers in the ear plugs, corpora albicantia in the ovaries, and growth zones in the baleen plates.

Ear Plugs.—In balaenopterid whales, the number of growth layers in the ear plug is generally considered to be the most useful indicator of age (Purves, 1955; Laws and Purves, 1956). Each layer consists of one light and one dark lamina. There has been controversy, however, over the correlation between number of growth layers and absolute age. Data on ear plugs collected from fin whales marked more than 25 years previously, and several independent lines of indirect evidence, support the hypothesis that only about one growth layer is formed each year, at least in sexually mature fin whales (Ohsumi, 1964*a*). Ichihara (1966) provided evidence suggesting that in immature fin whales the rate of accumulation of ear plug laminae is irregular, varying from one to two annually, with a mean of one and one-half. Roe (1967*a*, 1967*b*), however, on the basis of histological examination of the ear plugs of fin whales collected in all months of the year, concluded that one growth layer is produced each year in both immature and adult whales of both sexes. He found that the light laminae are formed in summer and the dark laminae in winter. He also noted that the ear plugs of immature whales usually have minor laminae similar to but much thinner than the normal laminae; their significance is obscure, but he concluded that they should not be included in lamina counts for age determination.

Ear plugs of gray whales (Figs. 9–11) are soft, especially in the smaller animals, and difficult to remove without distortion or breakage. Some of the plugs have a fibrous, columnar, or amorphous

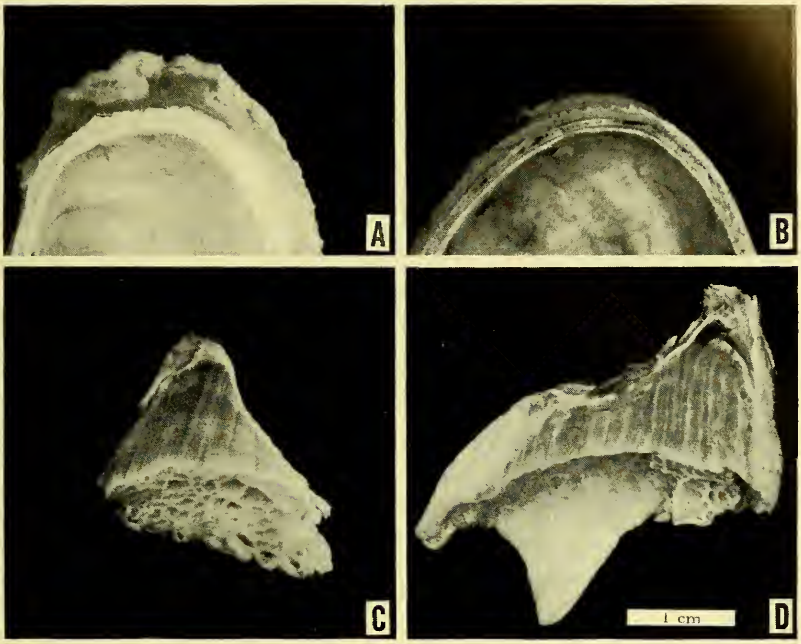

FIG. 9. Ear plugs of immature gray whales bisected longitudinally. A, 9.8-meter male, estimated age one year (attached to the "glove finger" of the tympanic membrane); B, 8.6-meter female, estimated age one year (attached to "glove finger"); C, 10.1-meter male with three growth layers; D, 11.3-meter female with six growth layers. All plugs are to same scale.

structure in which no laminae can be discerned. In the remaining plugs, laminae are vaguely to moderately well defined. Readable ear plugs were obtained from only 100 (60 per cent) of 166 males and 68 (45 per cent) of 150 females. On the better plugs, repeated counts of the laminae were consistent to within plus or minus 10 per cent of the total count. Males more often show regular laminae than do females, presumably because the annual physiological rhythm of females is modified by their longer and more irregular reproductive cycle.

The ear plug laminae are broad and poorly defined in immature whales but narrow and more sharply defined in adults. In many plugs from mature gray whales, the laminae are clear in the basal portion but indistinct or absent in the distal portion. This dif-

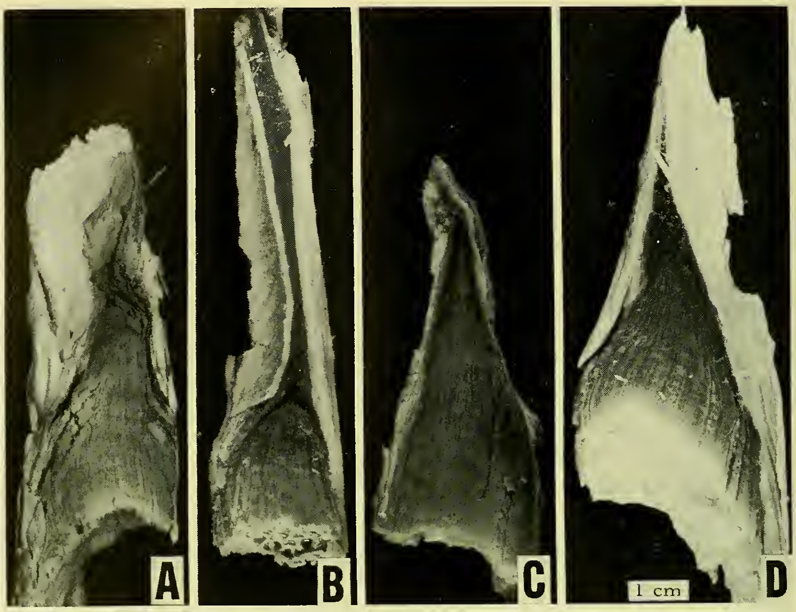

Fig. 10. Ear plugs of adult gray whales bisected longitudinally. A, 11.7-meter male with 11 growth layers; B, 11.4-meter female with 14 growth layers; C, 12.8-meter female with 18 growth layers; D, 12.3-meter male with 21 growth layers. All plugs are to same scale.

ference in the two regions suggests that the laminae laid down during immaturity may disappear as the plug grows. Another possible explanation—that some animals do not begin to produce clear laminae until they attain sexual maturity—appears unlikely, because the proportion of readable plugs was higher in immature than in mature whales (65 compared to 59 per cent in males and 56 compared to 42 per cent in females).

We found no ear plugs in several near-term fetuses that we dissected, and found no individuals with only one growth layer in the ear plugs. The smallest animals collected, 8.63 to 10.34 meters long, had two growth layers. We assumed that most of these animals were yearlings, and that the first layer forms during the nursing period and the second in late summer after weaning. As a working hypothesis, we assumed that each subsequent growth layer represented one year of growth in both immature and mature whales

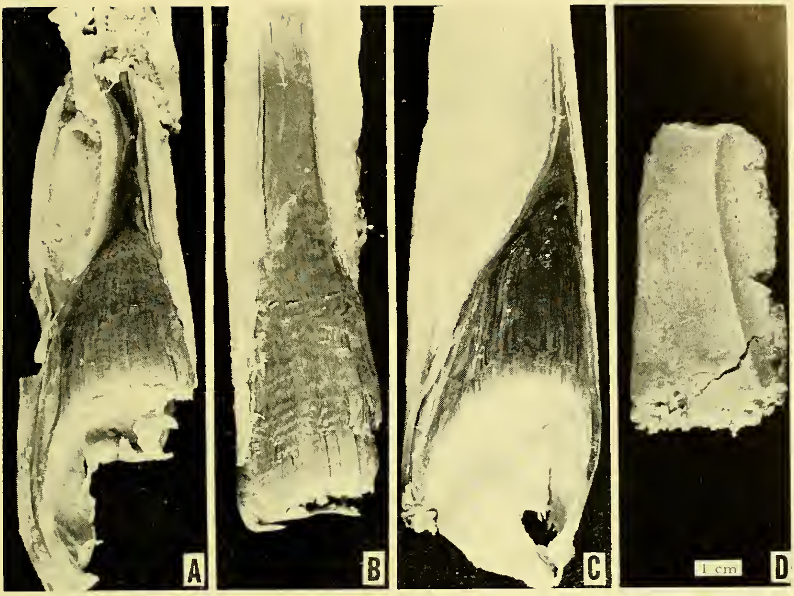

FIG. 11. Ear plugs of adult gray whales. A, 11.7-meter male with 23 growth layers; B, 12.5-meter female with 24 growth layers; C, 12.5-meter male with 40 growth layers; D, 11.7-meter male with amorphous plug showing no growth layers. All plugs are to same scale.

This interpretation is consistent with our estimate of the rate of accumulation of corpora albicantia in the ovaries (see discussion of reproductive cycle beyond). As it appears that two layers are formed the first year, the age of a whale in years should be one less than the number of growth layers in its ear plug. If, as suggested above, the earlier layers disappear in older animals, the count of growth layers provides only a minimum estimate of age.

OVARIES.—As the ovulation rate appears to be regular at about 0.50 per year, and the corpora albicantia remain permanently visible in the ovaries, the number of corpora in the ovaries provides a reliable estimate of the number of years elapsed since a female attained puberty. The mean age at puberty appears to be about 8 years (see below). Therefore, the age of a recently ovulated or early pregnant female is about twice the number of corpora (including

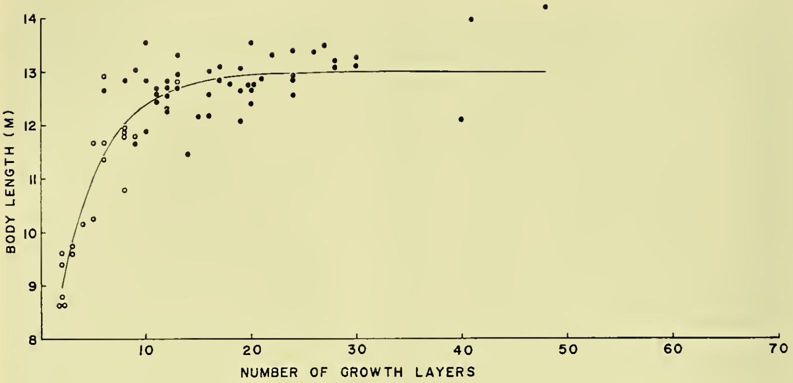

FIG. 12. Body length in relation to number of growth layers in ear plugs of female gray whales (open circles, immature females; solid circles, adult females; line, von Bertalanffy growth curve).

the corpus luteum) in her ovaries plus 6 years, and that of a late pregnant or postpartum female twice the number of corpora plus 7 years.

BALEEN PLATES.—Ruud (1940, 1945) found that the growth of baleen plates of blue (*Balaenoptera musculus*), sei (*B. borealis*), and fin whales is characterized by seasonal changes in thickness and that the pattern of variation in thickness can be used to estimate the age of the whales (see van Utrecht-Cock, 1965). Because of constant wear, there is rarely more than 5 or 6 years of growth present in a baleen plate. Thus this method is useful only for young whales.

Baleen plates of most gray whales show moderately well-defined "steps," or growth zones, each of which presumably represents one year of growth. None of the baleen plates we examined showed more than four growth zones, regardless of the age of the whale as estimated from the ear plugs. The number of growth zones in the baleen plates of most whales was less than the number of growth layers in the ear plug, and in no specimen was it greater. It thus appears that wear on the baleen plates of the gray whale is more rapid than in other baleen whales, probably because of greater abrasion resulting from bottom-feeding habits.

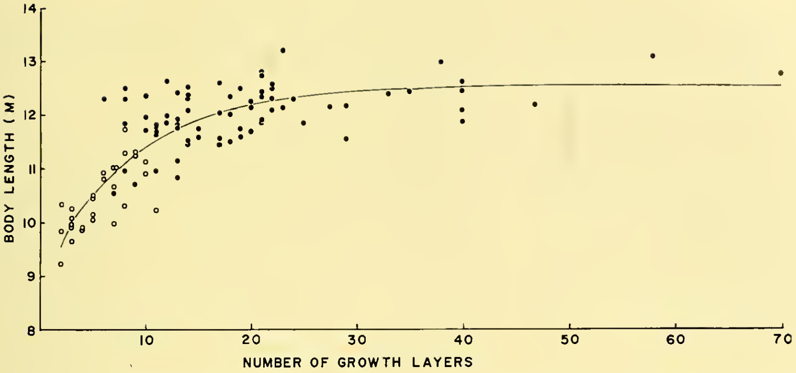

FIG. 13. Body length in relation to number of growth layers in ear plugs of male gray whales (open circles, immature males; solid circles, adult males; line, von Bertalanffy growth curve).

Growth

The external morphology and osteology of the gray whale have been described in detail by Andrews (1914), Zenkovich (1934*a*), and Tomilin (1957). Further data on growth in length, ontogenetic changes in body proportions, and sexual dimorphism were obtained in this study.

LENGTH.—Body lengths of males and females one year old and older have been plotted against the number of growth layers in the ear plugs in Figs. 12 and 13. Growth curves for each sex were calculated by using the von Bertalanffy equation (von Bertalanffy, 1938; Beverton and Holt, 1957) as follows: $l_t = L_\infty \, [1 - e^{-K(t-t_0)}]$, where l = body length in meters, L_∞ = asymptotic body length, K = rate at which length approaches the asymptote, and t = time in years. The results are given below (mean and standard deviation).

Females			Males		
L_∞	= 12.97	± 0.11	L_∞	= 12.43	± 0.12
K	= 0.246	± 0.035	K	= 0.141	± 0.021
t_0	= −2.842	± 0.772	t_0	= −8.346	± 1.721

It should be emphasized that because of the small sample sizes and the difficulty of reading ear plugs these curves are not com-

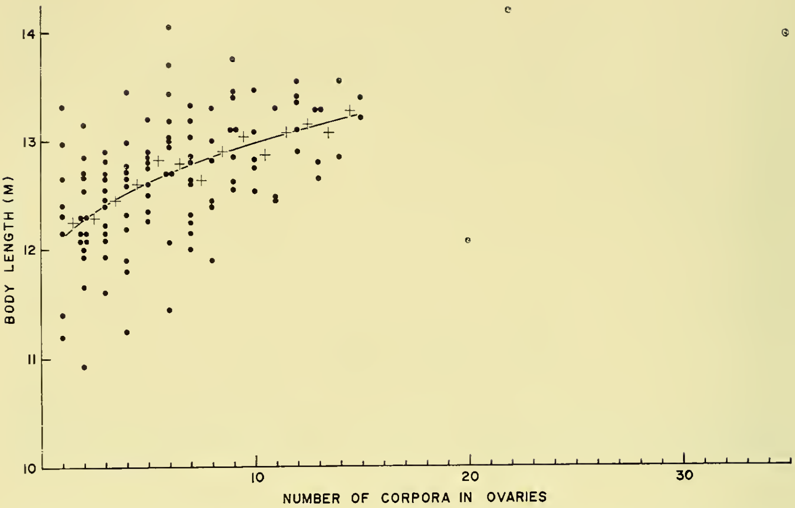

FIG. 14. Body length in relation to number of corpora albicantia and corpora lutea in ovaries of adult female gray whales. Crosses are running means of two; growth curve fitted by eye to mean values.

pletely reliable. The samples of the younger age groups are biased in favor of the larger individuals. Furthermore, possible disappearance of some ear plug laminae in older animals may have resulted in the estimated mean length at any given age being greater than the true mean.

In Fig. 14, the body length of adult females has been plotted against the number of corpora in the ovaries and a curve fitted by eye to the running means of two. This curve is probably a more accurate representation of the growth characteristics of adult females than the von Bertalanffy curve.

From a mean length at birth in January of about 4.9 meters, calves grow to a mean length of about 8.5 meters at weaning in August and to 9.3 meters by the following winter. With this first annual increment of 90 per cent of neonatal size, the females attain 66 per cent of their ultimate body length and the males 72 per cent. The growth rate drops to 7 per cent during the second year and continues to decline in subsequent years, but growth continues until at least about 30 years of age.

TABLE 6

BODY PROPORTIONS (EXPRESSED AS PERCENTAGE OF TOTAL BODY LENGTH) OF NEAR-TERM FETUSES AND POSTNATAL GRAY WHALES. SEE TEXT FOR DESCRIPTION OF MEASUREMENTS.

	Females				Males			
	Fetuses		Postnatals		Fetuses		Postnatals	
Measurement	*N*	Mean ± SD	*N*	Mean ± SD	*N*	Mean ± SD	*N*	Mean ± SD
Head length	17	22.4 ± 1.1	136	23.2 ± 1.0	25	22.5 ± 1.3	155	23.3 ± 0.9
Tail length	25	28.4 ± 2.4	147	30.3 ± 1.6	30	28.2 ± 2.6	167	29.7 ± 1.3
Fluke span	25	22.8 ± 1.8	120	24.3 ± 1.8	30	22.6 ± 1.8	138	24.9 ± 1.6
Fluke breadth	25	7.6 ± 0.6	141	7.3 ± 0.5	30	7.3 ± 0.6	152	7.3 ± 0.6
Flipper length	25	19.6 ± 1.0	147	17.3 ± 1.1	29	19.9 ± 0.8	166	17.8 ± 1.2
Flipper width	25	6.8 ± 0.5	144	6.5 ± 0.5	29	7.0 ± 0.4	166	6.7 ± 0.6

PROPORTIONS.—We have analyzed the following six body measurements to determine if body proportions change with age: (1) head length, (2) tail length, (3) span of flukes, (4) breadth of flukes, (5) length of flippers, and (6) width of flippers.

A comparison of these measurements (expressed as a percentage of body length) of near-term fetuses with those of postnatal whales (Table 6) shows that mean tail length increases from 28.2 to 29.7 per cent in males ($P < .05$) and from 28.4 to 30.3 per cent in females ($P < .001$). Relative flipper length decreases from 19.9 to 17.8 per cent ($P < .001$) in males and from 19.6 to 17.3 per cent ($P < .001$) in females. Fluke span increases from 22.6 to 24.9 per cent ($P < .005$) in males and from 22.8 to 24.3 per cent ($P < .01$) in females. Examination of near-term fetuses suggests that the apparent increase in relative fluke span does not represent differential growth, but instead is simply the result of postnatal abduction of the flukes in the horizontal plane from the adducted and folded position *in utero*. There are no significant age differences in relative head length, fluke breadth, or flipper width.

The magnitude of changes in body proportions of gray whales from one year of age to physical maturity also was examined. All postnatal animals of each sex were grouped into one-meter length classes. The mean and standard deviation of each measurement for each length class were calculated and the mean expressed as a percentage of total body length (Table 7). Only specimens for which all six measurements were available were included. For each series of measurements, we calculated the allometric equation $Y = bX^d$, where X = body length and Y = measurement being compared with X. The constant of allometry, d, does not differ significantly ($P > .05$) from unity for any of the series of measurements for either sex, indicating that body proportions change little after one year of age.

SEXUAL DIMORPHISM.—There was no significant difference between the sexes in body length of near-term fetuses. As noted above, females grow more rapidly after birth and average larger than males at any given age, as is true for all other species of baleen whales.

The data in Tables 6 and 7 reveal small but statistically significant postnatal differences between the sexes in some body proportions. Thus, males have longer flippers ($P < .01$) and shorter tails ($P < .01$) than females. There is no sexual dimorphism in number of throat grooves, baleen plates, or crenulations on the dorsal ridge of the caudal peduncle.

Puberty and Sexual Maturity

As ordinarily used by cetologists, puberty refers to the age at which gametes are first produced, and sexual maturity is the age at which the animal reaches its full reproductive power. For purposes of this study, any animal that had attained puberty is referred to as an adult.

Puberty in the female is indicated by the presence of a corpus luteum or at least one corpus albicans in the ovaries. Females are considered to be sexually mature at the onset of the first pregnancy. Evidence of sexual maturity thus is pregnancy, lactation, or the presence of mature but involuted mammary glands and a parous type uterus. In the female gray whale, attainment of puberty and sexual maturity usually coincide, but in five of 15 nulliparous and primiparous females, the presence of a corpus albicans (in one case, three corpora), in addition to a corpus luteum or recently ovulated follicle, indicated that they had attained puberty but had not conceived at least a year before their most recent estrous cycle.

Males are considered to be sexually mature when first capable of successfully impregnating females. It is impossible to make a distinction between puberty and sexual maturity in the male on

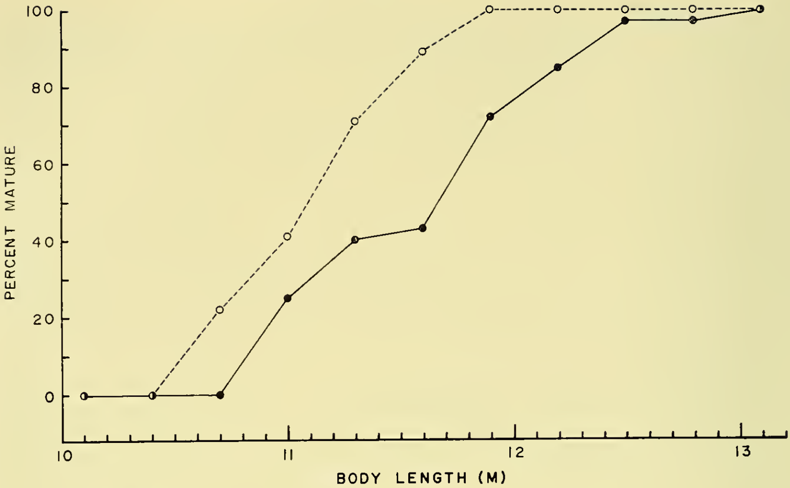

FIG. 15. Percentage of adult gray whales according to body length (grouped by 0.3-meter length classes). Open circles and broken lines represent males; solid circles and unbroken lines represent females.

the basis of our data. We determined the attainment of puberty by histological examination of the testes and regarded as adult all males whose testes showed evidence of spermatogenesis.

Fig. 15 shows that 50 per cent of the females have attained puberty by the time they reach a length of about 11.7 meters. The two smallest females that had reached puberty were 10.92 meters and 11.20 meters long; both were nulliparous and had recently ovulated for the first time. The smallest parous female was 11.24 meters long, whereas the largest immature female was 12.92 meters in length.

Fifty per cent of the males had attained puberty at a length of 11.1 meters (Fig. 15). The smallest male showing spermatogenic activity was 10.56 meters long, and the largest immature male was 11.75 meters long.

The age at puberty was estimated by plotting the percentage of animals that had attained puberty against the number of growth layers in the ear plug (Fig. 16). The mean number of growth layers at puberty was nine, giving an estimated age of 8 years. In both males and females, the fewest growth layers found in the ear plug

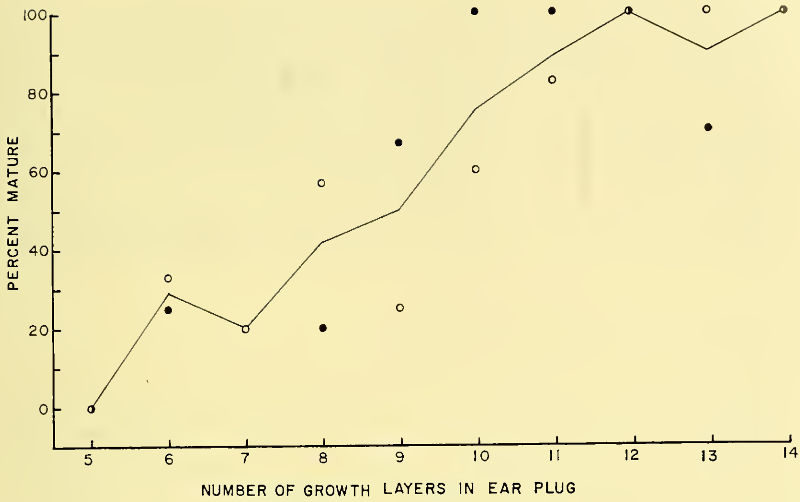

Fig. 16. Percentage of adult gray whales in relation to number of growth layers in ear plugs. Open circles represent males and solid circles represent females; line connects running means of three for both sexes combined.

of an adult animal was six, whereas the highest number in an immature animal was 11 (excepting one female with 13). On this basis, age at puberty is estimated to range from 5 to at least 11 years. Because of the difficulty of counting growth layers in ear plugs of immature animals, these figures may not be entirely reliable.

Physical Maturity

We collected few physically mature animals, as determined by the complete fusion of the vertebral epiphyses with the centra. Only two of the females examined fell in this class. They were 13.98 and 14.20 meters long. The smaller had 35 corpora in the ovaries and about 41 growth layers in the ear plugs, whereas the larger had 22 corpora and 43 laminae in the ear plugs. Physically immature females had 20 or fewer corpora and as many as 40 growth layers. Except for one individual with unreadable ear plugs that was 14.05 meters long, physically immature females were 13.75 meters or less in length.

Five males were regarded as physically mature. They ranged from 12.75 to 13.30 meters in length. The smallest had only 21 growth layers in the ear plug, whereas the others had 38 to 70 (the plugs of one were unreadable). Physically immature males did not exceed a length of 12.80 meters, except for one with 23 growth layers that was 13.23 meters long.

The largest reliably measured gray whales on record are males 14.3 meters long and a female 15.0 meters in length (Zenkovich, 1937*a*).

Discussion and Conclusions

Growth layers in the ear plugs have limited use for age determination in the gray whale because of uncertainty in counting them and because not all individuals have readable plugs. They provide a minimum estimate of age because laminae produced early in life may disappear in older whales. The number of corpora in the ovaries appears to be a more reliable method for age determination in adult females. Growth zones in the baleen plates are of little use for age determination because of the rapid wear of the plates.

Gray whales grow rapidly during their first year. Rapid initial growth is essential in large aquatic mammals that depend primarily on size for thermoregulation and protection from predators.

Between late fetal life and one year of age, relative length of the flipper decreases slightly and relative length of the tail increases slightly. There are no appreciable changes in body proportions from one year to physical maturity. The latter conclusion is contrary to the findings for blue whales and fin whales (Mackintosh and Wheeler, 1929; Ohsumi, 1960), sei whales (Matthews, 1938), humpback whales (Matthews, 1937), right whales, *Balaena glacialis* (Omura *et al.*, 1969), and bowhead whales, *Balaena mysticetus* (Eschricht and Reinhardt, 1866). In most of these species, as body length increases the head becomes relatively longer, the tail relatively shorter, and the flippers and flukes relatively shorter and narrower.

Sexual maturity is attained in both sexes at a mean age of 8 years (range, 5 to 11), at a mean length of 11.1 meters in males and 11.7 meters in females. This estimate of age at sexual maturity is in general agreement with estimates for fin whales (Nishiwaki *et al.*, 1958) and humpback whales (Chittleborough, 1959) that were based on counts of growth layers in the ear plugs. Physical maturity is attained at a mean length of about 13.0 meters in males and 14.1 meters in females, at a mean age of about 40 years. As in other baleen whales, females are larger than males. Sexual dimorphism in body proportions is slight, but males have slightly larger flippers and shorter tails than females.

FEMALE REPRODUCTIVE CYCLE

Reproduction in cetaceans has been reviewed by Harrison (1969), Rice (1967), and Slijper (1956, 1963). Our collection of 116 adult females included animals in four stages of the reproductive cycle (sample sizes in parentheses): southbound females that had recently ovulated (28); northbound females in early pregnancy (22); southbound females in late pregnancy (56, including one recently aborted individual); and northbound postpartum females (two, neither of which was lactating, apparently having lost their calves). In addition, eight northbound metestrous and anestrous females, which had failed to conceive, were included in the sample. Some anestrous females would also be expected on the southward migration, but none was collected in this study.

Where appropriate, the data on the 15 females undergoing their first reproductive cycle were analyzed separately from the data on the 101 females that had previously experienced one or more cycles. We defined a female as *nulliparous* if she has never given birth (or aborted) and was not visibly pregnant (although she may contain a macroscopically undetectable conceptus), as *primiparous* if she was in her first pregnancy or had given birth (or aborted) only once, and as *multiparous* if she had given birth (or aborted) at least twice or had given birth (or aborted) only once and was currently pregnant; *parous* refers to any female that had conceived at least once (North Pacific Fur Seal Commission, 1963). Nulliparous females and primiparous females in early pregnancy were recognized by the condition of the mammary glands and uterus as described below. Females in late pregnancy and postpartum females with a single corpus luteum and no corpora albicantia were obviously primiparous, and those with at least one corpus albicans in addition to the corpus luteum were regarded as multiparous.

Ovarian Cycle

The ovaries of the gray whale are morphologically similar to those of the fin whale (Laws, 1961; Mackintosh and Wheeler, 1929; Ommanney, 1932), and the humpback whale (Dempsey and Wislocki,

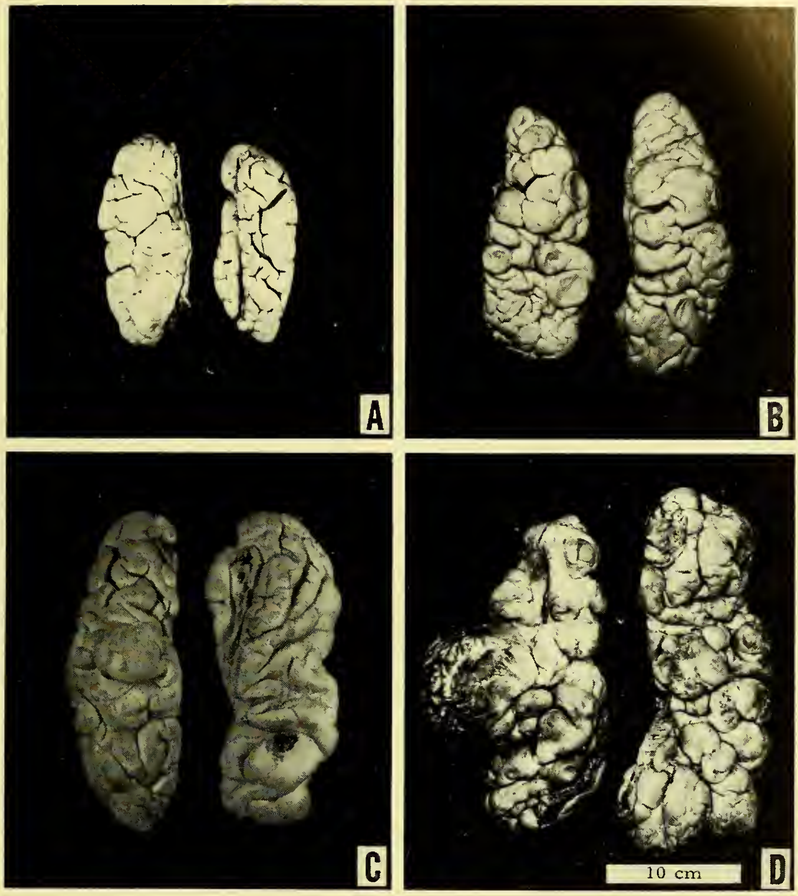

Fig. 17. Ovaries of gray whales showing various stages of ovarian cycle. A, 8.6-meter immature female with no large Graafian follicles; B, 11.2-meter immature female with enlarged Graafian follicles; C, southbound female with recently ruptured Graafian follicle in right ovary and corpus luteum of ovulation in left ovary; D, southbound, recently ovulated female with developing corpus luteum in left ovary. All ovaries are to same scale.

1941). They are elongate, flattened, and oval, with the anterior end slightly larger than the posterior end. Some are exceptionally long and narrow, being almost strap-shaped. The larger Graafian follicles and corpora albicantia protrude from the surface. Ovaries

representative of various stages of the reproductive cycle are shown in Figs. 17 to 20.

Ovary Weights.—There is no marked or consistent difference in weight between left and right ovaries. The mean weight of both ovaries of sexually immature females is plotted against body length in Fig. 21. In the smaller individuals, ovary weights range from 70 to 250 grams, with a mean of 136. At a body length of 11.2 to 11.4 meters, corresponding to an estimated age of about 5 years,

Fig. 19. Ovaries of gray whales showing various stages of the ovarian cycle. A, northbound, early pregnant female (90-millimeter fetus) with corpus luteum in left ovary; B, southbound late pregnant female (4.86-meter fetus) with corpus luteum in right ovary; C, northbound postpartum female (that had lost her calf) with regressing corpus luteum in left ovary; D, northbound anestrous female with large corpus albicans derived from the most recent corpus luteum in right ovary. All ovaries are to same scale.

ovarian weight increases abruptly to 250 to 550 grams (mean, 312), approximating that of younger sexually mature females.

The weight of the ovaries of sexually mature females is greatly increased when a corpus luteum is present. As most mature females

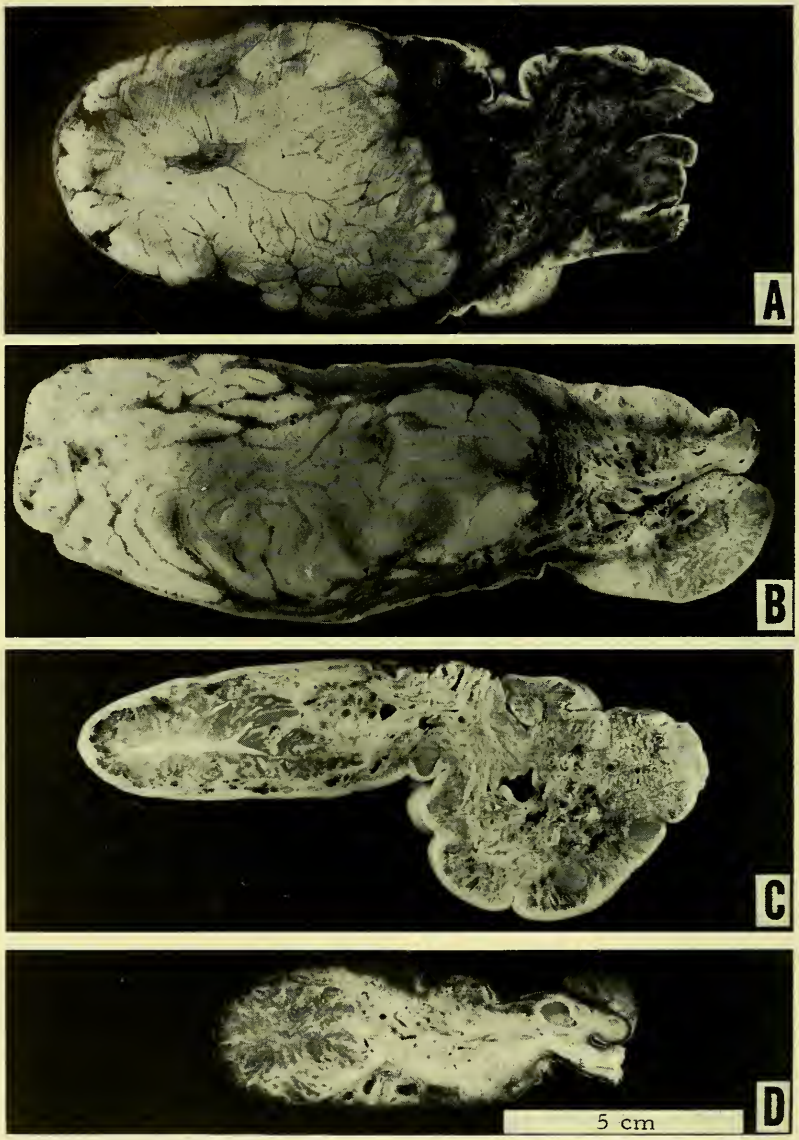

Fig. 20. Transverse sections through the most recent corpus in each pair of ovaries shown in Fig. 19. All sections are to same scale.

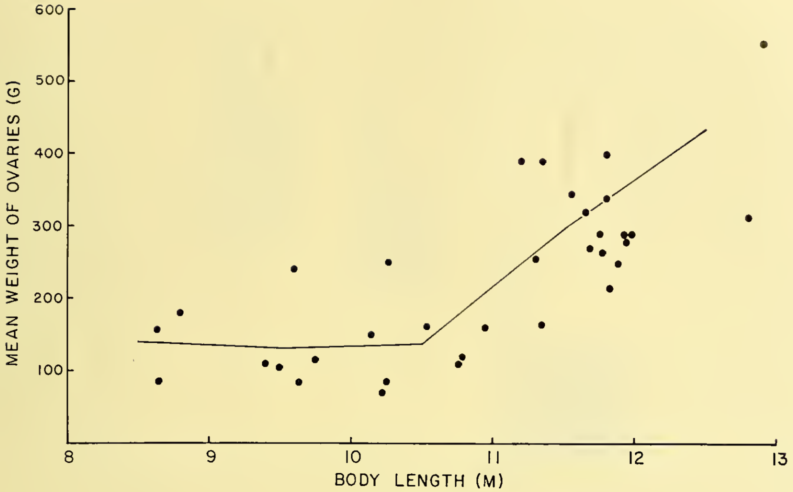

FIG. 21. Ovary weights of immature female gray whales plotted against body length. Line connects mean weights at one-meter length intervals.

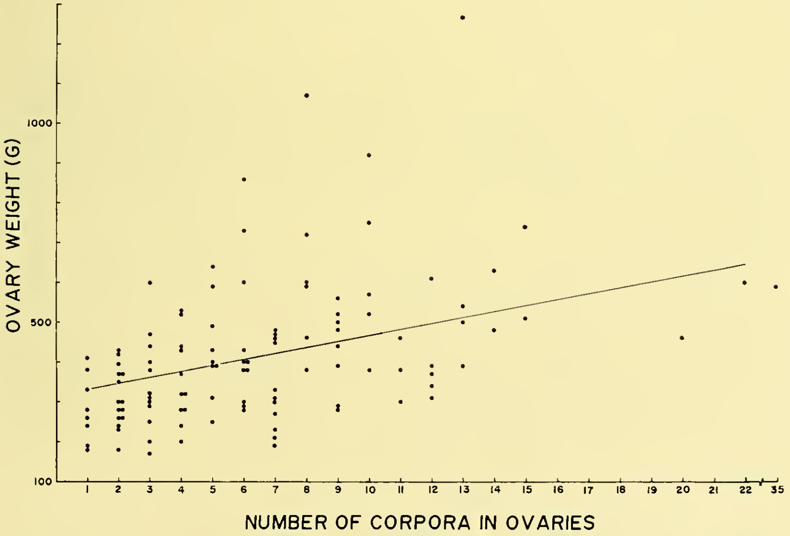

FIG. 22. Ovary weights of adult female gray whales plotted against number of corpora in ovaries.

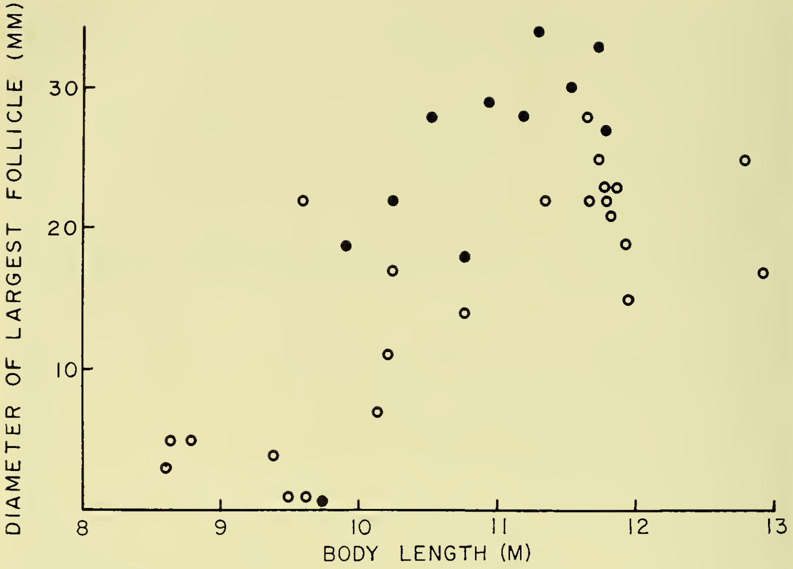

Fig. 23. Diameter of largest Graafian follicle versus body length of immature female gray whales. Solid circles indicate southbound migrants; open circles indicate northbound migrants.

had a corpus luteum in one ovary, we have used only the weight of the other ovary in making comparisons. For females without a corpus luteum, we have used the mean weight of the two ovaries. In Fig. 22, these weights are plotted against the number of corpora in both ovaries.

The weights of mature ovaries without a corpus luteum vary from 170 to 1270 grams. The regression of ovary weight on number of corpora is $Y = 316 + 15X$, where Y = ovary weight in grams and X = number of corpora. As the slope of this line differs significantly from zero ($P < .001$), ovarian weight apparently increases with age from a mean of 331 grams at puberty to 646 grams at an age of 50 years.

Follicles.—None of the follicles in the ovaries of immature females up to 9.6 meters long exceeded 7 millimeters in diameter; in all immature females longer than 10.2 meters, the largest follicle

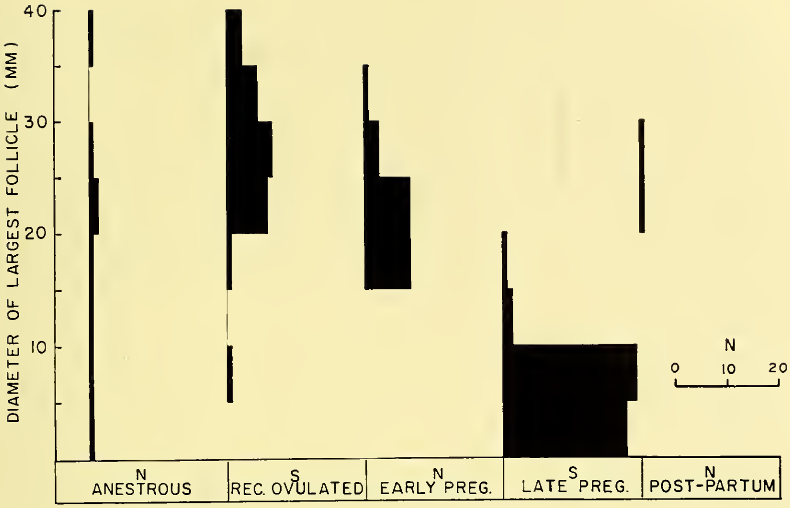

FIG. 24. Frequency distribution of diameter of largest Graafian follicle in ovaries of adult female gray whales in different phases of the reproductive cycle (N, northbound migrants; S, southbound migrants).

in either ovary exceeded 14 millimeters (Fig. 23). In the latter animals the largest follicles ranged from 18 to 34 millimeters (mean, 27) in southbound animals and from 14 to 28 millimeters (mean, 21) in northbound animals. These data suggest that females first begin to undergo a seasonal cycle of follicle-stimulating hormone secretion when they reach a length of between 9.6 and 10.2 meters at an estimated age of 2 or 3 years. Laws (1961) found a seasonal follicular cycle in immature fin whales. It should be noted that the follicles in these older immature females are significantly larger than those of late pregnant or postpartum females and slightly larger than those of northbound anestrous females. It is probable that the southbound immature females with follicles about 30 millimeters in diameter or larger (see below) are destined to ovulate for the first time later in the same season.

The size of the largest follicle in either ovary of adult females differs markedly in various phases of the reproductive cycle (Fig. 24). All southbound females not carrying near-term fetuses had recently ovulated. The largest follicle in these specimens ranged from 18 to 40 millimeters (mean, 28) in diameter (except for one nulliparous animal in which maximum follicle diameter was only 6 millimeters). Assuming that the largest follicle had ovulated, the biggest remaining follicle in these females would have been the second largest follicle just before ovulation. It thus appears that in gray whales the follicle exceeds 30 millimeters and may reach 40 before rupturing. Chittleborough (1954) found that the follicles of humpback whales exceed 30 millimeters before ovulation.

In the northbound early-pregnant females, the diameter of the largest follicles average less than two months earlier, ranging from 16 to 33 millimeters, with a mean of 22.

In strong contrast to females that had recently ovulated, southbound pregnant females carrying near-term fetuses had no greatly enlarged follicles. The largest follicle varied from 3 to 16 millimeters, with a mean of only 6. A female taken on 8 January that had apparently aborted recently likewise had no follicles larger than 6 millimeters. Such follicles are significantly smaller than those of anestrous females. The small size of follicles in late-pregnant females suggests that the progesterone secreted by the corpus luteum suppresses follicular maturation. Chittleborough (1954) found that the follicles of humpback whales in late pregnancy were smaller than those in anestrous animals. No such marked reduction has been found in blue whales and fin whales examined mostly during midpregnancy (Laws, 1961; Mackintosh and Wheeler, 1929; Nishiwaki and Oye, 1951).

In the two northbound females examined that were nonlactating and postpartum, the largest follicles were 24 and 29 millimeters in diameter. Their size suggests a resumption of follicular maturation after regression of the corpus luteum.

Northbound females that were neither pregnant nor postpartum had follicles ranging from 1 to 37 millimeters (mean, 18) in diameter. In three of these females that had recently ovulated, the largest follicles ranged from 14 to 37 millimeters, with a mean of 24. These approximate maximum follicle sizes of southbound females that had recently ovulated and were presumably pregnant. These three females probably should be regarded as being in metestrus. Five anestrous females that had not ovulated recently had follicles with maximum diameters of 1 to 25 millimeters, with a mean of 14.

This size range is probably closest to that of follicles of fully anestrous females.

Nine pairs of ovaries contained one to several thin-walled, fluid-filled cysts up to about 8 centimeters in diameter. Presumably, these are cystic follicles.

FREQUENCY OF OVULATION.—Nonpregnant adult females regularly ovulate in late November and early December (see discussion of gestation period and fetal growth beyond), while still north of central California on the southward migration. All of the adult females collected in southward migration that were not carrying near-term fetuses had recently ovulated, as revealed by the presence of recently ruptured follicles or developing copora lutea. The mean number of recent ovulations in these females was 1.14 for nulliparous animals and 1.10 for parous animals (Table 8). It is possible that some of these whales would have ovulated again later if their most recent ovulation did not result in conception.

The mean number of recent ovulations in northbound females (excluding postpartum animals) was 1.33 in the nulliparous and the primiparous pregnant females and 0.85 in the parous nonpregnant and the multiparous pregnant females. The diameter of the largest corpus albicans in the ovaries of each metestrous and anestrous female suggests, however, that some of these may have been fairly recently formed corpora whose recent origin was no longer apparent. These corpora ranged from 24 to 39 millimeters in diameter, with a mean and standard error of 32.3 ± 3.0, whereas the largest corpus albicans in each early pregnant female ranged from 18 to 42 millimeters, with a mean and standard error of 27.4 ± 1.6. The latter presumably were the corpora lutea of the previous pregnancy that had regressed after the end of lactation several months earlier.

The mean ovulation rate estimated for females during their regular biennial breeding season was 1.20 for nulliparous females, 0.96 for parous females, and 1.00 for all females (Table 8). For reasons stated above, these estimates may be slightly low.

Each of two females taken on 16 and 18 January had both recently ruptured follicles and a corpus luteum of ovulation. This observation suggests that about 40 days intervene between successive ovulations during one breeding season.

TABLE 8
Number of Recent Ovulations in Adult Female Gray Whales, Excluding Late Pregnant and Postpartum Females.

Direction of migration and reproductive status	Number of whales	Number of recent ovulations[1]				Total recent ovulations	Ovulation rate

[1] Figures in body of table indicate the number of whales that had the number of recent ovulations shown at the top of each column.

The only evidence for multiple (simultaneous) ovulation was one female with two recently ruptured follicles of the same size.

The nature of the estrous cycle in baleen whales has been the subject of controversy, because few specimens taken during the breeding season have been available for study, and conclusions have had to be drawn mostly from indirect evidence. Harvey (1963) reviewed the relevant literature and concluded that balaenopterid whales are monestrous. Chittleborough (1965), however, presented direct evidence that female humpback whales, although they usually conceive after ovulating only once, may undergo two or three estrous cycles if pregnancy does not intervene. Gambell's (1968) data strongly suggest a similar condition in sei whales. Potential polyestry would be of considerable selective advantage in a species that can produce no more than one offspring every 2 years, that does not form permanent pair bonds, and that may be so widely dispersed that a male might not be available when the female first comes into estrus.

As southbound female gray whales carrying near-term fetuses had no enlarged follicles, it may be concluded that there is usually no postpartum estrus in this species. However, postpartum estrus sometimes occurs in other whale species. A postpartum estrus resulting in pregnancy almost invariably occurs in the minke whale, *Balaenoptera acutorostrata* (Jonsgård, 1951; Omura and Sakiura, 1956). Postpartum estrus in a high proportion of Southern Hemisphere humpback whales also is indicated by the fact that eight (44 per cent) of 19 lactating animals examined in one study were simultaneously pregnant (Chittleborough, 1958). Likewise, 15 (12 per cent) of 129 lactating Southern Hemisphere fin whales also were pregnant (Laws, 1961). According to Gambell (1968) an estimated 11 per cent of female Southern Hemisphere sei whales experienced postpartum estrus.

The two nonlactating postpartum females examined had not recently ovulated, but the fact that they had follicles (24 and 29 millimeters) much larger than any late pregnant female and larger than the average for anestrous females indicates a resumption of follicular maturation after the corpus luteum starts to regress and progesterone secretion is reduced. It is possible that such follicles may develop sufficiently to undergo ovulation. Chittleborough (1958) has shown that humpback whales usually recommence estrous cycles immediately after stillbirth or early loss of the calf. Ovulation following stillbirth or loss of a calf would be so infrequent that it would not significantly affect the mean ovulation rate.

The possibility of postlactation ovulation, or ovulation by any nonpregnant females during the summer, remains to be considered. The southbound females that had recently ovulated, most of which presumably had ceased lactating about 5 months previously, gave no evidence of having ovulated more than once since that time.

In each, the largest corpus albicans was 22 to 38 millimeters in diameter (mean, 29); this was no doubt the regressing corpus luteum of lactation. Only data from females collected on the summer grounds can provide direct evidence on this point. There is evidence that a considerable proportion of Southern Hemisphere fin whales experience a postlactation ovulation (Laws, 1961), and about 12.5 per cent of the female Southern Hemisphere sei whales ovulate in the summer (Gambell, 1968). These summer ovulations almost never result in pregnancy. In humpback whales, which lactate for approximately 10½ months, an estrous cycle usually commences immediately following the end of lactation; this cycle corresponds with the normal winter breeding season and usually results in pregnancy (Chittleborough, 1958).

The two oldest females studied, with 19 and 34 corpora albicantia, were pregnant, so there is no indication of cessation of breeding in old females.

In summary, female gray whales normally experience one estrous cycle every 2 years, although rarely they may ovulate twice or perhaps three times during one breeding season. The mean ovulation rate for parous females is 0.96 per breeding season. A female that fails to conceive during one breeding season probably undergoes an estrous cycle again the following year. As the pregnancy rate is 0.46 (see below), the mean ovulation rate per year of parous females is 0.52 ([1.00 – 0.46] × 0.96).

CORPORA LUTEA.—Our material included three ovaries with recently ruptured Graafian follicles that provided data on early development of the corpus luteum. In one case the rupture site was still open (Figs. 17 and 18), and in the other two the rupture sites were still obvious as dark spots, although no actual openings were visible. These follicles, 24, 25, and 25 millimeters in diameter, were smaller than mature unruptured follicles. Loss of fluid presumably causes the follicle to collapse immediately after rupture. There is a marked infolding of the walls and a proliferation of luteal tissue from the membrana granulosa. The luteal tissue fills almost the entire antrum. One corpus contained a small amount of liquor folliculi in the central cavity. Subsequent development of the corpus luteum depends upon whether or not pregnancy ensues.

It is difficult to distinguish corpora lutea of ovulation from corpora lutea of pregnancy, because failure to find a visible conceptus in the uterus is not proof that an animal has not conceived. Only in the four females that had recently undergone more than one estrous cycle was it certain that corpora lutea of ovulation were present (Figs. 17 and 18). In these animals the penultimate corpora were 13, 15, 21, and 25 millimeters in diameter. Because of their small size, they did not greatly protrude from the surface of the ovaries. In cross section, the corpora were somewhat irregular or stellate in outline. The layer of luteal tissue was thin and greatly plicated, and no cavity remained. The luteal tissue was pale yellow, as in corpora lutea of pregnancy, in the larger two of the four corpora and more orange-yellow in the two smaller corpora.

Three northbound females had corpora lutea 22, 81, and 102 millimeters in diameter but showed no macroscopic evidence of pregnancy. The two larger corpora in this series were indistinguishable from corpora lutea of pregnancy.

The above data indicate that corpora lutea of ovulation do not attain a size greater than about 25 millimeters and rapidly regress if the female comes into estrus again after a brief diestrous period. The fate of the corpus luteum when the female does not become pregnant or undergo another estrous cycle requires further study.

Corpora lutea of pregnancy in the gray whale (Figs. 17 and 20) are similar to those of the fin whale (Laws, 1961) and humpback whale (Chittleborough, 1954). They protrude from the body of the ovary, from which they are separated by a constricted neck.

In most of the southbound females that had recently ovulated but were not yet visibly pregnant, the corpora lutea ranged from 37 to 87 millimeters (mean, 56; standard deviation, 16). Females with small fetuses collected two months later during northward migration had corpora lutea ranging from 61 to 100 millimeters in diameter (mean, 82; standard deviation, 11). In these animals, the size of the corpus luteum was correlated with the length of the fetus. The female carrying the smallest fetus (25 millimeters long) had a corpus luteum only 63 millimeters in diameter. In females with fetuses 120 to 140 millimeters in length (estimated age 87 to 89 days), the average diameter of the corpus luteum was 84 millimeters, which is not significantly different from that in late pregnant females.

Chittleborough (1954) has shown that it takes nearly three months for the corpus luteum of the humpback whale to reach maximum size. In southbound female gray whales with near-term fetuses, the corpora lutea varied from 61 to 115 millimeters in diameter (mean, 87; standard deviation, 12). No data were obtained on the condition of the corpora lutea in lactating females.

Twenty-one per cent of the corpora lutea of pregnancy contained central vesicles filled with liquor folliculi. Thus, in this species the presence or absence of a central vesicle is of no use in distinguishing corpora lutea of ovulation from those of pregnancy. Laws (1961) has refuted the contention of some authors (for example, Robins, 1954) that the absence of a central vesicle is diagnostic of corpora lutea of ovulation in balaenopterid whales. The largest vesicle in our animals was 54 millimeters in diameter. A few were irregularly shaped or eccentrically located. Some corpora lutea had gel-filled cavities up to 24 millimeters in diameter located around their periphery or at the base (Fig. 20). Although these structures resemble large, flattened follicles, their close association with the corpus luteum suggests that they are part of it.

Only one whale, a primiparous late pregnant female, had an accessory corpus luteum (in the opposite ovary from the primary corpus luteum). It was 14 millimeters in diameter and lacked a stigma, suggesting that it must have developed from an unruptured follicle.

Corpora Albicantia.—The corpora albicantia (Fig. 20F) of gray whales are morphologically similar to those of balaenopterid whales, and the sequence of changes during regression is essentially the same as described by Laws (1961) and van Lennep (1950) for the fin whale.

The earliest stages of regression were seen in the two postpartum females that had recently lost their calves (Figs. 19, 20). The corpora lutea in these individuals were 53 and 60 millimeters in diameter. The connective tissue septa characteristic of corpora albicantia were already obvious, and the color of the luteal tissue was more orange than is typical of the corpus luteum of pregnancy.

As the corpus albicans continues to shrink, it recedes below the surface of the ovary. The color changes to brown as collagen

TABLE 9

Diameter (mm) of Corpora Albicantia in Ovaries of Gray Whales at Different Stages of the Reproductive Cycle. See Text for Explanation of Size Class.

replaces the luteal cells, and the proportion of connective tissue increases. Some of the smaller corpora albicantia consist almost entirely of unpigmented connective tissue.

The corpora albicantia persist throughout life in the ovaries of fin whales (Laws, 1961) and this probably applies to all large balaenopterids. This also occurs in sperm whales (Best, 1967), but not in at least some of the smaller odontocetes, such as the pilot whale, *Globicephala melaena* (Harrison, 1949; Sergeant, 1962).

The corpora persist as permanently recognizable structures in the ovaries of gray whales. The corpora albicantia of each female (excluding nulliparous and primiparous ones) were classified according to relative size in the following manner: class 1, the largest corpus in each whale; class 2, the second largest, and so on. The mean, standard error, and range for each of these classes in females in each phase of the reproductive cycle are presented in Table 9. It is apparent from the size distribution that after an initial phase of rapid regression, there is little further decrease in size of the corpora albicantia. Few were less than 12 millimeters in diameter.

In the discussion of time and frequency of ovulation, it was concluded that females usually ovulate only once every 2 years. If this is true, and the corpora albicantia persist for life, the rate of accumulation of corpora albicantia would be close to 0.5 per year. We examined two other lines of evidence bearing on this question: the size frequency distribution of the corpora albicantia and the correlation between number of corpora albicantia and number of growth layers in the ear plug.

The means, standard errors, and ranges of the diameters of the corpora lutea and two largest corpora albicantia of females in each stage of the reproductive cycle are shown in Fig. 25. We assumed that each female ovulates only once every 2 years, and adjusted the horizontal time scale accordingly. The smooth line shows the presumed rate of regression in size of the corpus albicans during the first 4 years. If the smaller corpora albicantia (Table 9) were similarly plotted, the line would gradually approach the horizontal at about 14 millimeters beyond 20 years. It is apparent from Fig. 25 that a presumed accumulation rate of one corpus albicans every 2 years is consistent with the observed size-frequency distribution of

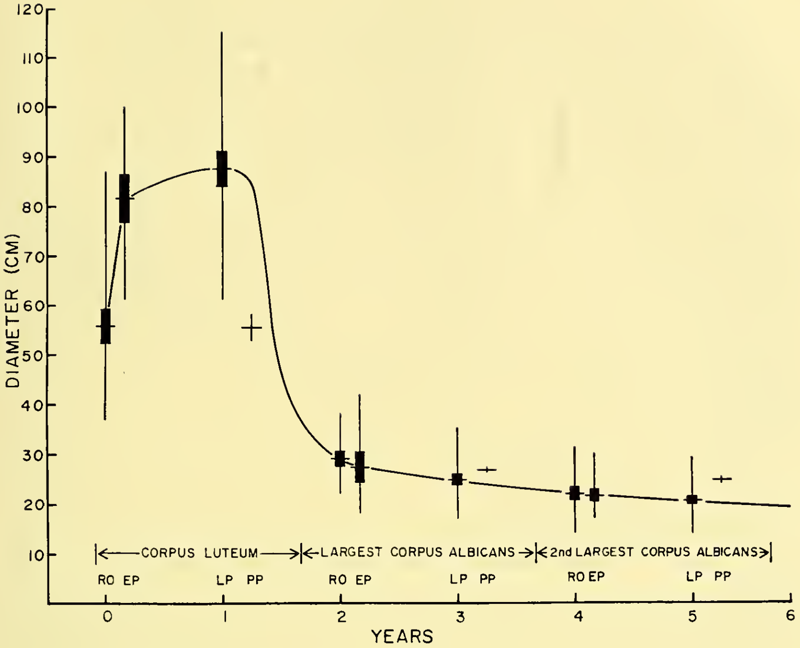

FIG. 25. Diameter of corpus luteum and two largest corpora albicantia in ovaries of gray whales in different stages of the reproductive cycle. The horizontal scale represents the age of each corpus, assuming one ovulation every two years. RO, recently ovulated females; EP, early pregnant females; LP, late pregnant females; PP, postpartum females. The two postpartum females had lost their calves, thus their corpora lutea were smaller than in lactating animals. Horizontal dashes, mean; vertical bars, two standard errors on either side of mean; vertical lines, range. Curve fitted by eye to mean diameters of corpora.

corpora. If the ovulation rate were significantly greater, the size-frequency data would not show such a regular decline. The data on ovulation further indicate that the rate cannot be less than about 0.5 per year.

The relationship between number of corpora albicantia and the number of growth layers in the ear plug is presented in Fig. 26. The solid line ($Y = 0.5X - 3.5$) represents the expected correlation between number of corpora and number of growth layers under the assumptions that two growth layers are formed the first year

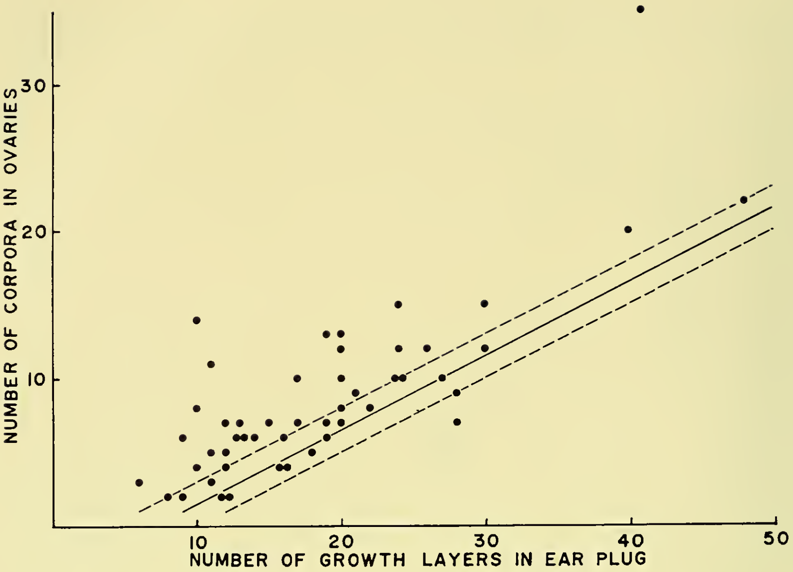

FIG. 26. Number of corpora in the ovaries versus the number of growth layers in the ear plugs of adult female gray whales. The hypothetical correlation is represented by the unbroken line (mean) and the broken lines (range).

and one each year thereafter, and that one corpus is formed every 2 years beginning at 8 years of age (mean age at sexual maturity). The two broken lines ($Y = 0.5X - 2.0$ and $Y = 0.5X - 5.0$) represent the lower and upper limits, respectively, of variation expected because of the variation in the age at sexual maturity of from 5 to 11 years. Deviations from the hypothetical mean number of growth layers are markedly skewed. The mode falls on the lower limit (–3); 41 per cent of the specimens fall within the expected limits (–3 to +3). Only one whale falls above the expected limits (+7); 57 per cent fall below the lower limit (–3 to –37), with 33 per cent falling between –3 and –7. These data are thus consistent with the conclusions that corpora accumulate at a rate of 0.5 per year and growth layers in the ear plug accumulate at a rate of one per year, although the earlier layers may not be discernible.

The only corpora albicantia that are unquestionably derived from corpora lutea of ovulation are those in nulliparous and primiparous females. These corpora do not differ in size or other respects from those representing corpora lutea of pregnancy. In three recently ovulated nulliparous females, the largest corpora albicantia were 23, 30, and 34 millimeters in diameter, and in two primiparous females in early pregnancy they were 13 and 29 millimeters in diameter. All except the smallest of these were within the size range of the largest corpora albicantia in multiparous females in corresponding phases of the reproductive cycle (Table 9).

In addition to normal corpora albicantia, the ovaries of 13 females each contained one to three small orange bodies 4 to 9 millimeters in diameter and which were either compressed and elongate, or stellate, in cross section. The total number of these structures in the 13 animals was 17, which was 2 per cent of the corpora albicantia present in all the females. They are similar to the corpora atretica described by Laws (1961) for the fin whale and presumably originate by atresia of follicles that have not ovulated. This assumption is supported by the finding of a few unruptured follicles with a partial lining of yellow-orange colored tissue. These corpora apparently do not represent ovulations and they were not included in counts of corpora albicantia.

FUNCTIONAL SYMMETRY AND POLARITY OF OVARIES.—Of the total of 756 corpora, 418 (55.3 per cent) were in the left ovary and 338 (44.7 per cent) in the right ovary. The probability of this ratio occurring in a random distribution is less than .05, suggesting that the observed dominance of the left ovary may be real. Laws (1961) found a slight but statistically insignificant dominance of the right ovary in fin and blue whales. In many odontocetes, most ovulations occur in the left ovary (Ohsumi, 1964*b*).

The position of each of 179 corpora in the anterior, second, third, or posterior quarter (measured linearly) of 52 mature ovaries was recorded. There was a significant ($P < .005$) preponderance of corpora toward the anterior pole. The numbers of corpora in each quarter, from anterior to posterior, were: 61 (34 per cent), 48 (27 per cent), 45 (25 per cent), and 25 (14 per cent). A preponderance of ovulations from the anterior pole of the ovary was also found in fin and sei whales (Laws, 1957) and in the sperm whale (Best, 1968), but not in the pilot whale (Harrison, 1949; Sergeant, 1962) or false killer whale, *Pseudorca crassidens* (Comrie and Adam, 1938).

Pregnancy

Pregnancy Rate.—The pregnancy rate is difficult to determine directly because of bias introduced into the sample by the temporal and spatial differences in migration patterns between females in different phases of the reproductive cycle and by gunner selection for the larger animals. In the series of 84 southbound migrants examined, the ratio of late pregnant females to other mature females was two to one, whereas the actual ratio in the population must be less than one to one. The sample of northbound adult females consisted of 22 early pregnant females and eight anestrous females, but only two postpartum females. As it is logical to assume that the number of postpartum females in the spring population should be nearly equal to the number of pregnant females, the sample was obviously biased.

Because the proportion of late pregnant and postpartum females in the samples was biased, these animals were excluded from calculations of the pregnancy rate and appropriate corrections made to determine the overall pregnancy rate in the adult female segment of the population.

The pregnancy rate of females that had already undergone at least one pregnancy will be considered first. During the southward migration, all females that were not carrying near-term fetuses had a developing corpus luteum. If we assume that all of them had conceived, their pregnancy rate would be 1.00. As a few may not have conceived, this figure may be a slight overestimate. During northward migration, 20 of 27 females (exclusive of postpartum females) were pregnant, giving a pregnancy rate of 0.74. Two of the females that were not visibly pregnant each had a corpus luteum that we assumed to be a corpus luteum of ovulation. Although it is possible that they had recently conceived and were carrying a conceptus too small to detect, we think this is unlikely so late in the season. Considering both the northbound and southbound migrants, 41 of the 48 were pregnant or could reasonably be assumed to have already conceived. This gives a pregnancy rate of 0.85 per breeding season.

Considering females that had not undergone a previous pregnancy, all seven taken on the southward migration had recently ovulated. Each of five animals had a single corpus luteum 19 to 62 millimeters in diameter and were assumed to have already conceived. One with a recently ruptured follicle and a corpus luteum of ovulation (25 millimeters in diameter) possibly had done so. The last had what appeared to be a corpus luteum of ovulation (27 millimeters in diameter) and Graafian follicles up to 35 millimeters in diameter, so it might have ovulated again later and then conceived. Of the three northbound animals examined, two were pregnant. The third had two fairly recent corpora lutea (22 and 13 millimeters in diameter) and was probably not pregnant. Thus, of 10 females that had not previously been pregnant, seven were pregnant, two were not pregnant but probably would have conceived later, and one probably would not have conceived that season. These data indicate a probable pregnancy rate of 0.90 per breeding season, but further data are needed to determine whether newly mature females are as fertile as older individuals.

The combined pregnancy rate for nulliparous and parous females, exclusive of late pregnant and postpartum animals, is 0.86. To determine the overall pregnancy rate for all adult females in the population, we made a correction for the biased representation of late pregnant and postpartum females in the sample. If the pregnancy rate remains constant from year to year, or if the sample was taken over a period of several years, the overall pregnancy rate may be calculated as 0.86/1.86, or 0.46 per year.

Zenkovich (1937*a*) examined a large series of gray whales taken in the Bering Sea between August and October from 1933 to 1936. Assuming that all females 12.0 meters or more in length were sexually mature, there were 57 mature females in his sample. Of these, only 16 were pregnant, giving a calculated pregnancy rate of only 0.28. G. C. Pike (unpublished data) reported that only one of three adult females he examined off British Columbia in April was pregnant.

Of the seven northbound adult females (exclusive of postpartum individuals) that were not pregnant, only three had recently ovulated, indicating that missed pregnancies may result from either failure to ovulate or failure to conceive following ovulation.

Breeding Season.—Almost all of the adult females (except those carrying near-term fetuses) taken during southward migration

TABLE 10

8 March		135
10 March		120

probably had already conceived, although none was visibly pregnant. The mean conception date calculated from the fetal growth curve (see below) is 5 December. We calculated the duration of the breeding season by estimating the ages of the 22 embryos and early fetuses collected. The estimated ages were based on certain assumptions about early fetal growth discussed below. The calculated conception dates fall between 27 November and 13 December, except for one on 22 December and one on 5 January. The female that conceived about 22 December was multiparous and showed evidence of two recent ovulations, indicating that she had failed to conceive following her first ovulation that season. The female that conceived about 5 January was primiparous; Laws (1961) found that newly mature female fin whales conceive, on the average, later than multiparous females.

The duration of the breeding season also was estimated on the basis of length measurements for 16 fetuses collected in late summer by Zenkovich (1937*a*). The estimated conception dates of 12 (75 per cent) of these fetuses fall between 23 November and 14 December, and all fall between 13 November and 10 January. Individual variations in growth rate will give a spurious spread to the calculated range, so that the actual breeding season is doubtless even shorter than these data indicate. For the same reason, the

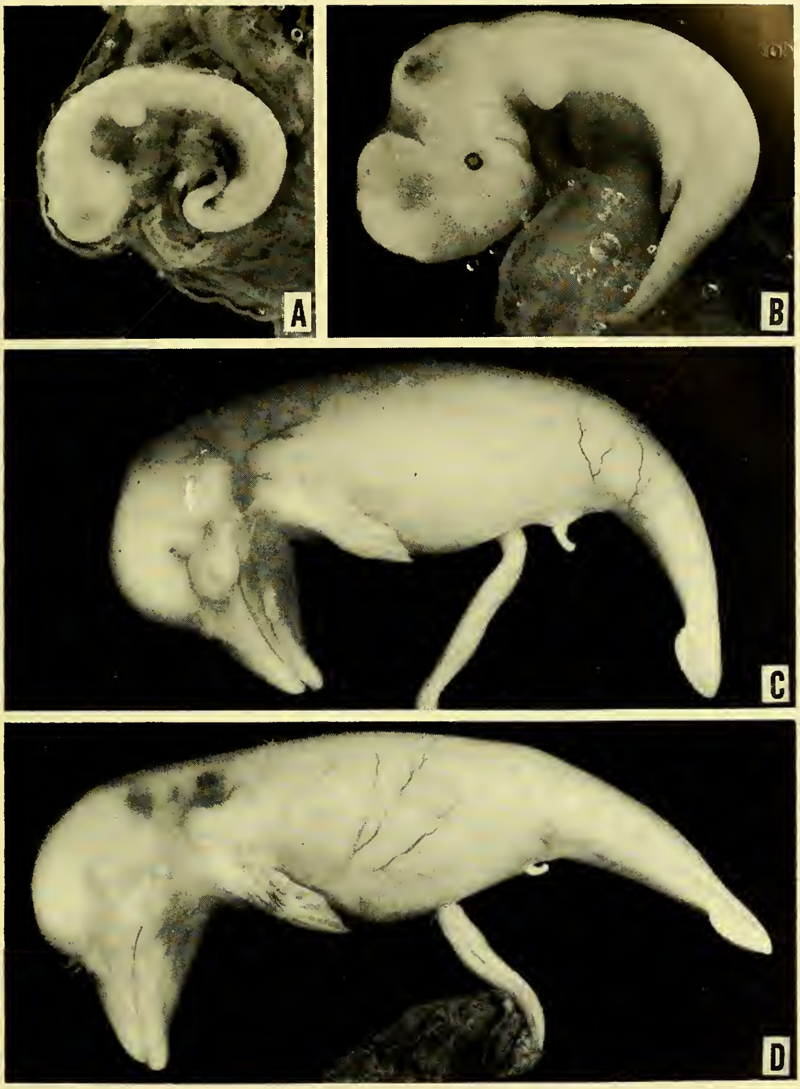

Fig. 27. Embryos and early fetuses of gray whales. A, 25-millimeter (10 millimeters crown-rump) female embryo, estimated age 55 days; B, 39-millimeter (16 millimeters crown-rump) male embryo, estimated age 70 days (note hind limb buds); C, 120-millimeter male fetus, estimated age 87 days (note size and position of penis); D, 110-millimeter female fetus, estimated age 86 days (note size and position of clitoris).

data from near-term fetuses are even less useful for calculating conception dates.

GESTATION PERIOD AND FETAL GROWTH.—Available measurements of fetuses are limited to the periods of early and late pregnancy.

A total of 22 embryos and early fetuses was collected between 21 February and 10 March (Table 10, Fig. 27). Body length, measured from the crown to the tip of the straightened tail varied between 25 and 140 millimeters (mean, 96; standard error, 6).

Additional data on fetal sizes in the gray whale are contained in a number of reports. Scammon (1874) examined five embryos taken on the California coast, but gave no measurements or dates. Andrews (1914) reported fetuses 180 and 250 millimeters long taken on 13 and 14 March 1912, on the coast of Korea. Pike (unpublished data) found a 250-millimeter fetus the first week of April from the coast of Vancouver Island, British Columbia. Zenkovich (1937*a*) published data for 16 fetuses collected in the Bering Sea between 8 August and 24 September. Their lengths ranged from 1.70 to 2.64 meters, with a mean and standard error of 2.05 ± 0.06. Townsend (1887) examined four fetuses taken in December 1885 at San Simeon, California, and stated: "Their average length was about 12 feet [3.66 meters]; the longest . . . 17 feet [5.18 meters] long." Andrews (1914) inconsistently reported one fetus taken at Ulsan, Korea, on 8 January 1912, as 4.35 and 4.76 meters long.

We measured 55 near-term fetuses (30 males, 25 females) collected during a 38-day period from 14 December to 20 January. The length varied between 3.60 and 5.31 meters, with a mean and standard error of 4.62 ± 0.05 (Table 11, Fig. 28). The average length of females (4.65 ± 0.06 meters) was slightly greater than that of males (4.60 ± 0.08), but the difference was not statistically significant ($P > .10$). If these measurements are grouped by shorter time periods, they show no change in mean length from mid-December until late January. This suggests that the timing of migration of a pregnant female depends upon how advanced her pregnancy is.

The statistics for Norwegian factory ship operations near the calving grounds on the west coast of Baja California from 1924 to 1927 (published in part by Risting, 1928) list 20 fetuses taken from 29 December to 16 February with estimated (not actually

measured) lengths ranging from 6 to 18 Norwegian feet (1.90 to 4.71 meters).

Measurements of six recently born calves found dead at Laguna Ojo de Liebre, Baja California, in late January and early February, are given by Eberhardt and Norris (1964). These ranged from 3.95 to 5.40 meters (mean, 4.68; standard error, 0.245). Gilmore (1960*a*) also listed measurements of seven recently born calves found in the same lagoon. The total lengths given for these calves (3.54 to 4.51 meters, mean, 4.05) are well below those presented by Eberhardt and Norris and even average less than our December fetuses. Therefore, we can only conclude that Gilmore made his measurements differently or that the published figures are in error.

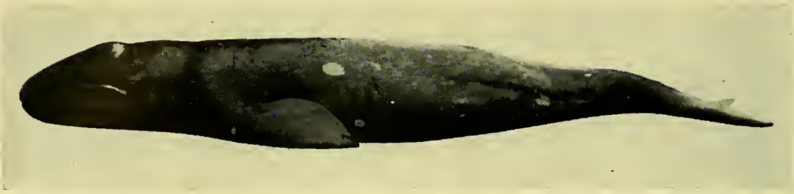

FIG. 28. Near-term gray whale fetus 4.54 meters long. Note color pattern of whitish rings and blotches (the other marks are postmortem abrasions).

Only three of the series of measurements presently available are large enough to provide statistically reliable data for use in constructing a fetal growth curve for the gray whale. These include our series of early embryos and fetuses, Zenkovich's series taken in late summer, and our series of near-term fetuses. The means for these three sets of measurements have been plotted in Fig. 29. It is apparent that the points do not fall on a straight line. Laws (1959) found that in balaenopterid whales, excepting the earliest

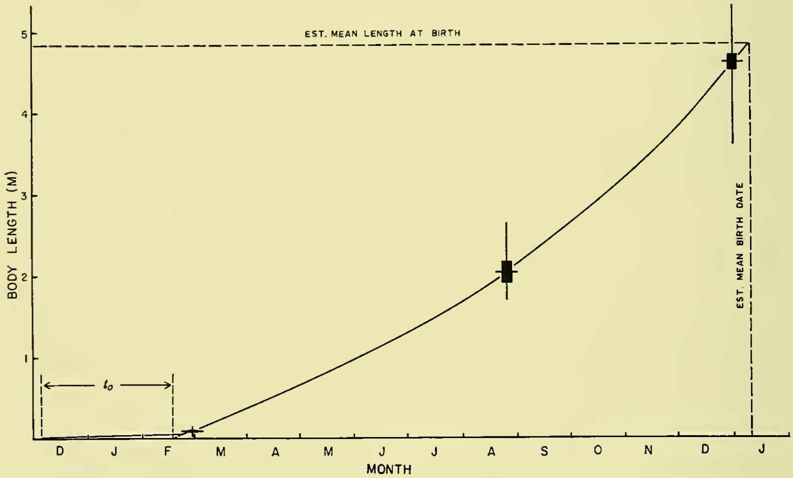

FIG. 29. Estimated prenatal growth curve based on measurements of 22 embryos and early fetuses collected in February and March, Zenkovich's (1937*a*) 16 mid-term fetuses collected in August and September, and 55 near-term fetuses collected in December and January. Horizontal dashes indicate means; vertical bars represent two standard errors on either side of mean, and vertical lines represent the range. For estimation of t_0 see text.

part of pregnancy, the length of the fetus increases linearly during the first half of pregnancy and logarithmically during the last half. A similar curve fits the present data (Fig. 29). From the slope of the lower portion of this curve, we estimated the "specific fetal growth velocity," or *a* of Huggett and Widdas (1951), as 0.95.

To determine the total gestation period, it is necessary to estimate the length of the gestation period before the beginning of the linear growth phase, termed t_0 by Huggett and Widdas (1951). J. G. Sinclair, who is studying the anatomy of two early fetuses (25 and 39 millimeters long from crown to tip of tail, and 10 and 16 millimeters in crown-rump length), has, on the basis of their stage of development, estimated their ages at about 55 and 70 days. According to Sinclair, the rapid linear growth phase starts when ossification begins, at a crown-rump length of about 35 millimeters; this is equivalent to a length of about 55 from crown to tip of tail. Judging from the estimated ages of the two early embryos, this length would be reached at an age of at least 80 days, or perhaps slightly more. An estimate of t_0 will therefore be $80 - (5.5 \times 0.95)$, or about 75 days. The growth curve, extrapolated backwards, intercepts the abscissa on 18 February (Fig. 29). Adding to this the estimate of t_0, the calculated mean conception date falls on 5 December.

If the growth curve is projected forward, it intercepts the mean length of the six newborn calves observed by Eberhardt and Norris (1964) on 2 January, only 2 days later than the mean date of passage of pregnant females past San Francisco. Considering the speed of migration, it would take the whales at least 9 to 12 days to travel from San Francisco to the major calving grounds at Laguna Ojo de Liebre, Laguna San Ignacio, and Bahia Magdalena. Therefore, the mean birth date would be about 10 January, when the projected growth curve reaches 4.90 meters. This estimate of length at birth falls within one standard error of the mean of newly born calves, so the agreement is close.

Based upon the calculated mean dates of conception and parturition, the mean length of the gestation period is estimated to be slightly more than 13 months, or about 400 days.

Applying Laws (1959) method of estimating t_0 for baleen whales to the data of this study yields values of only 31 days for t_0 and

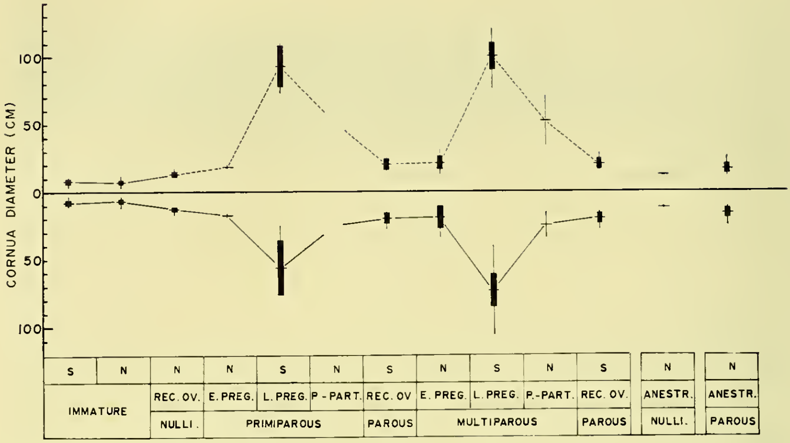

Fig. 30. Diameter of the uterine cornua of gray whales in different stages of the reproductive cycle. For pregnant and postpartum females, measurements of the horn in which implantation occurred are plotted above the base line and those for the other horn below. Symbols are as follows: horizontal dashes, mean; vertical bars, one standard deviation on either side of the mean; vertical lines, range; S, southbound migrants; N, northbound migrants.

no more than one year for total gestation period, which are not consistent with the actual data. The discrepancy results from the way in which Laws interpreted data for several species of terrestrial mammals given by Huggett and Widdas (1951) in estimating the length of t_0 for three species of odontocetes in which fetal growth is linear until the end of pregnancy. His estimates showed an *inverse* relationship between t_0 and length of gestation period (and also a). Huggett and Widdas' data show, however, that "t_0 *increases as gestation times lengthen* but forms a decreasing fraction of total gestation time" (italics added). There are no data to justify Laws' conclusions; his error appears to be the result of using imprecise, arbitrary percentage values for t_0. Laws then estimated the length of t_0 in the humpback whale as 38 days on the basis of published fetal length data and Chittleborough's (1954, 1958) data on the mating and calving seasons. Chittleborough's data suggest, however, a peak conception date in late July, not early August as stated by Laws, so Laws' estimate of t_0 is doubtless too short. Since his four estimates of t_0, for three species of odontocetes and one mysticete, showed an apparently consistent inverse relationship between t_0 and a, he extrapolated these results to other species of baleen whales. This resulted in his inexplicable and anomalous conclusion that the larger species of balaenopterid whales have shorter gestation periods than the smaller ones. Any logical extrapolation of the data presented by Huggett and Widdas would result in an estimate of at least 50 or 60 days for the duration of t_0 in larger cetaceans. In any event, it is dangerous to extrapolate from small terrestrial mammals to large cetaceans.

We suspect that when more direct evidence is available on early embryonic growth, most large mysticetes will be found to have a gestation period of about a year or somewhat longer. It is certainly approximately 13 months in the gray whale, and probably more than a year in the humpback whale. A gestation period longer than one year would not preclude an occasional pregnancy resulting from a postpartum ovulation, as has been reported in fin whales (Laws, 1961) and humpback whales (Chittleborough, 1958), but it does indicate that such pregnancies cannot occur regularly if a marked seasonality of breeding is to be maintained.

CALVING SEASON.—The mean calving date, as indicated above, is estimated to be about 10 January. The duration of the calving season should be generally similar to that of the breeding season, but slightly more prolonged because of individual variation in the length of the gestation period. As noted above, the timing of the southward migration of pregnant females depends on the stage of gestation. Because late pregnant females pass San Francisco for at least 38 days, we may assume that the calving season lasts about that many days. Therefore, we estimate that calving occupies a period of 5 or 6 weeks from late December to early February. This is corroborated by field observations of recently born calves (Eberhardt and Norris, 1964; Gilmore, 1960*a*, 1960*b*; Gilmore and Ewing, 1954; Hubbs and Hubbs, 1967).

CYCLIC CHANGES IN THE UTERUS.—Gray whales have a bipartite uterus similar to that of other baleen whales (Mackintosh and Wheeler, 1929; Matthews, 1948). The placenta is of the diffuse, nondeciduate, epitheliochorial type. Measurements of the diameter of the uterine cornua of specimens examined in this study are presented in Fig. 30. Histological characteristics of the endometrium

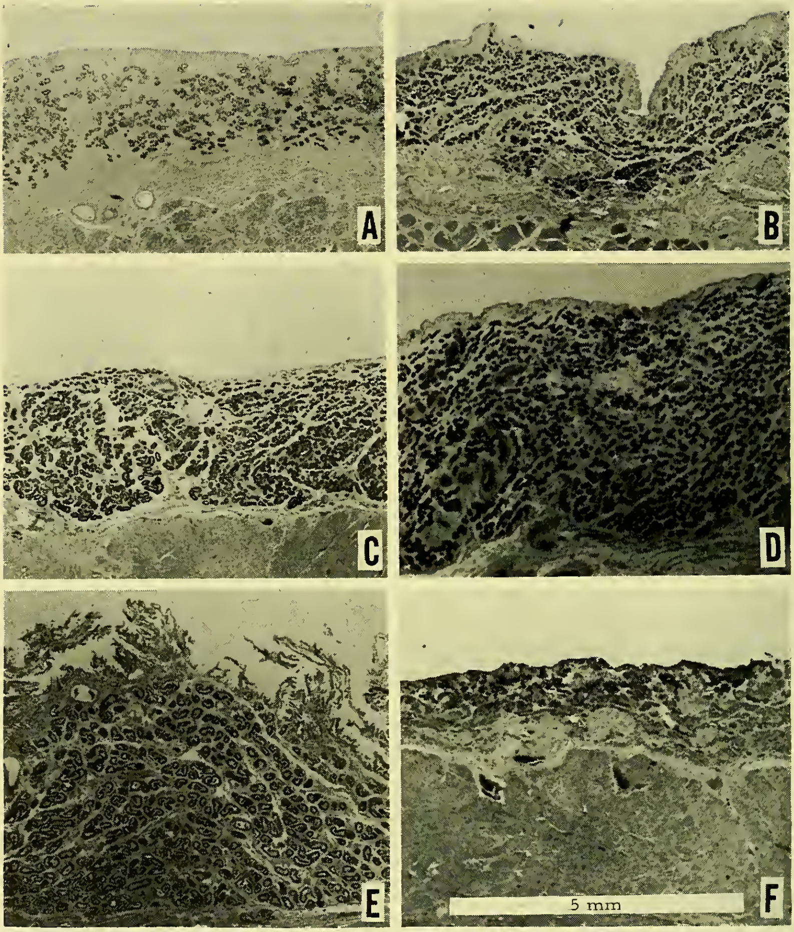

Fig. 31. Photomicrographs of sections of the endometrium of gray whales in different stages of the reproductive cycle. A, immature female; B, northbound anestrous female; C, southbound recently ovulated female; D, northbound early pregnant female (110-millimeter fetus); E, southbound late pregnant female (3.60-meter fetus); F, northbound postpartum female. All sections are to same scale.

[3] N = 45 for stratum compactum thickness.

are illustrated in Fig. 31 and endometrial measurements are presented in Table 12. There was no endometrial epithelium in any of our specimens, probably because of postmortem changes.

In immature whales (Fig. 31A), the diameter of the uterine cornua ranges from 3.5 to 12.0 centimeters. The average thickness of the wall is 9 millimeters and the mean height of cornual folds is 10 millimeters. The average thickness of the endometrium is 2.9 millimeters in southbound animals and 1.6 in northbound animals. The surface of the endometrium is fairly smooth, with only a few small furrows, and it has few glandular ducts that have a mean diameter of 44 microns. The lumina of the glands are either small or not visible. Capillaries are scattered but fairly numerous.

At any stage of the reproductive cycle the uterine cornua of primiparous females average smaller than the cornua of females that have undergone a previous pregnancy, but they cannot be distinguished on the basis of histological criteria.

The cornua of northbound, sexually mature, anestrous females (Fig. 31B) are in the fully involuted condition. They range from 11 to 26 centimeters in diameter and 19 millimeters in thickness, and the folds are high, averaging 15 millimeters. The mean thickness of the endometrium is 1.8 millimeters, of which the stratum compactum comprises 96 microns. The area of division between the stratum compactum and the stratum spongiosum is poorly defined. The glands are small, with a mean diameter of 39 microns, and are more closely spaced than in immature females.

The cornua of southbound whales that have recently ovulated (Fig. 31C) are slightly larger than those of anestrous females. They range from 15 to 28 centimeters in diameter. Mean fold height has decreased to 10 millimeters, and the mean thickness of the endometrium and stratum compactum have increased to 3.3 millimeters and 135 microns, respectively. The inner surface of the uterus is more uneven than in immature individuals, with deeper furrows and a greater number of glandular openings. The average diameter of the glands has increased to 61 microns, and the lumina are mostly open. These data on gray whales differ from Matthew's (1948) observation (based on one specimen) that in fin whales there is a marked temporary increase in endometrial thickness and gland diameter at the time of ovulation.

In early pregnancy (Fig. 31D), the cornua range from 12 to 34 centimeters in diameter, the difference between gravid and nongravid cornua not being statistically significant. Mean fold height is 10 millimeters. The endometrium (mean, 3.4 millimeters) and the stratum compactum (mean, 153 microns) are slightly thicker than in recently ovulated animals, and there are many large vessels visible in the stratum spongiosum. The glands have a mean diameter of 57 microns, slightly less than in females that have recently ovulated. No dendritic structures are visible yet, though the surface is quite uneven and numerous crypts are visible in the stratum compactum.

Whales in advanced pregnancy (Fig. 31E) have wide cornua, ranging from 76 to 120 centimeters in diameter in the horn carrying the fetus and from 40 to 105 in the other horn. The nongravid horn contains part of the placental membranes of the fetus and is filled with fluid. The uterine wall is greatly thickened, mostly as a result of an increase in the thickness of the inner layer of circular muscles. The folds have almost disappeared, contrary to the condition reported in blue and fin whales by Slijper (1956). Their disappearance seems to be a direct result of the distension of the uterine wall, and they tend to reappear when samples of the wall contract in fixatives. The endometrium is relatively thick (mean, 3.9 millimeters) because of highly developed dendritic structures, which average 724 microns in height. One female with a length of 12.98 meters had a maximum stratum compactum thickness of 3600 microns. This is markedly thicker than that of the fin and blue whales in late pregnancy which Matthews (1948) examined, the thickest of which was 200 to 1000 microns. Vessels in the stratum spongiosum are large and many are filled with blood cells. The mean diameter of the glands has increased to 128 microns.

In the two postpartum whales examined (Fig. 31F), the cornua that had contained the fetus were 34 and 70 centimeters wide, whereas the others were 16 and 34. The uterine folds were 14 and 25 millimeters high. The thickness of the endometrium had decreased to 1.0 to 2.1 millimeters and the stratum compactum to 70 to 80 microns. Dendritic structures were absent, and blood vessels were fewer and smaller. Gland diameters also had decreased to 30 to 50 microns.

Position of the Fetus.—All near-term fetuses were positioned in the uterus with the tail towards the cervix; this would ensure caudal presentation at birth, as is usual in cetaceans (Slijper, 1956). Inasmuch as the uterine horns are curved during advanced pregnancy, the head of the fetus is actually oriented towards the tail of the mother.

There was no evidence of differential tendency for implantation to occur in the right or left uterine horns. In 76 pregnant females, the fetus was in the left cornu in 37 and in the right in 39. In three cases, the fetus was in the cornu on the side opposite the ovary containing the corpus luteum, indicating transuterine migration of the ovum.

Weight Gain During Pregnancy.—During the southward migration, females carrying near-term fetuses averaged 35 per cent heavier than those that had recently ovulated and most of which had presumably weaned a calf a few months previously (Table 3; Figs. 7–8). About 1000 to 2000 kilograms of this difference can be attributed to the fetus and fetal membranes and fluids, so that the gain in body weight attributable to fat stores is about 25 to 30 per cent. As there is no difference in blubber thickness between these two classes of females, most of the weight increase may be attributed to increased body fat stores.

Extra energy stores are necessary in late pregnant females to sustain rapid fetal growth and maintain the newborn calf, as well as provide for their own needs during the southward migration, the winter, and the northward migration. Acquisition of extra fat stores during pregnancy is characteristic of some other marine mammals that fast throughout the entire lactation period (Kenyon and Rice, 1959; Rice, 1960).

Lactation

Lactation Period.—According to Tomilin (1957), juvenile gray whales taken during August, September, and October in the Bering and Chukchi seas had already been weaned. He assumed that animals 8.5 to 9.5 meters long were calves of the year, an assumption supported by our data (see section on growth). None had milk in its stomach and even the smallest had been feeding on crustaceans, although many still accompanied their mothers (Zenkovich, 1937*a*). These Russian workers examined 57 sexually mature females (we are assuming that females 12.0 meters or more in length were sexually mature); of these, 16 were pregnant. Of the remaining 41, only three were still lactating, including one collected on 21 August and another on 1 September. The collection date for the third is not given.

Maher (1960) reported the capture of two lactating females accompanied by calves at Barrow, Alaska, on 19 July and 13 September. The calf of the specimen taken in July had an estimated length of 25 to 28 feet (7.6 to 8.5 meters) and the young of the other was also about 25 feet. On 10 August a 25-foot calf associating with an adult was killed in the same area.

Tomilin and Zenkovich estimated 6 months as the mean length of the lactation period. They believed that most calves were born in February. As the present data indicate mid-January as the peak of the calving season, 7 months seems a more reasonable estimate of the mean duration of lactation. However, more data are needed. As with other cetaceans, weaning is probably gradual and prolonged.

CYCLIC CHANGES IN THE MAMMARY GLANDS.—In gross anatomy, position, and relative size, the mammary glands of gray whales are similar to those of other baleen whales. Changes in thickness of the gland at different phases of the reproductive cycle are shown in Fig. 32. The histological specimens were not fresh enough at time of fixation to allow study of cellular details.

The mammary glands of one 11.8-meter, sexually immature female were 77 centimeters long and 17 wide. The maximum thickness of the glands of immature females was 1.0 to 6.5 centimeters. The fresh tissue of mammary glands of virgin females is pinkish in color. The glands consist mostly of stroma. The lacteal ducts are small, widely spaced, and surrounded by only a thin layer of glandular tissue.

The mammary glands of nulliparous females at puberty and females early in their first pregnancy resemble those of virgin females in their histology, but they may be slightly thicker (up to 9.0 centimeters). The mammary glands of primiparous females in late pregnancy consist of 66 to 91 per cent (mean, 81) glandular

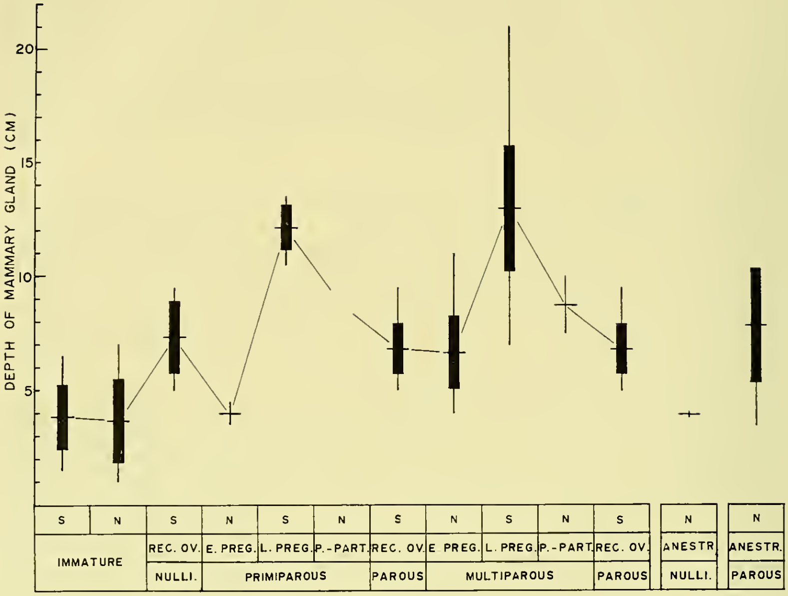

Fig. 32. Thickness of mammary glands of gray whales in different stages of the reproductive cycle. Symbols are as follows: horizontal dashes, mean; vertical bars, one standard deviation on either side of mean; vertical lines, range; S, southbound migrants; N, northbound migrants. Values plotted for post-partum females were from nonlactating individuals.

tissue and are grossly and histologically indistinguishable from those of multiparous females.

The involuted glands of parous animals in anestrus taken during the spring migration are larger than those of virgin individuals. One female 13.3-meters long had mammary glands 145 centimeters long and 32 wide. The mammary tissue varies from 3.5 to 10.0 centimeters (mean, 7.8) in thickness and is pale yellowish-brown in color. Histologically, the glands consist of 37 to 66 per cent (mean, 56) glandular tissue separated by a moderate amount of stroma. They show an extensive system of secretory lobules, which in section are somewhat polygonal and flattened. No secretory activity is apparent.

All females collected during southward migration that had recently ovulated, the majority of which had presumably ceased lactating about the previous July, had nearly or completely involuted glands 5.0 to 9.5 centimeters in thickness. They consisted of 41 to 65 per cent (mean, 53) glandular tissue, and were not distinguishable histologically from the glands of the anestrous females taken in spring. No secretory activity was noted.

The mammary glands of northbound females in early pregnancy also were grossly and histologically indistinguishable from the involuted glands of anestrous females. They consisted of 24 to 63 per cent (mean, 43) glandular tissue.

The mean depth of the lacteal tissue of females in advanced pregnancy was 13.0 centimeters. The mammary tissue is pink and softer than that of involuted glands, and histologically it shows extensive proliferation of the lobule-alveolar system. In section the lobules are large and round, comprising 67 to 91 per cent (mean, 80) of the gland, with relatively little stroma. In a few of the glands examined at this stage, no secretory activity was noticeable, but most already showed a considerable amount of secretory activity. Some had only a small amount of translucent, yellowish fluid in the ducts, others contained so much fluid (colostrum?) that it spurted from the teats when the animals were hauled onto the flensing deck. One female that apparently had recently aborted (or was immediately postpartum), killed on 8 January, had the thickest glands (21.0 centimeters) of any examined and was secreting colostrum copiously.

Unfortunately, we collected no actively lactating animals. The glands of the two nonlactating, postpartum females were grossly and histologically indistinguishable from those of females in late pregnancy. Their thickness was slightly reduced; they consisted of 56 to 72 per cent (mean, 64) glandular tissue and were secreting yellowish, translucent fluid.

Zenkovich (1938) reported that the milk of gray whales taken in August near the end of the lactation period consisted of 53.04 per cent fat, 6.38 per cent dry residue, and 40.58 per cent water. The fat content is greater than has been reported for any other species of cetacean.

Anestrus

Females are probably in anestrus for 3 to 4 months from the end of lactation about August until the onset of the next estrous period in late November or December. As noted earlier, a few females fail to come into estrus at this time and presumably would not do so again until at least a year later; they would thus undergo an anestrous period of 16 months or longer. Other females come into estrus but fail to conceive and return to the anestrous state, probably nearly a year in duration.

Discussion and Conclusions

The complete reproductive cycle of the female gray whale occupies 2 years. Females come into estrus during about a 3-week period in late November and early December. They usually conceive following their first ovulation, but if they fail to do so, they may undergo another estrous cycle about 40 days later. Pregnancy lasts for about 13 months (400 days). Parturition occurs within a period of 5 to 6 weeks from late December to early February. The calf is nursed for about 7 months. After weaning their calf about August, females are in anestrus for 3 or 4 months until November or December, when most of them go into estrus and commence a new pregnancy. A few either fail to ovulate, or ovulate but fail to conceive, and are in anestrus for another year. There is no evidence for postpartum or postlactation ovulation. Evidence for the possible occurrence of ovulation following stillbirth or early loss of the calf is suggestive but inconclusive.

The reproductive cycle of the female gray whale is basically similar to that of the larger rorquals. One important difference is that the extremely long migration route and restricted calving grounds of the gray whale impose a much stricter annual schedule. For example, the majority of gray whale calves are born during a period of 5 to 6 weeks, as contrasted with about 5 months in the rorquals.

The gray whale's ovulation rate of about 0.50 per year is less than that reported by some authors for rorquals. The ovulation rate of the fin whale was estimated as 1.40 per year by Laws (1961) and 1.25 per year by van Utrecht-Cock (1965). Laws, however, admitted that the rate may be only half his estimate. Nishiwaki *et al.* (1958) estimated the ovulation rate of southern fin whales as 0.90 per year and that of North Pacific fin whales as 0.80 per year. Chittleborough (1959) estimated the ovulation rate of humpback whales at 1.10 per year. Nishiwaki *et al.* and Chittleborough assumed that two growth layers were formed in the ear plug each year, so the true ovulation rates are probably nearer 0.40 to 0.45 per year for fin whales and 0.55 per year for humpback whales. The annual ovulation rate of Southern Hemisphere sei whales is 0.69 (Gambell, 1968). Rorquals, apparently unlike gray whales, sometimes experience postpartum and postlactation or summer ovulations.

When comparing ovulation and pregnancy rates of different species and stocks of whales, it must be borne in mind that the reproductive performances of mammals—even large, late maturing and slow breeding species—are quite labile in response to population density in relation to carrying capacity of the range. Laws (1962) and S. Ohsumi and Y. Shimadzu (personal communication) have shown a reduction in age at sexual maturity and an increase in the pregnancy rate of Southern Hemisphere fin whales in response to excessive exploitation. Among large terrestrial mammals, Buss and Smith (1966) have shown a marked decrease in pregnancy rate in a population of African elephants, *Loxodonta africana*, brought about by an increase in population density and resultant deterioration of the habitat.

Presumably population density influences reproduction through nutrition or through ethological factors. In the gray whale, nutrition could be of critical importance, because the pregnant female must accumulate enough energy stores during the summer to support herself and her fetus through a long migration, to support herself and the newborn calf for a month or more on the wintering grounds, and to sustain both herself and the rapidly growing calf during the long return migration to the summer feeding grounds. Under such conditions, selective pressure for suppression of ovulation at times when the female is not physiologically capable of carrying a new pregnancy to term might be expected. Thus it may be that in the gray whale the potentiality for a postpartum estrous cycle is being or has been genetically eliminated from the population.

MALE REPRODUCTIVE CYCLE

DATA on the reproductive biology of the male gray whale were obtained from a sample of 166 animals. Of this number, 123 had attained puberty, including 67 southbound and 56 northbound migrants.

Testes

The testes of gray whales are cylindrical, moderately elongate, and generally similar to those of rorquals.

WEIGHTS.—No significant or consistent difference in weight between left and right testes was found.

In all sexually immature males examined, both testes weighed less than 8.2 kilograms and, in all individuals except three, the combined weight of the testes was less than 5.0 kilograms (Fig. 33). With one exception, the testes of mature males weighed more than 5.7 kilograms and few had testes lighter than 17.0 kilograms. The exception was a mature northbound animal with unusually small testes that weighed only 0.8 kilogram. Following the abrupt increase in testis weight immediately after puberty, the rate of increase rapidly declines with increasing body length.

The paired testes of the southward migrating adult males taken in December and January ranged from 7.9 to 67.5 kilograms, with a mean and standard error of 38.4 ± 1.4. Mean testis weights for 10-day intervals throughout the southward migration period show no significant changes (Table 13). In northbound adults, the testes were much lighter, ranging from 5.7 to 44.8 kilograms with a mean and standard error of 22.5 ± 0.9. Mean testis weights decreased from 24.8 kilograms in late February to 18.0 kilograms by the end of March. Zimushko (1969*b*) found that the testes of 25 adults taken from July through October ranged from 14 to 27 kilograms (mean, 23).

HISTOLOGY.—Because of the rapidity of postmortem degeneration of testis tissue, detailed cytological study of our material was not possible. Representative histological sections are shown in Fig. 34.

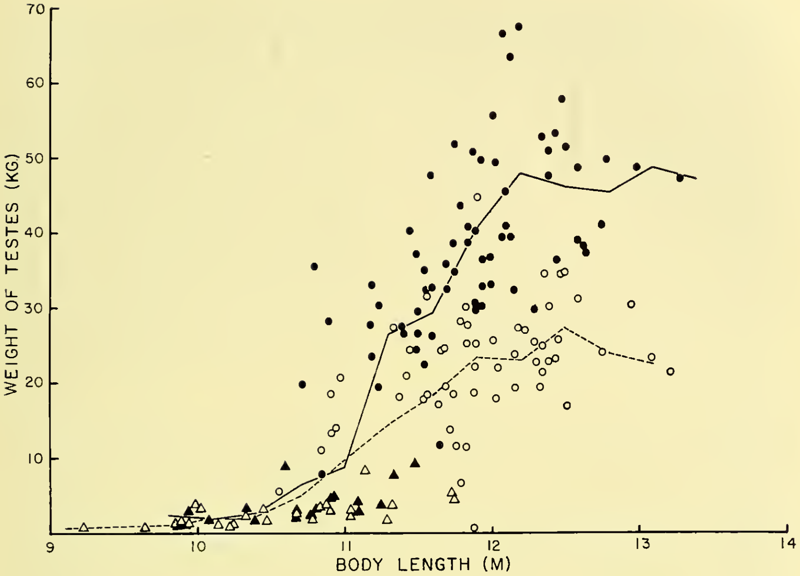

FIG. 33. Testes weights of gray whales in relation to body length. Symbols are as follows: solid triangles, southbound immature males; solid circles, southbound adult males; open triangles, northbound immature males; open circles, northbound adult males. Unbroken line connects means of 0.3-meter length groups of southbound males; broken line connects means of 0.3-meter length groups of northbound males.

In immature testes, the seminiferous tubules were closed and small, their average diameters ranging from 45 to 102 microns (mean, 75). In mature testes, the tubules had open lumina and average diameters ranging from 104 to 214 microns. In males that have reached puberty, there is a significant ($P < .001$) positive correlation between tubule diameter and testis weight (Fig. 35). This correlation is expressed by the formula $Y = 120 + 1.3X$, where Y = tubule diameter in microns and X = testis weight in kilograms.

Mean tubule diameters of the testes of southbound migrants ranged from 114 to 214 microns (mean, 177; standard error, 2). Mean tubule diameter of northbound migrants was significantly smaller, ranging from 104 to 186 microns, with a mean of 148 and a standard error of 3). Mean tubule diameters for each 10-day

2–11 March	24	24.0 ± 1.4	11.5–44.8	24	148 ± 4	104–176
12–21 March	15	21.8 ± 1.6	5.7–31.5	14	143 ± 6	107–186
22–31 March	9	18.0 ± 1.4	11.7–23.3	9	156 ± 4	142–186

[1] One male with abnormally small testes weighing 0.8 kg omitted.

interval do not reveal any significant increase or decrease within either migration period (Table 13).

The seminiferous tubules of almost all adult males appeared to be undergoing spermatogenesis, but it was difficult or impossible to ascertain the precise stages. The vasa deferentia and epididymides of all postpubertal males that were examined contained abundant fluid. Because of the long postmortem time, we did not attempt to collect vas deferens fluid for counts of sperm density.

Penis

The penis of the gray whale is an elongate, evenly tapering, conical, flesh-colored organ similar to that of the rorquals, and unlike the slender cylindrical black organ of right whales.

The length of the penis ranged from 55 to 145 centimeters in immature males and from 100 to 170 in adults. There is a significant ($P < .001$) positive correlation between penis length and body length (Fig. 36). This correlation is expressed by the formula $Y = 0.21X - 1.14$, where Y = penis length in meters and X = body length in meters. On the basis of this formula, at a body length of 11.1 meters, which is the average length at puberty, mean penis length is 1.08 meters. A penis length of 114 centimeters correctly separates 79 per cent of our specimens into immature and adult categories.

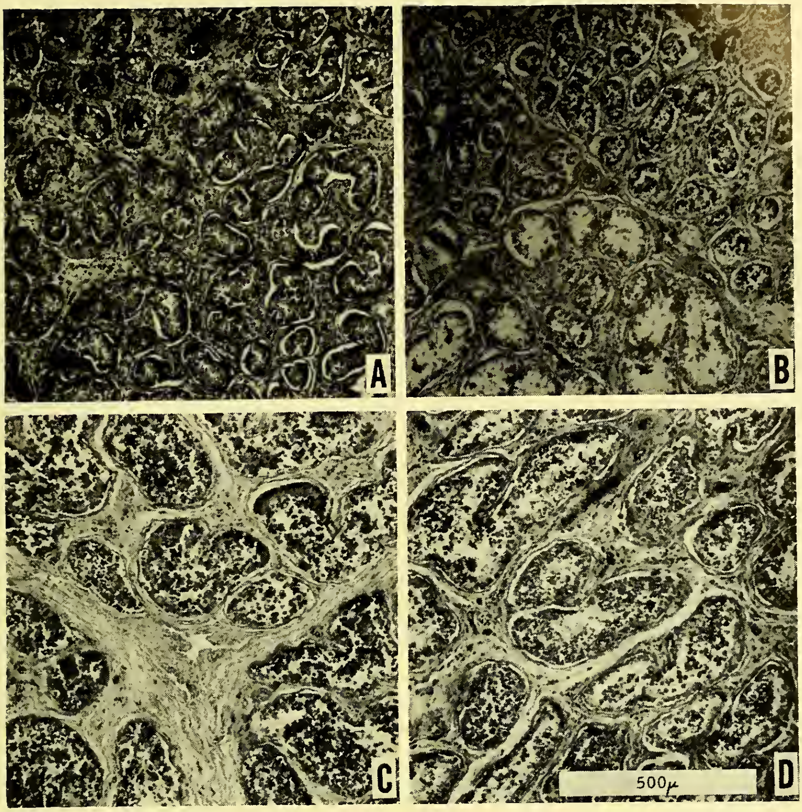

Fig. 34. Photomicrographs of sections of testes of gray whales in different stages of the reproductive cycle. A, immature male; B, pubertal male with both closed and open seminiferous tubules; C, adult southbound male; D, adult northbound male. All sections are to same scale.

Discussion and Conclusions

Testes weighing more than 5.0 kilograms are a reliable indication of maturity in male gray whales. A penis length greater than 1.1 meters also separates most mature animals from those that are sexually immature.

The much heavier testes and larger seminiferous tubules of males taken during southward migration compared with those of males collected during northward migration and on the summer grounds indicate that male gray whales have a marked seasonal sexual

Fig. 35. Relation between size of seminiferous tubules and weight of testes of gray whales. Fig. 36. Relation between penis length and body length of gray whales. Open circles represent immature males and closed circles represent adult males.

cycle, with a peak of spermatogenetic activity in late autumn or early winter. This period correlates closely with the time females come into estrus. Although there are no reported field observations of copulation at this time, biologists have not studied the behavior of gray whales in southward migration north of San Francisco. Courting and copulating gray whales often are seen on and near the calving grounds in Baja California in January (Gilmore, 1960*a*); this period coincides with the second estrous cycle of those few females that are not impregnated during their first cycle. Apparent courtship behavior, including males with an erect penis, has been observed during northward migration on the coast of California in March (Houck, 1962) and on the coast of Washington as late as April (C. E. Munsen, personal communication). Courtship behavior and apparent copulation also have been observed in the Bering Sea in June, July, August, and September (Sauer, 1963; Fay, 1963; Tomilin, 1937). Its significance at these times is unknown; certainly it never results in successful conception. In the bottlenose dolphin *(Tursiops truncatus)*, copulation behavior does not necessarily indicate sexual fertility in males, as males born in captivity may begin to copulate frequently when only a few days old (Caldwell and Caldwell, 1968).

The existence of a male reproductive cycle in other mysticetes appears to be variable. Male humpback whales show a marked seasonal variation in weight of the testes and spermatogenetic activity (Chittleborough, 1955; Nishiwaki, 1959; Omura, 1953; Symons and Weston, 1958). In blue and fin whales there is a less well-marked seasonal cycle in spermatogenetic activity, although available data do not clearly demonstrate an associated cycle in testis weight (Laws, 1961; Mackintosh and Wheeler, 1929). In sei whales there is no seasonal variation in either weight or histology of the testes (Gambell, 1968).

PREDATORS

KILLER whales, *Orcinus orca,* are the only known predators of baleen whales (Nishiwaki and Handa, 1958). Killer whales rarely have been observed attacking gray whales. However, Scammon (1874) saw three killer whales attack and kill a gray whale calf accompanied by its mother in a lagoon in Baja California. Gilmore (1961) reported an unsuccessful attack by six killer whales on two gray whales at La Jolla, California. Morejohn (1968) observed an unsuccessful attack by seven killer whales on three gray whales, including a female with a calf, at Moss Landing, California. V. B. Scheffer (personal communication) saw six killer whales unsuccessfully attack a gray whale in Monterey Bay, California, on 9 March 1952. Burrage (1964) observed avoidance behavior of a pod of six gray whales on the approach of five killer whales at La Jolla. Pike and MacAskie (1969) reported killer whales attacking a pair of gray whales off the Queen Charlotte Islands. Andrews (1914) recounted descriptions by whalers of the reaction of gray whales to the approach of killer whales in Korean waters and reported killers feeding on the carcasses of gray whales being towed by catcher boats.

We found healed parallel scars that were obviously the tooth marks of killer whales on 57 (18 per cent) of the gray whales that we examined. Other whales doubtless bore unrecognizable killer whale tooth scars. Fifty-two of the whales had scars on the flukes, and 15 animals had scars on one or both flippers. Eight other whales had scars elsewhere on the body, as follows (number of individuals in parentheses): flanks (four), caudal peduncle (one), anal region (one), dorsal hump (one), throat (one), and snout (one). The predominance of scars on the flukes and flippers suggests that killer whales usually attempt to kill gray whales by seizing their flukes and flippers so as to immobilize and drown them. The number of scarred animals indicates a fairly high frequency of unsuccessful attacks on gray whales by killer whales. The proportion of successful attacks is unknown. Like other predators such as the wolf, *Canis lupus,* killer whales probably succeed in killing only a small proportion of the large prey that they attack (Mech, 1966). Jonsgård (1968) has pointed out that there is no incontrovertible proof that killer whales are capable of killing baleen whales that are not incapacitated or otherwise at a disadvantage.

We found no gray whale remains in the stomachs of 10 killer whales taken in the eastern North Pacific, although five of the killer whales were collected at a time when gray whales were present in the vicinity (Rice, 1968).

PARASITES AND EPIZOITES

Ectoparasites and Epizoites

All gray whales examined were heavily infested with ectoparasites and epizoites, including three species of cyamids and one species of barnacle. Zenkovich (1937*a*) reported that a few gray whales, which had presumably just emerged from brackish lagoons bordering the Bering Sea, carried no cyamids and no live barnacles. He experimentally showed that brief immersion in fresh or brackish waters kills these parasites. We found small patches of an olive-colored skin film on a few whales, but were unable to find any diatoms in scrapings from such areas. Hubbs' (1959) report of kelp growing on gray whales probably was based on observation of whales that had temporarily picked up strands of kelp while swimming through kelp beds. The baleen plates of the whales examined in this study were generally clean and carried no film of microorganisms.

Barnacles.—*Cryptolepas rhachianecti* Dall, 1872 (Fig. 37), is the only barnacle found on gray whales, to which it is host-specific. This sessile species is closely related to the genus *Coronula,* which occurs regularly on humpback whales but rarely on other species. Its mode of attachment to the skin appears to be similar to that of *Coronula* (Darwin, 1854).

These barnacles were present on every whale examined, which has been the experience of other workers who have studied gray whales. They may occur in small clusters almost anywhere on the trunk or on the surfaces of the flukes and flippers, but are most abundant on areas that are exposed to the air when the whale surfaces. They often form a continuous mass on the dorsal aspect of the rostrum and the most anterior part of the back. These areas also are those most directly exposed to food-carrying water currents as the whale stirs up the bottom sediments. The barnacles are oriented with their cirri generally directed towards the anterior end of the whale (Kasuya and Rice, 1970).

Virtually all barnacles on whales taken during the southbound migration are large (20 to 40 millimeters in diameter). Only one

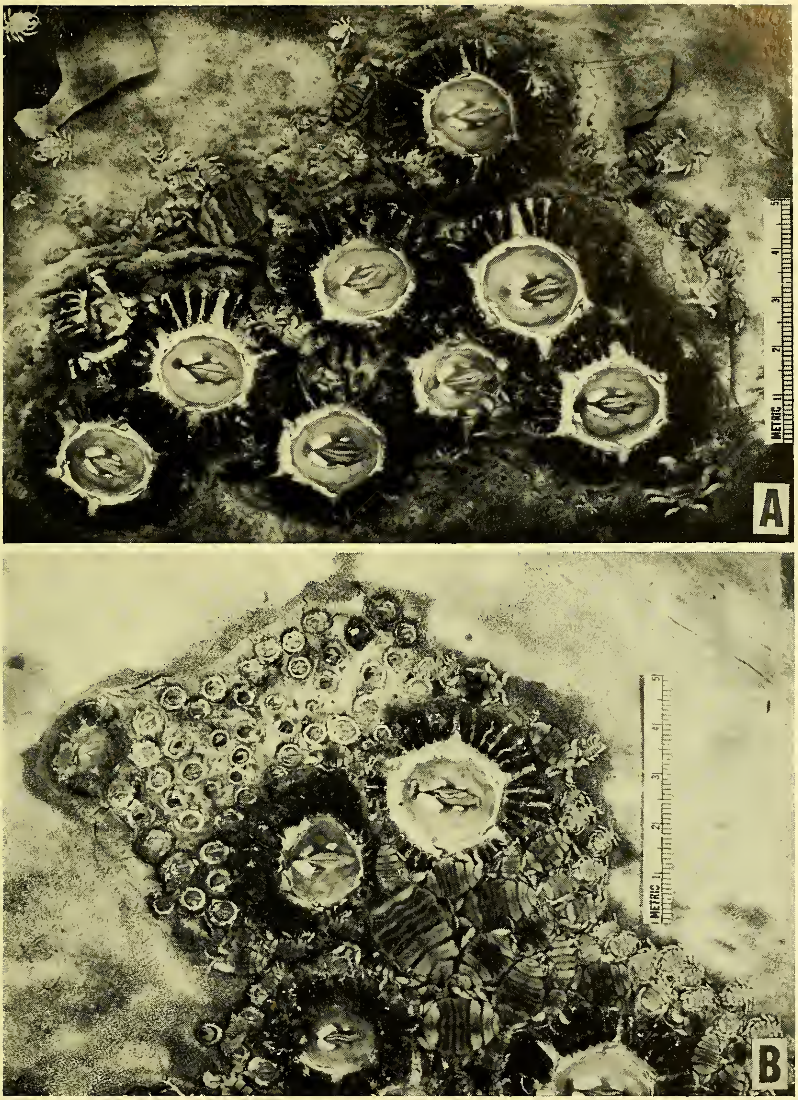

FIG. 37. Barnacles *Cryptolepas rhachianecti* on skin of gray whales. A, southbound whale with large barnacles only; B, northbound whale with many small as well as large barnacles. The anterior end of each whale is to the left. Note the many *Cyamus scammoni* on the barnacle clusters and a few *C. ceti* mostly around the periphery of the clusters.

southbound whale, a pregnant female taken on 27 December 1968, bore small barnacles (3 to 5 millimeters in diameter). Northbound whales carry two discrete size groups of barnacles. Besides the large individuals that are 20 to 40 millimeters in diameter, there are usually large numbers of small individuals that range from 2 to 5 millimeters in diameter. Thus it is apparent that barnacles spawn while the whales are concentrated on their winter grounds and when the cypris larvae of the barnacles have the greatest opportunity for finding a new host. The small barnacles often are located close together, so there must be much mortality due to crowding as they grow.

Cyamids.—Gray whales are host to three species of cyamids (Fig. 37). Most previous workers have reported only one species, the unique and easily recognized *Cyamus scammoni,* but they doubtless overlooked the other species. Hurley and Mohr (1957) were the first to report the other two, *Cyamus ceti* and *C. kessleri.* Few cetaceans are host to more than one species of cyamid. The only other cetaceans on which three species have been found are the right whale and the sperm whale (Leung, 1967), but it is not known how frequently three species of cyamids may occur on a single individual of these host species. All except one of our gray whales were lightly to heavily infested with cyamids, and the three species occurred together on 310 (98.1 per cent) of the 316 examined. However, they tended to segregate on different parts of the body as described below.

Cyamus scammoni Dall, 1872, is invariably the most abundant cyamid on the gray whale and is restricted to this host. We found it on 315 (99.7 per cent) of the 316 whales examined. It is found mostly around clusters of barnacles. A few individuals may be scattered elsewhere on the body, most often in the fold at the axilla of the flippers, in the notch of the flukes, in the umbilicus, and sometimes in the genital groove. We found no trace of the cornified area on the dorsal surface of the rostrum reported by Andrews (1914) and supposed by him to be produced by the action of cyamids. On several whales, we found large numbers of *C. scammoni* in fairly fresh wounds. The two most notable cases were a large adult male taken on 25 March 1964 with a deep wound 1.40 meters long and 0.35 of a meter wide in the blubber of the back slightly to the right of the middorsal line opposite the flipper; and a female taken on 20 December 1968 with a wound 0.85 by 0.85 meters and 14 centimeters deep on the back about 2 meters anterior to the dorsal hump. In both specimens, the wounds were completely filled with tightly packed masses of cyamids, mostly, if not entirely, *C. scammoni.* More than 100,000 were collected from the male (Leung, 1965). Many of the individuals were exceptionally large.

Cyamus ceti Linnaeus, 1758, was originally described from the bowhead whale from the Atlantic sector of the Arctic Ocean. Hurley and Mohr (1957) first found it on the gray whale at Barrow, Alaska. They reported that their specimens agreed closely with descriptions of this species and with specimens taken from bowhead whales captured at Barrow. L. Margolis (letter, July 1959), however, is somewhat doubtful about the identification of specimens from gray whales as *C. ceti,* because he has found minor differences between specimens from gray whales and those from Atlantic-Arctic bowheads. As most cyamids are host-specific, it would be most unusual for one species to infest hosts belonging to different families. This specificity is, no doubt, primarily a result of cyamids spending their entire life upon the host, so that transference can rarely occur except between members of a pair during copulation or between mother and calf during birth or suckling. This species is much less numerous than *C. scammoni,* but usually more frequent than *C. kessleri.* We recorded it on 314 (99.4 per cent) of 316 whales. It most commonly lives in grooves and skin folds on the body as follows: around the blowholes; in the angle of the gape; in the throat grooves; around the eyes; at the bases of the flippers; on the umbilicus; in the mammary slits; and, rarely, in the genital and anal grooves. Small patches of them are sometimes found elsewhere on bare skin. A few may be found adjacent to *C. scammoni* around the edges of clusters of barnacles, but competition with the larger species appears largely to exclude *C. ceti* from barnacle clusters.

Cyamus kessleri Brandt, 1872, was first described from an unidentified species of whale from the Bering Sea. Hurley and Mohr (1957) rediscovered it on a gray whale killed at Barrow, Alaska. It has subsequently been found only on gray whales. This is usually the least abundant species of cyamid on the gray whale. We found it on 310 (98.1 per cent) of 316 whales. It occurred almost exclusively around the anus and in the genital grooves. A few were occasionally located in the mammary slits and elsewhere on the body.

Endoparasites

Before these studies, no endoparasites had been identified from the gray whale, although an unidentified cestode was reported by Tomilin (1937) from individuals of this species in the Chukchi Sea. We found eight species of endoparasites in the digestive system, including three trematodes, two cestodes, one nematode, and two acanthocephalans. Some of these seem to represent undescribed species. The taxonomy of the cestodes is being studied by R. Rausch and that of the acanthocephalans by K. Neiland. We found no parasites in the kidneys, lungs, peribullary air sinuses, or blubber. Treshchev *et al.* (1969) have published an abstract of recent studies on the helminthofauna of gray whales in the Bering and Chukchi seas.

TREMATODES.—*Lecithodesmus goliath* van Beneden, 1959, was found in only two gray whales. These large flukes live in the bile ducts of the liver. Specimens from gray whales range from 35 to 54 millimeters (mean, 45) in length and 10 to 14 millimeters (mean, 12) in width. This species differs from *L. spinosus* Margolis, 1955, in its incompletely spined cuticle. *L. goliath* has been reported from many species of baleen whales (Delyamure, 1955). Two flukes were found in an immature female whale taken on 16 March 1969; no pathological conditions were grossly visible in the liver. Forty-seven flukes were recovered from a mature male whale taken on 13 March 1969, and many others were doubtless present. The bile ducts of this whale had distorted, inflamed biliary epithelium and were rimmed with thick walls of dense scar tissue. We have never observed such marked pathogenic effects associated with heavy infestations of *Lecithodesmus* in sei whales, which suggests that the gray whale is not a normal host for these flukes.

Orthosplanchnus pygmaeus was described by Yurakhno (1967) from the intestine of a gray whale taken off the Chukotskiy Peninsula. Other members of this genus infest the bile ducts and gall bladder of Arctic pinnipeds.

Ogmogaster pentalineatus Rausch and Fay, 1966, was described as a new species on the basis of our specimens and the type series collected by Fay from a gray whale at St. Lawrence Island, Alaska. The name *Ogmogaster delamurei* Treshchev (1966*a*), based upon specimens found in gray whales taken in the Chukchi Sea near Enurmino on the Chukotskiy Peninsula, is a junior synonym of *O. pentalineatus* (Skriabin, 1969). *O. pentalineatus* has been found only in gray whales. Entire specimens are easily recognized by the smoothly rounded or weakly undulate edge of the body and by the five ridges on the ventral surface. The species usually does not attain a length greater than about 3.5 millimeters, although one specimen measured 5.6 millimeters.

Field inspection of the surface of the mucosa of the small intestine at several randomly selected points revealed *O. pentalineatus* in only eight (2.5 per cent) whales. A more careful search of a section of the small intestine in a tray of water sometimes showed these flukes to be present in whales in which our spot-check had revealed none. The type series of more than 200 individuals was found in the small intestine (Rausch and Fay, 1966). In 1967, large numbers of this species were discovered in the rectum of one whale, so in 1968 and 1969 that portion of the rectum exposed on the inner side of the blubber after the blubber had been flensed from the whale was routinely examined. *O. pentalineatus* was recorded from 31 (22 per cent) of 139 whales examined in this manner. In all except seven cases, this species was living alongside *O. antarcticus*, although usually in lesser numbers. Of 1280 *Ogmogaster* collected from the rectum of 53 whales, only 227 (18 per cent) were *O. pentalineatus*. Usually fewer than 20 individuals of the latter species were present, but one whale contained well over 100.

Ogmogaster antarcticus Johnston, 1931, occurred in 46 (33 per cent) of 139 whales examined in 1968 and 1969. This species is distinguished from *O. pentalineatus* by the greater number of ridges (12 to 15) on the ventral surface, the 15 to 20 conspicuous marginal crenulations on each side of the body, and the four or five lateral loops in each intestinal caecum. It also typically attains larger size, reaching 6.0 millimeters in length. In rorquals (*Balaenoptera* species), this species has a maximum length of 10 millimeters (Rausch and Fay, 1966). Our specimens agree well with the descriptions of *O. antarcticus* as diagnosed by Delyamure (1955) and Rausch and Fay (1966). *O. antarcticus* has been reported previously from the intestines of Antarctic seals (tribe Lobodontini) and from the intestines of rorquals in the North Pacific and North Atlantic as well as the Southern Hemisphere. In this study *O. antarcticus* was found only in the rectum. The maximum number recovered from one whale was 199. In 24 of the 139 whales examined it was associated with lesser numbers of *O. pentalineatus.* Treshchev *et al.* (1969), strangely enough, did not find this species in gray whales collected on the summer grounds.

Ogmogaster plicatus Creplin, 1829, was reported in a gray whale obtained off the Chukotskiy Peninsula (Treshchev *et al.*, 1969). Otherwise the species has been found only in the intestines of rorquals in the North Pacific and North Atlantic; we have found it in fin whales collected off San Francisco. This species differs from *O. antarcticus* in having more ventral ridges (19 to 28), more than 20 marginal crenulations on each side of the body, and larger size (maximum length 14 millimeters).

The life histories of the species of *Ogmogaster* are unknown. The food habits of their definitive hosts suggest that their second intermediate hosts are crustaceans.

CESTODES.—The genus *Priapocephalus* includes cestodes characterized by a bulbous scolex that lacks suckers and has a basal collar. *P. eschrichtii* recently has been described by Murav'eva and Treshchev (1970) from gray whales in the Chukchi Sea. The other two described species are *P. grandis* Nybelin, 1922, from rorquals (*Balaenoptera* species) and right whales in the Southern Hemisphere, and *P. minor* Nybelin, 1928, from rorquals in the North Atlantic and North Pacific (Baer, 1954; Delyamure, 1955; Markowski, 1955). The larval host of *Priapocephalus* is unknown. We collected two kinds, apparently different species, from the gray whale.

The commonest species has a narrow (less than 1 millimeter wide) strobila that is of uniform width throughout. It is difficult to collect complete strobilae, but they attain a length of at least 25 centimeters. The proglottids are about 0.3 to 0.4 of a millimeter long, and the scolex is about 3 millimeters in diameter. This species was found in the small intestine of 94 (30 per cent) of the 316 whales. Usually infestations were light and rather local, although a few whales were heavily infested.

The second species differs from the previous species in that its strobila is much wider—2 to 4 millimeters. Although the proglottids adjacent to the scolex are as narrow as those of the previous species, they rapidly become wider distally. The proglottids are about 0.5 to 0.8 of a millimeter long. The scolex is similar to that of the previous species. This cestode was found in the large intestine of an immature female whale taken on 11 April 1968. The whale was heavily infested with this parasite, and no other species of cestode was present.

Tomilin (1937) reported an unidentified cestode from the gray whale. He stated (translation): "In 1934, internal parasites (tapeworms) Cestoda Ord. Pseudophaliidae [sic] (species not determined) 40 meters in length (deposited in parasitological laboratory of the Institute of Zoology, MGU) were found in the intestines of two gray whales. Their segments attained a width of 2 centimeters. The worms equaled about 48 liters in volume, in each animal." From their size, we would guess that these must be *Diplogonoporus balaenopterae* Lönnberg, 1891, a species frequently found in rorquals (*Balaenoptera* and *Megaptera*). The life cycle of *Diplogonoporus* is unknown, but the plerocercoids can be expected to occur in fishes (Rausch, 1964).

Nematodes.—*Anisakis simplex* Rudolphi, 1809, was found in only one gray whale. There were many immature individuals, 20 to 35 millimeters long, of this species in the first and second chambers of the stomach of an immature male killed on 3 April 1968. They were not attached to the mucosa. In a recent revision of this genus, J. T. Davey (personal communication) recognized only three species. Our specimens differ from *A. physeteris* Baylis, 1923, in the possession of a sigmoid esophagus. Only mature males of *A. simplex* can be distinguished from *A. typica* Diesing, 1860. *A. simplex* occurs in all species of balaenopterid whales as well as many other species of marine mammals from all over the world, especially from colder seas, whereas *A. typica* is known only from delphinids from warmer seas. Therefore Davey (personal communication) had little hesitation in assigning our specimens to *A. simplex*. The life cycle of *Anisakis* is unknown, but it is probable that two intermediate hosts are needed (Berland, 1961). Fishes are the usual source of infestations in marine mammals (van Thiel, 1966), in which these worms reach maturity.

ACANTHOCEPHALANS.—*Corynosoma* sp. was found in 18 (5.7 per cent) of the 316 gray whales studied. They were rather loosely attached to the mucosa of the small intestine. Most infestations were light, the heaviest being a whale that had 60 individuals within a 0.3-meter section of intestine. Specimens from gray whales are 4 to 5 millimeters long; the anterior half of the trunk is bulbous, the posterior half elongate and tapering. Treshchev (1966*b*) described a new species, *C. septentrionalis,* and reported (Treshchev *et al.*, 1969) *C. semerme* Forssell, 1904, *C. strumosum* Rudolphi, 1802, and *C. validum* Van Cleave, 1953, from gray whales collected off the Chukotskiy Peninsula. The life cycles of a few species of *Corynosoma* are known. All these involve crustaceans as first intermediate hosts, and fishes as second intermediate hosts (Golvan, 1959). Seals and aquatic birds are the definitive hosts of most species of this genus; a few species parasitize toothed whales (Delyamure, 1955; Golvan, 1959). The discovery of species of this genus in gray whales is the first known occurrence in a baleen whale, although we recently have found *Corynosoma* in fin whales.

Bolbosoma sp. was present in the small intestine of an immature male whale captured on 3 April 1968. The two specimens found were white and about 30 millimeters long. The trunk (when turgid after being placed in fresh water) was slightly more than a millimeter in diameter. One was loosely attached to the mucosa; the head of the other was imbedded in a small, thick-walled, pus-filled cyst in the mucosa. The life cycles of species of *Bolbosoma* are unknown.

Discussion and Conclusions

The gray whale is more heavily infested with a greater variety of ectoparasites and epizoites than any other species of cetacean. This may be at least partly due to the fact that they swim slowly and live throughout the year in shallow coastal waters rich in nutrients. In contrast, they are infrequently infested with endoparasites. Their long period of fasting each year may inhibit the survival of parasites in the digestive tract. Except for liver flukes, none of the ectoparasites or endoparasites appears to have any significant pathogenic effects.

POPULATION

Although a reasonably complete understanding of the population dynamics of the California stock of gray whales will require further investigation, data obtained in the present study provide a basis for some tentative conclusions.

Present Numbers

Because gray whales migrate close to the coast, a large proportion of the population may be counted from vantage points on shore, providing an index of population size. Between the migration seasons of 1952–53 and 1960–61, four essentially full-time counts were made at the Point Loma coastal station (Gilmore, 1960*a*, 1960*b*; Rice, 1961). In the course of offshore cruises for marking whales of other species, beginning in 1964, we found unexpectedly large numbers of southbound gray whales passing the coast of southern California far offshore (Rice, 1965; unpublished data). However, in the area of the counting station south of Yankee Point, observations during whale marking cruises indicated that few gray whales pass so far offshore that they cannot be seen from land.

Daily counts of southbound whales migrating past these two points are shown in Fig. 38. In 1967–68, 3120 whales were counted at Yankee Point and 1324 at Point Loma. In 1968–69, 3280 were counted at Yankee Point and 1154 at Point Loma. Thus, of the number of whales that passed Yankee Point only 35 to 42 per cent were seen passing Point Loma. In 1969–70, 3345 were counted at Yankee Point, and no count was made at Point Loma.

To calculate total population size from these counts, we must estimate the number of whales that were missed because of poor visibility, the whales that passed too far offshore to be seen, and the whales that passed at night. We estimated the number of whales missed because of poor visibility by considering only the counts made during days when visibility was good. As visibility is limited most by fog, drizzle, or rain, and by winds strong enough to create whitecaps, we considered only the days when there was no precipitation or fog and winds were below 19 kilometers per

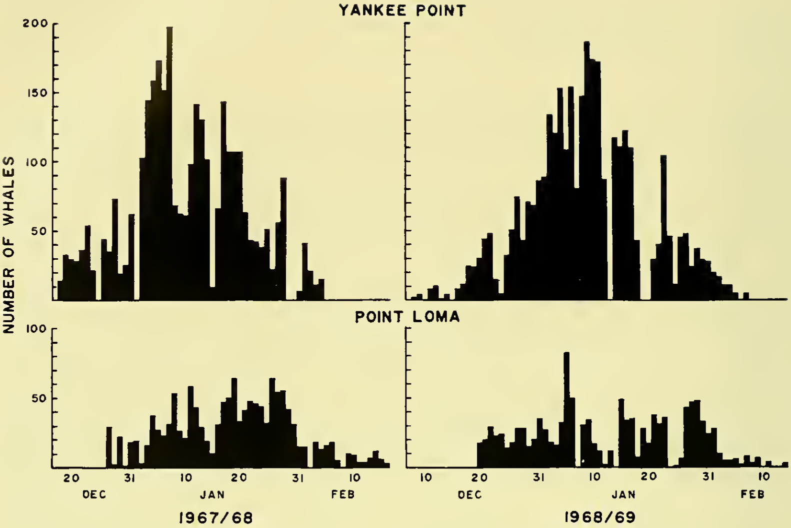

FIG. 38. Daily counts of gray whales passing Yankee Point and Point Loma, California, during the southward migrations of 1967–68 and 1968–69.

hour (10 knots). Days with good visibility and days with poor visibility were interspersed at random throughout each census period, so we extrapolated the counts made during the days with good visibility to include the entire period of each census. Some whales were doubtless missed even during days with good visibility, and, of course, a few passed early in the season before the counts began and late in the season after the counts ended.

To determine the number of whales passing too far offshore to be seen, we ran transect cruises from Yankee Point and Point Loma across the migration path of the whales. In a transect from Yankee Point on 18 January 1968, extending 37 kilometers offshore, no gray whales were seen farther from shore than 6 kilometers, and only nine of the 33 whales sighted were beyond 4.5 kilometers from shore. The remaining 24 were within 1.5 kilometers of land. Under conditions of good visibility, observers on shore could detect whales at an estimated distance of 7.4 kilometers, but 95 per cent of the whales were estimated to be within 1.9 kilometers of shore. Therefore, we conclude that the number of whales passing too far offshore from Yankee Point to be seen by the observers during periods of good visibility was insignificant.

Between 25 January and 9 February 1968, we ran seven transects totaling 1572 kilometers between Point Loma and longitude 119°20′ W, just beyond Tanner and Cortez Banks. During 100 kilometers of cruising within 9.3 kilometers of shore, 37 gray whales were seen, an average of 0.37 per kilometer cruised. During 1472 kilometers of cruising beyond 9.3 kilometers from shore, 40 gray whales were sighted, an average of 0.027 per kilometer. The width of the migration path at this latitude is at least 194.5 kilometers, of which 9.3 kilometers is within sight from Point Loma. The ratio of whales passing offshore to those passing within sight of land is thus (185.2 × 0.027) : (9.30 × 0.37) = 5.00 : 3.44. This ratio indicates that only 41 per cent of the whales migrating south past southern California passed within sight of Point Loma. This agrees with our estimates of 35 to 42 per cent based upon a comparison of the Point Loma and Yankee Point counts. Therefore, we have multiplied the Point Loma counts by 2.44 (100/41), to estimate the total number of whales moving past the latitude of Point Loma during daylight hours.

Because there is no evidence that migrating gray whales slow down at night, we have multiplied the estimated number of whales passing during the 10 hours of daylight during which counts were made by 2.4 to estimate the total number of whales passing each counting station during each of the two seasons.

Estimates of total population size, based on the foregoing corrections, are shown in Table 14. The Yankee Point estimates are probably more accurate than the Point Loma estimates, because of the greater possibility of error in adjusting for offshore migration at Point Loma. The 1968–69 and 1969–70 estimates are probably more accurate than those for 1967–68 because the counts started earlier in the season. The best estimate of the present population size of the California gray whale stock is approximately 11,000.

The reliability of this estimate is difficult to assess. A probable lower limit may be estimated by multiplying the actual counts at Yankee Point by 2.4 to allow for the whales passing at night, which gives figures of about 7500 for all three seasons. An upper

TABLE 14

COUNTS OF SOUTHWARD MIGRATING GRAY WHALES AND ADJUSTED ESTIMATES OF TOTAL GRAY WHALE POPULATION SIZE, 1967–68 TO 1969–70.

		Entire period		Days with good visibility					
Season	Locality	No. of days	No. of whales	No. of days	No. of whales	Whales per day	Estimate of whales passing during daylight	Adjusted for offshore migration	Adjusted for night migration
1967–68	Yankee Point	49[1]	3,120	32	2,430	76	3,724		8,938
	Point Loma	52	1,324	29	879	30	1,560	3,806	9,134
1968–69	Yankee Point	60	3,280	29	2,174	75	4,500		10,800
	Point Loma	57	1,154	26	758	29	1,653	4,033	9,679
1969–70	Yankee Point	64	3,345	32	2,257	71	4,544		10,906

[1] No count made on two of these days.

limit was estimated by drawing a line connecting the highest daily counts at Yankee Point and measuring the area under the line to estimate the number of whales passing during daylight. The total was then calculated by multiplying this value by 2.4 to compensate for night migration. The resulting estimates of the upper limit were about 13,000 in 1967–68, and 12,000 in 1968–69 and 1969–70.

Population Trends

In the decades prior to 1947, before legal protection was afforded by the International Convention for the Regulation of Whaling, the gray whale population is believed to have been considerably lower than it is now, but there are no quantitative data available upon which to base an estimate of its size during this period.

The estimated population size based upon four complete counts made at Point Loma from 1952–53 to 1959–60 (Gilmore, 1960*a*; Rice, 1961) showed a rather consistent increase of about 11 per cent per year. A regression analysis of the logarithms of these counts gives an estimate of the rate of population change as +12.2 per cent per year, with a 95 per cent confidence interval of –4.0 to +31.2 per cent. This study, however, has thrown doubt on the reliability of estimates of absolute population size based upon these counts.

The most questionable factor is the estimate of the extent of offshore movement, which Gilmore arbitrarily estimated at 5 per cent of the inshore movement. In contrast, present evidence indicates that offshore movement is about 144 per cent of the inshore movement along this stretch of coast.

The 1967–68 and 1968–69 counts at Point Loma were 44 and 51 per cent, respectively, below the 1959–60 count of 2344. Either some factor such as increase in small boat traffic has caused a larger proportion of the population to pass farther offshore at Point Loma, or the population in 1959–60 actually was much higher than estimated and has since decreased.

Hubbs and Hubbs (1967) made aerial surveys of the gray whale wintering grounds in Baja California between late January and early March in most years from 1952 to 1964. They suggested that the population increased from 1952 to 1954 and thereafter remained constant at about 3000. A regression analysis of the logarithms of their five complete counts from 1954 to 1964 gives an estimated rate of population change of +0.8 per cent per year, with a 95 per cent confidence interval of –4.5 to +6.4 per cent. Their estimate of absolute population size was based on an "admittedly rather intuitive estimate that about half of the population was observed on the flights." Between soundings, gray whales are at the surface or sufficiently near it to be visible for only about 1 out of every 5 minutes. Therefore, applying this correction to the data of Hubbs and Hubbs would give an estimate of about 7500 animals. Gilmore (1960*a*), who participated in some of these aerial counts, came to a similar conclusion.

In 1966–67, Adams (1968) made a partial count during the southward migration at Yankee Point. His counts were conducted only during periods of optimum visibility and included only 9.16 per cent of the daylight hours during the migration period. The number of whales actually counted was 1084. This count was adjusted to cover all daylight hours, increased by 5 per cent to account for offshore migration and 70 per cent for night migration, to yield a total estimate of 18,300. This estimate is probably too high because the counts were made only during limited periods when the most whales could be seen. Adams reported an average of up to 55 whales passing per hour, which extrapolates to a rate of 550 per 10-hour day; we never counted more than 46 whales in one hour nor more than 197 per day during our full-time counts from 1967–68 to 1969–70.

Our counts at Yankee Point suggest that the population remained essentially stable from 1967–68 to the 1969–70 season.

Density and Biomass

Population density is ecologically most significant in relation to the feeding grounds. The summer range of the gray whale in the Bering and Chukchi seas occupies about 1,000,000 square kilometers. With a population of about 10,000, the average density is approximately one whale per 100 square kilometers. Density, of course, may vary markedly between different portions of the summer grounds (Berzin and Rovnin, 1966).

The total biomass of the gray whale population based on estimated numbers, sex and age structure, and mean body weights of each sex, age, and reproductive category is estimated at approximately 1.4×10^5 metric tons. The weight of an average gray whale is thus about 14 metric tons. The mean biomass on the summer grounds would thus be about 14 metric tons per 100 square kilometers, or 140 kilograms per square kilometer.

As a gray whale requires an estimated 19 kilocalories per kilogram per day, a 14-ton individual will require about 2.7×10^5 kilocalories per day, or 9.7×10^7 kilocalories per year. Inasmuch as gray whales must consume enough food during about half the year to sustain them the entire year, their daily energy requirements on the summer grounds would be about 5.3×10^5 kilocalories. Thus, if one kilogram of amphipods supplies 500 kilocalories, a gray whale weighing 14 tons must consume about a ton, or approximately 7 per cent of its weight, of amphipods per day.

The gray whale population consumes about 10 kilograms of food per day, or nearly 2 tons a year, per square kilometer. This quantity represents about 0.2 to 1.0 per cent of the standing crop of benthos (Neiman, 1963). Energy exchange amounts to 5.3×10^3 kilocalories per day. Although these figures are rough approximations, they provide some indication of the magnitude of the ecological role of the gray whale in the shallow waters of the Bering and Chukchi seas.

TABLE 15

SEX RATIOS OF GRAY WHALE AGE GROUPS.

Age group	No. males	No. females	Per cent males
Early fetuses	9	13	41
Near-term fetuses	30	25	55
Immatures	43	34	56
Adults	123	116	51
Combined total	205	188	52

Population Structure

SEX RATIO.—The combined sex ratio of fetal, immature, and adult gray whales was 52 per cent males to 48 per cent females (Table 15). In none of the age classes does the ratio differ significantly from one to one. The observed slight preponderance of males is probably not real, especially in view of the fact that lactating females were not represented in the sample.

TABLE 16

AGE COMPOSITION OF ADULT FEMALE COMPONENT OF SAMPLE BASED ON COUNTS OF CORPORA IN OVARIES.

AGE COMPOSITION.—Age composition of our sample, based on counts of corpora in the ovaries of adult females and counts of growth layers in the ear plugs of both sexes, is given in Tables 16 and 17. Although corpora counts are believed to be more reliable than the data from ear plugs, the latter are useful because they are the only known means of determining the ages of males and of immature whales, and they permit a comparison between the sexes.

Immature whales comprised 24 per cent of the sample (26 per cent males, 23 per cent females). The data for this age class are biased because gunners select against smaller animals and because a larger proportion of immature whales have "readable" ear plugs. The proportion of immature whales in the population is certainly higher than indicated by our sample. If the apparent annual survival rate (S) of immature whales were the same as that of adults (0.92—see below) and sexual maturity were attained at 8 years of age, the proportion of immature whales 1 to 7 years old in the population would equal $1-S^7$, or 44 per cent. This is probably an underestimate, as the mortality of immatures is more likely to be greater than that of adults.

Another method of estimating the proportion of immature whales in the population based on the birth rate is applicable only if the population is stable. The birth rate is about 0.23 of the adult stock (see below). Since births must balance deaths in a stable population, the birth rate would be $(1-S)/S$, or 0.09 of the total stock alive at the beginning of the calving season. With a birth rate of 0.23 of the adult stock, the proportion of immature whales in the population would be $(0.23 - 0.09)/0.23$, or 61 per cent.

Population Dynamics

NATALITY.—On the basis of our estimate of a pregnancy rate in adult females of 0.46 per year and an assumption of an equal sex ratio, the birth rate in the California gray whale population is about 0.23 of the adult stock. As the present data indicate that adults constitute no more than 56 per cent of the population, the overall birth rate would not exceed 0.13. The approximate potential maximum rate of increase would approach this value.

MORTALITY.—The mean annual mortality rate of the adult female component of the sample, based on ages estimated from corpora counts, was calculated using Chapman and Robson's (1960) formula $M = 1 - (T/[N + T - 1])$, where M = annual mortality rate and T = Σ(age–8) (frequency). The resulting estimate of the mortality rate is 0.082.

The mortality rate for each sex was also calculated from the ear-plug data. As the proportion of immature whales in the sample is apparently biased, only whales of estimated ages of 8 years or older were used in the analysis, thus making the estimates directly comparable with those based on ovarian data. The resultant mortality values are 0.081 for males and 0.095 for females, which agree well with the estimates based on ovary analysis. They also indicate that there is probably little sex difference in mortality rate, a conclusion further supported by the essentially equal sex ratio at all ages.

Discussion and Conclusions

The California gray whale population was probably at least 8000 but less than 13,000 during the southward migration in 1969–70, with 11,000 being the most reasonable estimate.

Estimates of population size in earlier years based on shore counts at Point Loma (Gilmore, 1960*a*, 1960*b*; Rice, 1961) and aerial censuses in Baja California (Hubbs and Hubbs, 1967) are probably too low. However, they suggest that the population increased moderately from the early 1950's to 1960. The evidence for population trends from 1960 to 1967 is equivocal. The counts at Yankee Point suggest that the population has remained essentially stable from 1967–68 to 1969–70.

The sex ratio is about one to one at all ages. Probably at least 44 per cent of the population is sexually immature. The birth rate is 0.13 or slightly less. The age structure of the population suggests that the mortality rate has been 0.08. The size of any age class at a given time depends on its initial size and on its mortality rate. Therefore, the mortality rate calculated from the age composition represents the true mortality rate only if the initial size of each age class was the same, a situation likely to exist only in a stable population with a constant birth rate. In an increasing population with a constant birth rate, the initial size of each succeeding age class is greater. If the gray whale population was increasing at a rate of about 0.12 per year between 1952–53 and 1959–60, as the counts from Point Loma suggest, mortality would have to have been almost zero to produce the observed age structure. A low mortality rate would be expected in an initially small, rapidly increasing population comprised predominantly of younger animals. Inasmuch as the population has been stable since 1967, the mortality rate must have increased to equal the birth rate, but this change would have been too recent to have had a noticeable effect on the age structure of the population. However, additional data are needed, particularly on the actual age structure of the immature segment of the population and on population trends, before recruitment and mortality can be more accurately estimated.

EXPLOITATION

Aboriginal Whaling

The Nootka, Makah, Quillayute, and Quinault indians, the renowned aboriginal whalers living on the west coast of Vancouver Island and the State of Washington, regularly hunted gray whales since prehistoric times. Gray whale bones have been found in ancient middens near Lapush, Washington (Reagan, 1917). Indians chased whales in dugout canoes and struck them with harpoons attached to a line and float (Swan, 1870; Swanson, 1956; Waterman, 1920). Aboriginal whaling survived until 1928 on the coast of Washington (Anonymous, 1949).

Indians of the Kodiak Island and eastern Aleutian area killed whales with aconite-poisoned lances, a method also used by the Kamchadal in Kamchatka (Heizer, 1943). It is not known to what extent these people captured gray whales; their usual quarry was probably the right whale or the humpback whale.

The Koryaks who lived on the shores of Olyutorskiy Gulf north of the Kamchatka Peninsula in the 18th century regularly caught gray whales in large nets made of strips of walrus skin, which they set at the mouths of inlets (Krasheninnikov, 1755; Steller, 1774). Gray whales still are occasionally caught in this manner (Tomilin, 1957).

The Eskimos of Arctic Alaska and the Chukchi of eastern Siberia have for thousands of years hunted the bowhead whale and the gray whale from skin-covered "umiaks." In aboriginal times they used hand harpoons. After contact with American whalers in the late 19th century, they adopted the darting-gun and bomb-lance (Rainey, 1947). Whaling is still regularly practiced by the Eskimos of the villages of Barrow, Wainwright, and Point Hope on the Arctic coast of Alaska. In this area the catch is mostly bowhead whales. From 1954 through 1959, only nine gray whales were killed at Barrow and one at Wainwright (Maher, 1960). The natives of the village of Gambell on St. Lawrence Island (Francis H. Fay, personal communication) and the villages of Sireniki, Imtuk, Chaplino, Naukan, Uelen, and Enurmino on the Chukotskiy Peninsula

(Tomilin, 1957; Treshchev, 1966*a*) also still hunt whales. The catch in these areas is almost entirely gray whales. One hundred fourteen were killed in 1965 and 53 in 1966 off the Chukotskiy Peninsula (Zimushko, 1969*a*).

Commercial Whaling

Whaling in Japan dates back more than a thousand years, but it was not until about 1606 that commercial whaling was established. From the town of Taiji, the industry spread rapidly throughout the islands. At first, hand harpoons were used, but in 1674 the use of nets was introduced and widely adopted. Early 19th century Japanese illustrations show that gray whales were hunted in addition to the commonly taken right and humpback whales (Fraser, 1937; Japanese Fisheries Agency, 1954; Omura *et al.*, 1953).

The possibility that gray whales survived in the North Atlantic until the early 18th century and were pursued by New England whalers is suggested by Dudley's (1725) account of the enigmatic "scrag whale" mentioned earlier.

During the late 18th and 19th centuries the American high-seas, open-boat whale fishery developed and gradually spread to all oceans. In 1846, the whalers discovered the winter grounds of the Pacific gray whale along the west coast of Baja California. Scammon (1874) estimated the gray whale population as "probably not over 30,000" between 1853 and 1856. The annual congregations of gray whales in the lagoons attracted the American whalers, and by the winter of 1860–61 about 60 whaling vessels were engaged in lagoon whaling in Baja California (Starks, 1922). The first shore whaling station was established in 1854 (Starks, 1922), and by 1874, 11 shore stations were operating along the coast of California and Baja California (Scammon, 1874; Jordan, *in* Clark, 1887). Scammon estimated that about 10,800 gray whales were killed there between 1846 and 1874. Others were killed in the Bering Sea and Arctic Ocean. Scammon estimated the population of gray whales as 8000 to 10,000 in 1874. By 1886 only five shore whaling stations remained; they took 58 gray whales in 1883–84, 68 in 1884–85, and 41 in 1885–86 (Townsend, 1887). During the latter season, Townsend estimated that only 160 southbound gray whales passed

San Simeon, California, in December and January. Regular shore whaling ceased about 1900 (Starks, 1922).

During the early 20th century there was little exploitation of gray whales, although American whaling ships doubtless took a few; 31 were taken in waters off Mexico and California, and one off Alaska, by the whaling schooner "Carolyn Frances" as late as 1921 (Starks, 1922; Bower, 1923). During this period the stock probably increased.

The perfection of the modern harpoon gun in 1864 by the Norwegian whaler Svend Foyn ushered in the era of modern whaling. Captain H. G. Melsom of the Toyo Hogei Kabushiki Kaisha [Oriental Whaling Co., Ltd.] of Osaka, Japan, inaugurated a winter fishery for the gray whale at a shore station at Ulsan on the east coast of Korea, about 1899 (Andrews, 1914). A total of 1474 gray whales was killed off Korea from 1910 to 1933. Catches were declining by the 1920's, and whaling ceased after 1933, when only two gray whales were taken. This rapid decline suggests that the Korean stock numbered only some 1000 to 1500 whales in 1910, and was virtually extinct by 1933.

Exploitation of the California stock of gray whales by modern methods began with the establishment of several shore whaling stations along the west coast of North America, the first in 1905. Few gray whales were killed, however, because they were rare and could be taken only during the winter and early spring when the weather was bad. The few taken were brought into the stations at Port Hobron on Sitkalidak Island and Port Armstrong on Baranof Island, Alaska, Bay City, Washington, and Trinidad and Moss Landing, California.

The introduction of floating factory ships gave modern whalers a mobility that greatly increased their efficiency. Because whales were flensed while floating alongside the ship, these early floating factories could operate only in sheltered anchorages. A Norwegian factory ship, "Capella I," took 19 gray whales off Baja California in the spring of 1914. From 1924–25 until 1928–29, Norwegian whaling interests operated factory ships each winter and spring at Bahia Magdalena and other points along the coast of Baja California. Catches of gray whales steadily declined from 100 in 1924–25 to two in 1928–29 as the whalers turned their attention

[1] Catch by shore stations, almost all in Korea; for particulars see Mizue (1951). The whale taken in 1942 was killed in the Kuril Islands.

to the abundant and more profitable blue and humpback whales. A total of 181 gray whales was killed during these five seasons. One of these Norwegian factory ships, the "Kommandören I," took 33 gray whales in Natal'inskiy Bay, northeastern Kamchatka, in the summer of 1925. An American floating factory, the "Lansing," began operating in California in 1927. In 1932 she was replaced by the "California," which operated until 1937.

The invention of the stern slipway in 1925 made it possible to haul whales aboard the factory ship, thus permitting whalers to operate on the high seas and freeing them from regulation by national governments. The Soviet floating factory "Aleut" began operating in the western Bering Sea in 1933. Gray whales were an important part of her catch. The Japanese floating factory "Tonan Maru" took 58 gray whales in the Chukchi Sea in 1940, and the "Aleut" continued to take gray whales until 1946. From 1933 to 1946, a total of 681 gray whales was killed in the Bering and Chukchi seas. Annual catches provide no clear evidence of any changes in population size during this period.

The 1937 International Agreement for the Regulation of Whaling, which forbade the killing of gray whales, was adhered to by the governments of many whaling nations, including the United States, Canada, and Mexico, but not Japan or the Soviet Union. The 1946 International Convention for the Regulation of Whaling was ratified by the Governments of 17 nations, including Canada, Japan, Mexico, the Soviet Union, and the United States. This convention forbids the killing of gray whales, except by aborigines or a contracting government on behalf of aborigines and only when the meat and products are to be used exclusively for local consumption by the aborigines. Contracting governments may also grant special permits authorizing the collecting of gray whales for scientific research.

Statistics on catches of gray whales by modern style whaling as published in the International Whaling Statistics (IWS) are incomplete and in some instances erroneous; many data from prior to 1937 are combined under the category "North Pacific." We have attempted to compile a complete record of all gray whales killed from 1910 to 1946 (Table 18). No data are available on Korean catches before 1910. Although modern style whaling began on the west coast of North America in 1905, no gray whales were killed until 1913. No gray whales have been taken commercially since the International Convention for the Regulation of Whaling went into effect in 1947, except for one taken in error by the shore station at Coal Harbour, British Columbia, in 1951. In 1953, 10 specimens were taken under a special scientific permit at Coal Harbour. As far as we can ascertain, these statistics are complete except for possible catches off California during the years 1930 and 1932–36, as noted below, and for any that might be included under a few unspecified whales taken in California, British Columbia, and Alaska. The sources of our data for each area in which modern whaling has been conducted are given below.

Baja California.—Data on the 1914 catch of the floating factory "Capella I" are from Tønnessen (1967). Catch figures for 1924–25 through 1929 and for 1935 are from original daily catch records submitted by whaling companies to the Bureau of International Whaling Statistics and kindly made available by Einar Vangstein.

California.—Data from 1918 through 1929 are from Starks (1922), Radcliffe (1933), and Kellogg (1931). Catch statistics by species are not available for the floating factory "Lansing" in 1930 or the floating factory "California" from 1932 through 1936 (total catches for all species are listed in the annual statistical issues of "Pacific Fisherman"). No whaling was conducted in 1931. Catch statistics subsequent to 1936 are from files of the U. S. Bureau of Commercial Fisheries.

Washington.—Catch statistics of the shore station at Bay City, Washington, from 1911 to 1925, as compiled by Scheffer and Slipp (1948).

British Columbia.—Catch statistics for 1905 through 1946, compiled by Gordon Pike (1962*b*) from Annual Reports of the Canadian Department of Fisheries, list no gray whales.

Alaska.—Catch statistics are on file with the U. S. Bureau of Commercial Fisheries.

Bering and Chukchi seas.—Catch statistics for the Norwegian floating factory "Kommandören I" are from IWS, those for the Soviet floating factory "Aleut" are from Sleptsov (1955), and those for the Japanese floating factory "Tonan Maru" are from Sakiura *et al.* (1953).

Korea.—Catches by Korean shore stations are from Mizue (1951) and IWS. Their figures for the period 1920 to 1930 are erroneous; correct figures were published by Tønnessen (1967) and in Norsk Hvalfangst-Tidende, 16:13 (1927), 19:161 (1930), and 20:142 (1931).

Kuril Islands.—Mizue (1951) recorded one gray whale taken by a shore station at Otomae (on Shiashkotan Island), in the northern Kuril Islands, in 1942; this locality is outside the normal range of the species.

SUMMARY

1. This study is based on data obtained from 316 gray whales collected off the coast of central California between 1959 and 1969 and on field observations. The latter included counts of southward migrating whales from shore stations during the winters of 1967–68 to 1969–70, observations made during cruises off California and Mexico from 1962 to 1969, and aerial observations along the coast of Washington, Oregon, and California in 1969. In addition, the stomach contents of a gray whale killed by Eskimos at St. Lawrence Island, Alaska, were analyzed.

2. Gray whales usually travel within a few kilometers of shore while migrating from their summer grounds in the Bering and Chukchi seas to their winter grounds along the coast of Baja California, but off southern California the majority take a more direct offshore route from Point Conception to northern Baja California. The northward migration follows the same route, except that females with calves apparently travel offshore. Migrating gray whales swim at about 8.5 kilometers per hour; on the southward migration they travel about 185 kilometers per day. There is no evidence that the whales travel slower at night than during daylight. Migrating gray whales are temporally segregated according to sex, age, and reproductive status. During southward migration, the sequence of passage is as follows: females in late pregnancy, females that have recently ovulated, adult males, immature females, and immature males. During northward migration, the sequence is as follows: newly pregnant females, anestrous females, adult males, immature females, immature males, and postpartum females. The earliest southbound migrants (mostly late pregnant females) usually travel singly, whereas later migrants usually are in pods of two or more.

3. Food of gray whales on their summer grounds in the northern Bering and Chukchi seas includes at least 17 species of benthic gammaridean amphipods, among which *Ampelisca macrocephala* predominates. The nature of the food indicates that gray whales are bottom feeders. Virtually no food is consumed during migration,

although rarely small quantities of decapod nauplii (*Pachycheles rudis* and ?*Fabia* sp.) are eaten. There is little evidence that gray whales feed on their winter grounds off Baja California. In the interval between their southward and northward migration past San Francisco, the whales lose from 0.21 to 0.37 per cent of their body weight per day. This weight reduction is sufficient to account for the estimated energy expenditure during the winter. Blubber thickness and oil yield also decrease during winter.

4. Age may be estimated from the number of growth layers in the ear plug, indirect evidence suggesting that two layers are formed the first year and one each year thereafter. However, the value of ear plugs for age determination is limited because many plugs do not have clear laminations, and earlier laminations may disappear in older animals. The number of corpora albicantia in the ovaries provides a more reliable estimate of the age of adult females. Growth zones in the baleen plates are of little use for age determination because of rapid wear.

5. Mean body length at birth is about 4.9 meters. Mean length at weaning at an age of 7 months is about 8.5 meters. Puberty is attained at an estimated mean age of 8 years (range, 5 to 11 years) and a mean body length of about 11.1 meters in males and 11.7 meters in females. Physical maturity is attained at about 40 years at a mean body length of about 13.0 meters in males and 14.1 meters in females.

6. Ontogenetic changes in body proportions are slight. From late fetal life to a year of age, relative length of the flippers decreases and relative length of the tail increases. There are no significant changes in body proportions between the end of the first year and physical maturity. Females have slightly shorter flippers and longer tails than do males.

7. In immature females, seasonal enlargement of the follicles begins at a body length of about 9.9 meters and an age of 2 or 3 years. Mean weight of individual ovaries increases rapidly from about 140 to 300 grams when body length reaches about 11.3 meters at about 5 years of age. The ovaries weigh about 340 grams at sexual maturity and continue to increase slowly throughout life,

reaching about 646 grams at 50 years of age. The uterine cornua are 3.5 to 12.0 centimeters in diameter in immature females and more than 11.0 centimeters in adult females. The mammary glands do not develop until the female is well into her first pregnancy.

8. Female gray whales normally come into estrus biennially in late November and early December. Most individuals ovulate only once each season, although whales failing to conceive after their first ovulation may experience a second estrous cycle the same season. Multiple ovulations are extremely rare. Mean ovulation rates are 1.20 per breeding season for nulliparous females and 0.96 per breeding season (0.52 per year) for parous females. There is no evidence for postpartum ovulation or for ovulation at any other time of year. However, increase in follicle size following stillbirth or early loss of the calf suggests that females might ovulate following such an event. Females continue to breed at an advanced age. Corpora lutea of pregnancy average 8.7 centimeters in diameter, whereas corpora lutea of ovulation do not exceed 2.5 centimeters (at least if another estrous cycle soon follows). Corpora albicantia derived from corpora lutea of ovulation are indistinguishable from those derived from corpora lutea of pregnancy. Corpora albicantia persist in the ovaries throughout life. About 55 per cent of ovulations occur in the left ovary and 61 per cent occur in the anterior half of the ovaries.

9. Most conceptions occur within a 3-week period during southward migration, with a peak about 5 December. The pregnancy rate is 0.86 per breeding season (0.46 per year). The gestation period is about 13 months, and fetal growth is accelerated during the last half of pregnancy. During southward migration, late pregnant females (exclusive of their conceptus) average 25 to 30 per cent heavier than the other adult females. Births occur within a period of 5 to 6 weeks, with a peak occurring about 10 January. Caudal presentation at birth is normal.

10. Lactation lasts an average of about 7 months, ending in August.

11. Females are usually in anestrus from August to November or December. However, females that fail to ovulate or conceive

during the winter are probably in anestrus for the following 12 months.

12. In immature males, the weight of both testes is usually less than 5 kilograms, and the seminiferous tubules average 45 to 102 microns in diameter. Testis weight of sexually mature males is more than 5 kilograms, and the average diameter of the seminiferous tubules exceeds 104 microns. Penis length is correlated with body length and is usually less than 1.1 meters in immature males.

13. The average weight of the testes of adult males during southward migration in December and January is 38 kilograms, and the mean diameter of the seminiferous tubules is 177 microns. During northward migration in February and March, mean testes weight and tubule diameter are 22 kilograms and 148 microns, respectively. From July through October, the testes average 23 kilograms. These differences suggest a marked seasonal sexual cycle in the male, with a peak of spermatogenetic activity in autumn or early winter.

14. The killer whale, *Orcinus orca,* appears to be the only predator on gray whales. The mortality rate from killer whale attacks is unknown. However, frequency of tooth scars indicate that killer whale attacks on gray whales are often unsuccessful.

15. Epizoites of gray whales include the following (percentage of occurrence in parentheses): the barnacle *Cryptolepas rhachianecti* (100) and the cyamids *Cyamus scammoni* (99.7), *C. ceti* (99.4), and *C. kessleri* (98.1). Endoparasites collected include the trematodes *Lecithodesmus goliath* (0.6), *Ogmogaster pentalineatus* (more than 22), and *O. antarcticus* (33); two apparently undescribed species of the cestode *Priapocephalus,* one in the small intestine (30) and the other in the large intestine (0.3); the nematode *Anisakis simplex* (0.3); and two acanthocephalans, *Corynosoma* sp. (5.7) and *Bolbosoma* sp. (0.3). Obvious pathogenic effects were noted only for the liver fluke, *Lecithodesmus goliath.*

16. Population size of the California stock during the southward migration of 1969–70 was estimated to be about 11,000. Although previously published estimates of numbers of the California stock are questionable, the population appears to have increased from

1947 to 1960. Trends from 1960 to 1967 are uncertain. Since 1967, population size has remained essentially stable.

17. The sex ratio is essentially equal in all age groups. The birth rate does not exceed 0.13. The calculated annual death rate of adults is 0.08. This is probably an overestimate, although, if the population is now stable, the death rate must have recently increased to near the birth rate.

18. The California gray whale stock was severely overexploited between 1846 and 1900. During the present century this population has been only lightly exploited. Factory ships took an average of 36 gray whales per year in Mexico from 1924–25 to 1928–29 and an average of 48 per year in the Bering Sea from 1933 to 1946. Since then the species has been protected from commercial whaling by the International Convention for the Regulation of Whaling. The Korean stock was virtually exterminated between 1899 and 1933.

Demography and Phenology of Gray Whales and Evaluation of Whale-Watching Activities in Laguna San Ignacio, Baja California Sur, Mexico

Mary Lou Jones and Steven L. Swartz

Introduction

As whale-watching tourism, local fishing, and industrial activities increased throughout the southern range of the gray whale in the 1970s, the government of Mexico expressed a desire for detailed information on gray whales in their winter range with which to formulate management policy. The U.S. government raised the concern that

ISBN 0-12-389180-9

visits to the gray whale breeding lagoons by U.S.-based excursion companies may create environmental disturbance detrimental to the whales and thus constitute "harassment" and a violation of the U.S. Marine Mammal Protection Act[1] and the Endangered Species Act (Reeves, 1977; Bean, 1980; U.S. Marine Mammal Commission, Washington, D.C., personal communication. Literature on gray whale breeding biology and on the possible effects of whale-watching activity (or human activities) on gray whales was extremely limited, mostly anecdotal, and not quantified. One line of reasoning suggested that whale-watching activities or the mere presence of humans within the breeding lagoons would displace the whales and cause them to seek alternate, perhaps suboptimal, areas in which to mate and calve (Rice and Wolman, 1971; Reeves, 1977). Gard (1974) stated that the gray whales may abandon important habitats and shift their distribution from lagoon to lagoon in response to human activities, but the results of his surveys were not sufficiently conclusive to demonstrate any shift. During the 1960s, gray whales apparently abandoned the small lagoon of Guerrero Negro while it was used as a port for salt barges, and then reoccupied the lagoon following the departure of the salt company and its associated vessel traffic (Reeves, 1977; Chapter 15, this volume). Several investigators suggested "that disturbance from whale-watching may draw needed energy from the finely tuned energy budget of these animals" (Kaza, 1980); however, there were no data to substantiate this point. Still others proposed that if whale-watching operations (and other human activities) resulted in general disturbance that interrupted mating behavior frequently enough to lower reproductive success and increase calf mortality and was not benign over the long term, a decrease in the whale population and its productivity would be expected (Swartz and Cummings, 1978). None of the proposed consequences of disturbance due to whale watching within the lagoons could be evaluated as there was a scarcity of information available on the sensitivity of the whales to human activites.

In full recognition of the paramount importance of the breeding lagoons to the reproductive success and continued recovery of gray whales and of the economic, educational, and aesthetic value of controlled visitation to wildlife areas, the government of Mexico enacted as protective measures a series of legal and administrative provisions that established Laguna Ojo de Liebre (Scammon's Lagoon) and Laguna Guerrero Negro (Black Warrior Lagoon) as national refuges for gray whales, the first of their kind for any cetacean (Vargas, 1981). Beginning in 1972, all commercial vessels, domestic and foreign, were required to obtain permits before entering Laguna Ojo de Liebre, and in 1974 they were restricted to one lower channel near the lagoon inlet (Kaza, 1981).[2] With the restrictions on entry to Laguna Ojo de Liebre, the focus of whale-watching tourism shifted to the largely undisturbed Laguna San Ignacio approximately 150 km further south.

Lagura San Ignacio, the third largest breeding area of gray whales, is the least developed of all the major lagoons. Local Mexican fishing from outboard-powered, 5- or

6-m "pongas" was the only commercial activity prior to 1975, when large-vessel traffic associated with whale-watching tourism began to visit the lagoon. Nearly 100% of the visitors to Laguna San Ignacio utilized vessels to enter the lagoon or to explore the interior, after arriving by aircraft or overland. Considering the dearth of information on gray whale abundance and distribution in this lagoon and because of the recent influx of tourism, we conducted a reconnaissance study in 1977 to assess the need for and feasibility of an intensive long-term research program in Laguna San Ignacio (U.S. Marine Mammal Commission Contract No. MM7AC008). This initial investigation indicated that the majority of females and their calves occupied the middle and upper lagoon "nursery" areas early in the winter when the calves were young. These areas were separated from the lower lagoon and inlet area by a constriction of the main entry channel at Punta Piedra. The width of this constriction (1.5 km) relative to the middle and upper lagoon suggested that human activities there, if adverse, could impede the movement of pregnant near-term females and females with newborn calves into and out of the nursery areas. Also, disturbance in the lower lagoon could disrupt courtship and mating activity of whales without calves and possibly reduce reproductive success. It was clear that knowledge of "normal" gray whale abundance, distribution, and behavior was a prerequisite for understanding the biological significance of responses to any human disturbance (Swartz and Cummings, 1978).

In 1978 we initiated the first long-term systematic study of gray whales in Laguna San Ignacio with the two-fold aim of providing baseline information on the demography and phenology of breeding gray whales and evaluating the impact of whale-watching activities within the lagoon on the whales. It was hoped that the information generated by this research, in conjunction with on-going monitoring programs, would be used to detect and evaluate changes in the wintertime abundance, distribution, and movements of gray whales that may be correlated with future human development.

Following the second year of this study, Mexico declared Laguna San Ignacio a refuge for gray whales and enacted regulations to control the number of whale-watching vessels that visited the lagoon and restrict their activities to specific areas within it. The intent of this action was to protect areas essential to the females and their calves (nursery areas), while at the same time permitting controlled commercial activity in the lower lagoon nearest the sea.

The Laguna San Ignacio research program continued for five consecutive winters, beginning in 1978 and concluding in 1982. We felt that 5 years was the minimum period required to develop a meaningful data base on gray whale trends and to determine whether frequent or continuous vessel disturbance caused changes in gray whale utilization of the lagoon.

The specific objectives of the Laguna San Ignacio research program were to

1. Document the seasonal timetable of lagoon occupation by whales
2. Determine the number and distribution of gray whales inhabiting the lagoon interior and inlet
3. Estimate the proportion of females with calves to whales without calves that utilize the lagoon throughout the season

4. Identify specific nursery areas and the abundance of calves in these areas
5. Ascertain the seasonal mortality of calves, immatures, and adult whales
6. Monitor the level of whale-watching tourism and other human activities and evaluate its impact on the abundance and distribution of whales wintering in the lagoon.

In this chapter we report new findings on gray whale demography and phenology in Laguna San Ignacio; we provide detailed data on patterns of movement into and out of the lagoon, compare changes in the timing of the whales' occupation of the lagoon among all years, evaluate trends in relative abundance across the 5-year study, and present information on the impact of whale-watching activity on the whales. These findings are also compared with studies of gray whales in other breeding lagoons within their winter assembly area. This research establishes a data base on which to evaluate changes in abundance and habitat utilization of gray whales wintering in Laguna San Ignacio which may occur as a result of increasing vessel traffic, industrial development, and petroleum and natural gas production throughout virtually the entire range of this cetacean.

This research was conducted under Permit No. 163 issued by the U.S. Department of Commerce, National Oceanic and Atmospheric Administration, National Marine Fisheries Service. Permission to conduct scientific research in Mexico was authorized under permits No. 14203 (1977), No. 12-459-498 (1978), No. 920 (1979), No. 10919 (1980), No. 10455 (1981), and No. 4048 (1982) issued by the Secretaria de Pesca, Direccion General De Regulacion Pesquera de Mexico.

Methods

STUDY SITE

Description

Laguna San Ignacio is located on the Pacific coast of Baja California adjacent to Bahia Ballenas, approximately 680 km south of the International Border between 26°42′ and 27°00′N and 113°7′ and 113°18′W (Fig. 1). The lagoon is part of the Vizcaino Desert and borders a gently sloping, dry, coastal flood plain the sediments of which are presumed to be Cretaceous and Tertiary, capped by Pleistocene alluvium (Mina, 1957; Phelger and Ewing, 1962). The climate is arid with an annual average rainfall of 56 mm (2 in.) which falls mainly during winter months; there is no runoff and no freshwater streams or rivers flow into the lagoon (Bostic, 1975).

Prior to our study, the most recent hydrographic chart dated from 1896 (U.S. Hydrographic Chart No. 1494) and did not accurately represent the lagoon in its present state. Therefore, it was necessary for us to conduct a habitat study to establish the physical characteristics of the lagoon and to construct an accurate chart. The present-day shoreline, the location of major shoals, and an accurate estimate of the total lagoon acreage were determined from satellite imagery (LANSAT). Lagoon bathymetry was

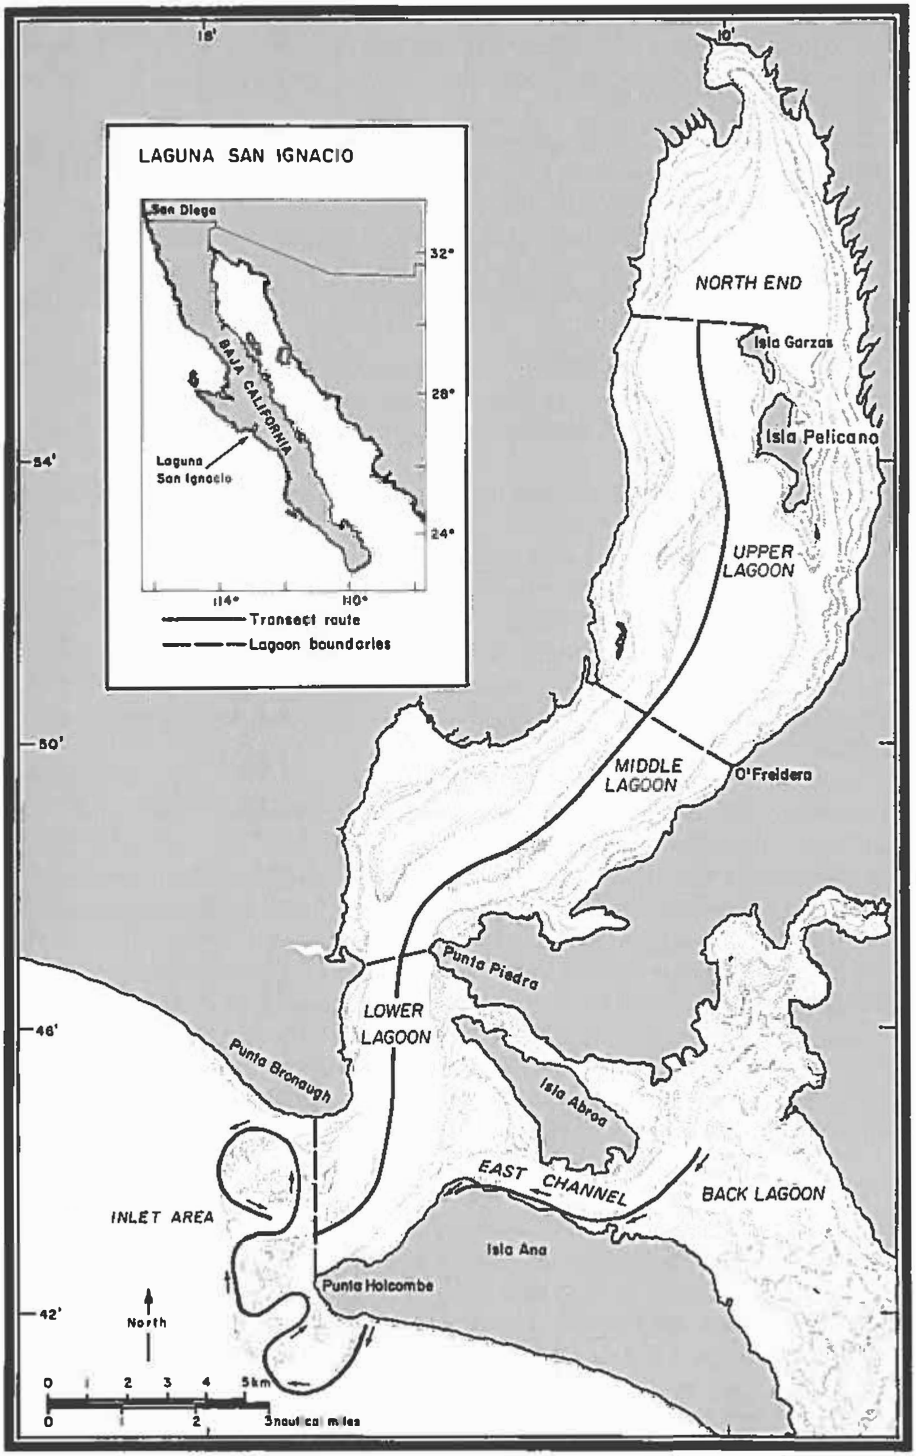

Fig. 1. *Laguna San Ignacio showing the boat transect trackline in the lower, middle, and upper lagoon areas and the aerial transect trackline in the east channel and inlet area. Arrows indicate the direction of flight of the aircraft.*

discerned from "echograms" made by a continuous-recording fathometer. Scuba divers made visual observations of the lagoon floor and sampled bottom sediments (Swartz and Jones, 1981).

The lagoon is a system of narrow, relatively deep channels surrounded by large intertidal flats. It lies on a north-to-south axis, extends inland approximately 32 km, ranges from 1.8 to 6.5 km wide, and has an area of 152 km^2, of which only approximately 57% or 87 km^2 is of sufficient depth (>2 m) to be navigable by whales. The area of the inlet is approximately 20.5 km^2, and the east channel adds approximately 3.6 km^2. The semidiurnal tide ranges from 0.9 to 2.4 m, and the tidal currents in the inlet and channels are very turbulent.

Laguna San Ignacio has a distinctive topography characteristic of lagoons with an appreciable tidal range. The bathymetry and sedimentology may be divided into five areas: the inlet, east channel, and the lower, middle, and upper lagoons (Swartz and Jones, 1981).

The 3.8-km-wide inlet is defined by a breaker line and includes a 1-km-wide entry channel with a maximum depth of 16.8 m, bordered by the inner inlet delta that averages 3.6 m in depth (Fig. 2, Profile 1). This steep-walled channel runs northward and parallels the west shore of the large barrier island, Isla Ana. The delta ends 1.5 km inside the inlet and the channel becomes deep over its entire width (Fig. 2, Profile 2). Sediments range from well-sorted, hard-packed, medium-grained sand with large shell fragments on the inner delta to irregular rock rubble covering the floor of the inlet channel. The delta is devoid of macroscophic plants, but the channel supports sparse algal vegetation in the rocky areas.

The lower lagoon consists of a steep-walled channel with a maximum depth of 25.9 m. It narrows from 3-km wide near the inlet to a constriction 1.8-km wide at Punta Piedra, where it terminates as the lagoon trends northeast. This segment is the widest relatively deep channel in the lagoon (Fig. 2, Profiles 3 and 4). West of Isla Ana, the 0.5-km-wide and 9.1-m-deep east channel tributary leaves the main lagoon, turns southeast behind Isla Ana, and runs 5.1 km to a shallow lagoon 1.5- to 2.4-m deep (Fig. 2, Profiles 13–15). Here the bottom is composed of poorly sorted coarse- and medium-grained sand with crushed shells. Extending north from Isla Ana, the main channel floor varies from a series of irregular sand ridges perpendicular to the lagoon axis to rocky areas (*coquina*) overlain with sand. The deepest regions of the channel are covered with poorly sorted, hard-packed, fine- to coarse-grained sand. West of Punta Piedra, medium-grained sand ridges are interspersed with occasional rock outcroppings 4- to 6-m tall.

The middle lagoon is characterized by a system of three channels ranging from 7.6 to 21.3 m deep, which become shallower and irregular in profile west of O'Freidera (Fig. 2, Profiles 5 and 6). Sediments are poorly sorted, fine- to coarse-grained sand with crushed shell, and some rocky areas. Extensive sand bars support stands of eelgrass (*Zostera marina*), but the channels contain little plant life.

The upper lagoon is a gently sloping basin with an average depth of 4.6 m. Two islands, Isla Garzas and Isla Pelicano, are separated by a shallow isthmus and located approximately mid-lagoon (Fig. 2, Profiles 8–12). The areas at the head of the lagoon

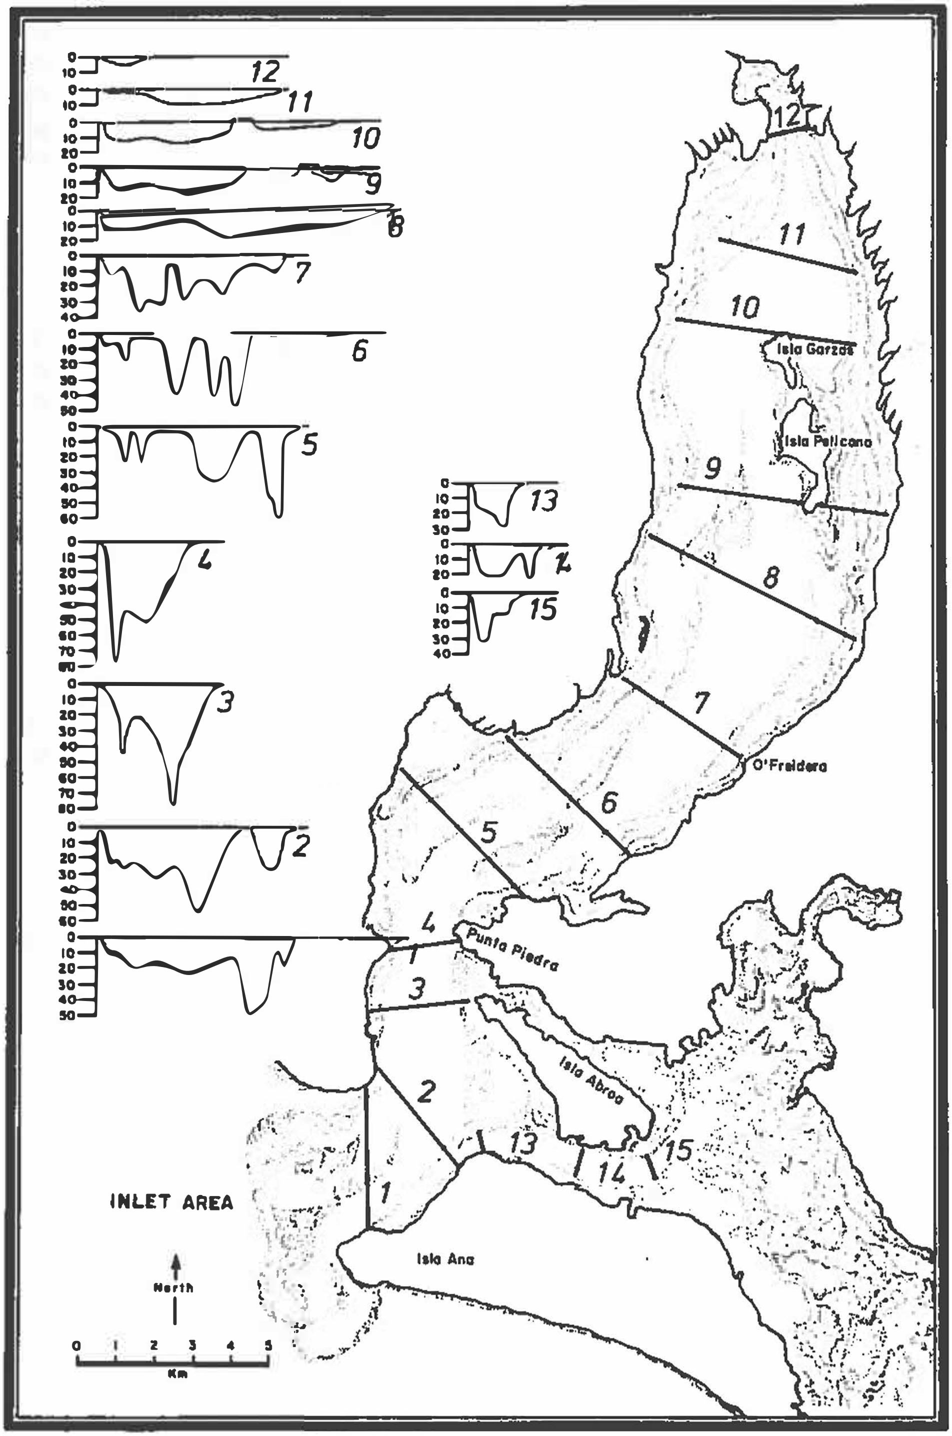

Fig. 2. *Depth profiles of Laguna San Ignacio based on echograms. Horizontal scale approximate. Soundings are in feet, and vertical exaggeration is 100×.*

north and east of the islands contain fine sand, silt, and clay. The bottom in the north is dominated by dense stands of eelgrass containing a variety of crustaceans, gastropods, pelecypods, encrusting hydroids, sponges, and tunicates. Red and brown algal epiphytes and encrusting invertebrates are attached to rocks, shells, and eelgrass blades.

Refuge Regulations

By 1975 almost all whale-watching tourism had switched from Laguna Ojo de Liebre to Laguna San Ignacio, and the need for regulation of commercial activities in this lagoon became apparent (Reeves, 1977). Our first two winters of research, 1977 and 1978, indicated the majority of females and their calves utilized the middle and upper lagoon areas early in the winter when the calves were young. In 1979 Mexico declared Laguna San Ignacio as a gray whale refuge, and our initial findings were used to designate the boundaries of the "closed" nursery area (middle and upper lagoon areas) and the "open area" in the lower lagoon where controlled tourism and fishing were permitted and to formulate regulations for the kinds of activities that would be permitted within the lagoon.[3] The regulations specify that between December 15 and March 15 each year all vessel traffic is restricted to the lower lagoon south of Punta Piedra, thus providing the upper two-thirds of the lagoon as a sanctuary free of human activities. In addition, no more than two commercial vessels are allowed within the lagoon at any one time. Individual permits issued to each vessel specify the number of days a vessel may remain within the lagoon, the number of passengers it may carry, the number of skiffs it may launch, and the kinds of activities permitted, such as whale watching, shore explorations, etc.

BOAT SURVEYS

Each of the field seasons was timed to coincide with the period during which most of the gray whales that utilized the lagoon could be observed. We began the first field season (1977–1978) on December 23, 1977, in an attempt to document the arrival of the earliest whales to the lagoon. In subsequent winters (1979–1982), field work began the second week in January, and in all years it continued until mid-April.

Each week, line transects (Eberhardt, 1978) of the entire lagoon interior were conducted to estimate whale abundance, to elucidate whale distribution and movement, and to document the seasonal timetable of lagoon occupation. Transects were executed in a 4.7-m inflatable boat powered by a 20-hp outboard engine and traveling at approximately 11 km/hr. Each transect required approximately 7 hr to complete. The crew included a left and a right observer and a vessel operator. Transects were run along an imaginary line drawn midlagoon from Punta Piedra south to the breaker line near the lagoon inlet, north to Isla Garzas at the northern end of the lagoon, and then south again to the starting point at Punta Piedra. In this way, the entire transect line was traversed twice. The maximum distance from the boat to the 2-m depth contour along shore was 2.6 km and the minimum 0.8 km; thus, whale-inhabitable water and both

---

[3] Diario Oficial de la Federation de los Estados Unidos Mexicanos, 16 July 1979.

shorelines were clearly visible at all times within the lagoon. Whales in the "North End" of the upper lagoon north of the transect termination were observed through binoculars from a 5-m-high bluff on the northern tip of Isla Garza (Fig. 1).

All whales sighted from the boat were counted when they were approximately abeam of the boat, and all observations were recorded on a cassette tape recorder. The higher number of whales counted from the two replicate transects was used as a minimum abundance count, an index of the whale population for that week. Because only two replicates could be obtained per census day, we did not estimate errors for these abundance counts. Whale distribution was determined by recording transect starting time, time each whale or group of whales was encountered, passage of landmarks, progression of tidal stages, and time of completion. To prevent observer anticipation of whales previously counted, observers viewed a different side of a transect leg on each replicate. Transects were discontinued when wind and wave conditions exceeded Beaufort Sea State No. 3 (winds 12–18 km/hr), which obscured whale blows, diminished the sightability of inconspicuous behaviors, and lowered the overall probability of sighting whales (particularly calves). Corrections for whales missed are discussed in the results.

Unless otherwise noted, "female–calf pairs" were considered a single unit, and counts of these pairs are equivalent to calf counts; "single whales" refer to nonparturient females, adult males, and immatures. Single whales often occurred in pairs or groups.

AERIAL SURVEYS

Aerial surveys augmented the boat surveys in 1980, allowing simultaneous estimation of whale abundance and distribution in areas not accessible by boat, namely the east channel, inlet, and nearshore waters adjacent to the lagoon. These surveys were flown in a Piper Super Cub (a two-passenger, single-engined, high-wing aircraft) at an altitude of 330 m and an average ground speed of 123 km/hr. Total coverage (100%) was attempted (Eberhardt, 1978) by flying a serpentine course over the inlet with observers making counts from each side of the aircraft. The east channel was surveyed by flying along its southeastern shore (Fig. 1). As with boat surveys, all observations were recorded on a cassette tape recorder. For larger whale groups, the aircraft diverted from course and circled until the observer's count stabilized, then returned immediately to the original course. Practice flights were flown to familiarize the pilot and observers with the transect route and survey procedure. Surveys were conducted during Beaufort Sea State No. 3 conditions or better, and surveys were flown between 0900 and 1500 hr to reduce the effects of surface glare on the water. Sighting cues indicating the presence of whales, such as bubble bursts, mud upwellings, or a series of whale "foot-prints," were counted as single animals.

MORTALITY

Beaches were searched by boat or aircraft for stranded dead whales at least twice per week, and additional information was requested of local fishermen who participated by reporting sightings of whale carcasses. The sex of dead whales was determined, and standard measurements were recorded. Length was measured as the distance from the tip of the snout (rostrum) to the notch of the flukes. Whale carcasses were marked and photographed, and their locations were recorded to prevent duplicate sightings of individuals in the event that the tide and winds moved bloated carcasses from their original site of discovery. The calf mortality rate for Laguna San Ignacio was calculated from the number of dead calves discovered and the estimated total calf production. Finally, we researched the records on natural mortality in other breeding areas for comparison with the Laguna San Ignacio data.

WHALE-WATCHING ACTIVITIES

When we began the gray whale study in Laguna San Ignacio in 1977, there was little information available from which to judge the possible reactions of the whales to the growing tourist industry within the lagoon. Gray whales seemed particularly vulnerable to human activities within the confinement of the lagoons because they cannot readily flee from an adverse disturbance as they can in the open ocean. Also, given that the lagoon is a critical habitat necessary for successful reproduction, exclusion from one or more lagoon areas could cause overcrowding in remaining areas or force whales to seek alternate and perhaps suboptimal areas in which to breed that may not provide the protective features offered by the lagoons.

To document the relative amount of disturbance introduced into the lagoon each winter by human activities, our first step was to qualitatively and quantitatively characterize human disturbance. A log was kept of the number, location, and hours of activity of all vessels entering or transiting through the lower lagoon, the area designated for commercial activities. For the whale-watching excursions, we determined the number of hours that vessels were present in the lagoon, the number of hours they were underway and at anchor, and the number of hours whale-watching skiffs were in operation. The sum of the hours of each disturbance category was then expressed as a percentage of each entire season, and these percentages were compared among years. It was, however, beyond the scope of the program to identify the specific attributes of vessels that might cause significant changes in the utilization of the lagoon by gray whales.

In our study, we employed natural experimental and observational approaches to evaluate the demographic reactions of gray whales to potential sources of disturbance from whale-watching activities over the 5 years. To determine whether whales showed a response to human disturbance in the lagoon among years, seasonal trends in whale abundance and distribution were statistically compared among years as levels of tourism increased and decreased. Specifically, we sought to identify the following possible responses to disturbance:

1. A decrease in seasonal abundance of gray whales utilizing the entire lagoon
2. A decrease in the number of females and calves utilizing the nursery area
3. A decrease in the seasonal abundance of gray whales in the lower lagoon, the area utilized by tour vessels, and
4. An increase in the seasonal mortality of whales, especially calves.

Although interactions between whales and people have a variety of forms, in designing our study we believed that the consequences of changes in these parameters would be immediately "meaningful" from a management point of view. Findings on gray whale behavioral reactions to vessel disturbance such as changes in the relative frequency, duration, and context of social behavior, aerial behavior, sexual behavior, swimming direction, and breathing rates are reported elsewhere (Swartz and Jones, 1978, 1981; Jones and Swartz, 1984).

In addition to the analysis of seasonal demographic trends among years, we compared gray whale abundance and distribution within years during "control" periods without human activity and "experimental" periods with human activity (specifically tourism) in the lagoon. Here, the potential adverse effects of whale-watching tested for were responses 1, 2, and 3 mentioned earlier.

To evaluate these potential effects, boat transect counts from consecutive pairs of days were compared; these pairs included a day preceding and a day following the arrival of a vessel, two days with vessel activity, and a day before and a day following a vessel departure. We tested the null hypothesis that whale-watching activities did *not* cause significant changes in gray whale abundance, density, and distribution in the lagoon as a whole, in the nursery area, and in areas where whale and human activities occurred simultaneously.

The proposed consequences of exposure to human disturbance (i.e., whale-watching activities) constituted our operational definition of "harassment" or disturbance to whales.

Results

ABUNDANCE, DISTRIBUTION, AND OCCUPATION TIMETABLE

Correction for Unseen Whales

Raw boat transect counts may be biased toward underestimating the actual number of whales in an area for two primary reasons, (1) some whales that are present but are below the water's surface while the transect vessel passes through the survey area are not detected, and (2) some whales that are at the surface may be missed by the observer (Caughley, 1977; Eberhardt, 1978; Eberhardt *et al.*, 1979; Davis *et al.*, 1982). The first source of bias is a function of the length of time the observer has to view the survey area and the whale's surface interval and duration of dives. A correction factor to determine the probability that a whale will surface while the observer is viewing the survey area is given by Eberhardt (1978) as

$$P = \frac{s}{s+u} + \frac{t}{s+u} = \frac{s+t}{s+u} \qquad (1)$$

where s is the mean duration of surfacings (i.e., the mean surface interval), u is the mean duration of dives, and t is the length of time a point along the transect line is visible to the observer. To allow for submerged animals, raw whale counts should be divided by P. Two of the assumptions of this formula are that t is less than or equal to u and that s and u are constant; however, because our gray whale values for u were very much less than t and because the duration of surface intervals and dive durations varied with the behavior of the whales in Laguna San Ignacio, these assumptions were not valid for our boat surveys. Under these conditions, Eberhardt (1978), and Eberhardt *et al.* (1979) suggest that $P = (s + t)/(s + u)$ is inappropriate to compute the probability that a whale will be detected, but, to our knowledge, no alternate method has been published.

We employed a different approach to determine whether to adjust our raw whale counts for whales missed while they were below the surface. First, to calculate t, the duration of potential detectability during our boat survey, we divided the observer's field of view by the boat survey speed. We estimated that the length of the observer's field of view was 1.5 km, beginning approximately 1.0 km ahead of the boat and ending 0.5 km behind. The survey speed of 11 km per hour was selected for three reasons: (1) it was faster than the observed range of normal gray whale swimming speeds of up to 6 km per hour (Gilmore, 1960; Pike, 1962; Sumich, 1983) and thereby reduced the possibility of counting the same whale twice; (2) it allowed adequate time to view most whales more than once (see below); and (3) it allowed us to complete two transect replicates per census. Thus, our value of t was

$$t = \frac{1.5\ \text{km}}{11\ \text{km/hr}} = 8.18\ \text{min}, \tag{2}$$

the period during which a point along the transect line was within the observer's view.

Our next step was to determine how many times a whale was likely to surface within the period of potential detectability. To do this we used the mean surfacing rate and mean surfacing interval calculated by Mate and Harvey (1981) and Harvey and Mate (Chapter 24, this volume) for 10 radio-tagged gray whales in Laguna San Ignacio. Because their radio tag only transmitted signals when the antenna broke the surface, Harvey and Mate obtained the most precise estimates available for these parameters during 307 hr of monitoring.[4] Their mean surfacing rate for adult whales was 35.6 ± SE 0.8 surfacings/hr ($n = 202$), or 0.59 surfacings/min. In addition to the data for radio-tagged whales, from their shore observations they reported a rate of surfacing for gray whale calves of 100.2 surfacings/hr, or 1.67 surfacings/min (sample size not reported). Adult whales, then, would be expected to surface once every 1.69 min (1 min and 41 sec) and calves once every 0.59 min (35 sec). From these surfacing rates, the mean number of times an adult whale would be expected to surface within the observer's duration of detectability was calculated as 8.18 min × 0.59 surfacings/min = 4.8 surfacings. Simi-

---

[4] Surface intervals may have been slightly longer than those reported by Mate and Harvey because their radio tags were placed behind the whale's blowholes; thus, as the animals arched and rolled while beginning a dive the antenna would submerge a moment before the entire animal.

larly, the mean number of surfacings expected for a calf would be 8.18 min × 1.67 surfacings/min = 13.7 surfacings.

To determine how many seconds a whale would be visible during the period of potential detectability, we used Harvey and Mate's mean surface interval for adult whales of 0.07 ± SE 0.01 min ($n = 11{,}229$ surfacings) or 4.2 sec. They did not report a mean surface interval for calves. The mean proportion of the duration of potential detectability that an adult whale would be visible was calculated as the number of surfacings multiplied by the surface interval, divided by the duration of potential detectability or

$$\frac{4.8 \text{ surfacings} \times 0.07 \text{ min}}{8.18 \text{ min}} = 0.041 \qquad (3)$$

or approximately 20 sec during every 8.18 min.

Our estimate of a mean of 4.8 surfacings and a mean total surface duration of 20 sec during the period of potential detectability suggests that we had an opportunity to see most if not all whales (including calves) one or more times during a transect. For this reason, we did not adjust our raw whale counts for whales missed because they were below the surface.

The second source of bias, whales at the surface but missed by the observer, is a function of environmental conditions affecting visibility during the survey and the observer's sighting ability and experience (Leatherwood *et al.*, 1978; Davis *et al.*, 1982). Again, we did not correct for this bias, but, to minimize this source of error, transects were conducted only during ideal conditions, Beaufort Sea State No. 3 or less, and excellent through-air visibility (no rain, mist, or fog). In addition, all observers were experienced at surveying gray whales in Laguna San Ignacio; new observers participated in training transects and accompanied experienced observers on actual transects before they conducted counts on their own. Despite these precautions, some whales were undoubtedly missed. For this reason, we chose the highest count from the two transect replicates as the minimum whale abundance estimate for that day.

Inlet and Lagoon Interior

Counts of gray whales in the inlet and the east channel of the lagoon (Fig. 1) were obtained from 16 systematic aerial surveys conducted between January 16 and March 28, 1980. Seasonal counts of single whales and female–calf pairs in the inlet are shown in Fig. 3. An overview of the total seasonal whale abundance for the entire Laguna San Ignacio system was obtained for 1980 by combining aerial counts with corresponding boat counts of the lagoon interior (Fig. 4A).

The maximum combined count (single whales + female–calf pairs) for the entire system occurred on February 16 and was 458 whales (333 single whales and 125 female–calf pairs). These whales were distributed as follows: 27% (119 single whales and 5 female–calf pairs) were in the inlet, 72% (214 single whales and 118 female–calf pairs) were in the lagoon interior, and 1% (2 female–calf pairs) was in the east channel (Fig. 4A).

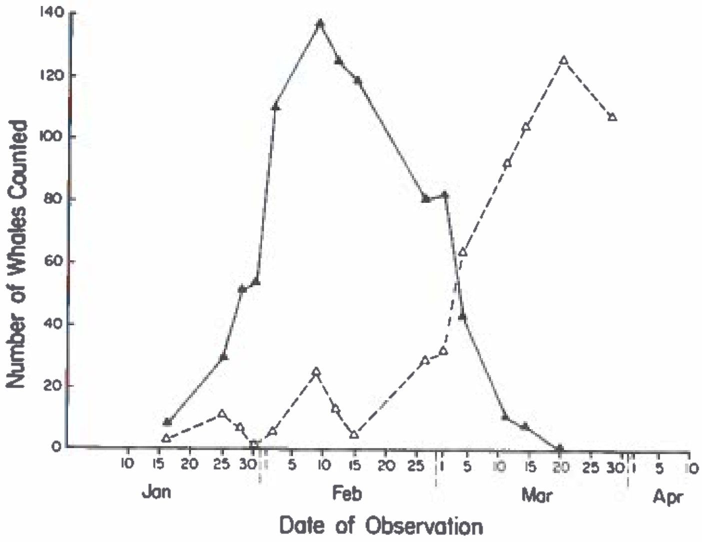

Fig. 3. *The number of single whales (solid triangles) and female-calf pairs (open triangles) counted in 16 aerial transects of the inlet of Laguna San Ignacio during the 1980 winter.*

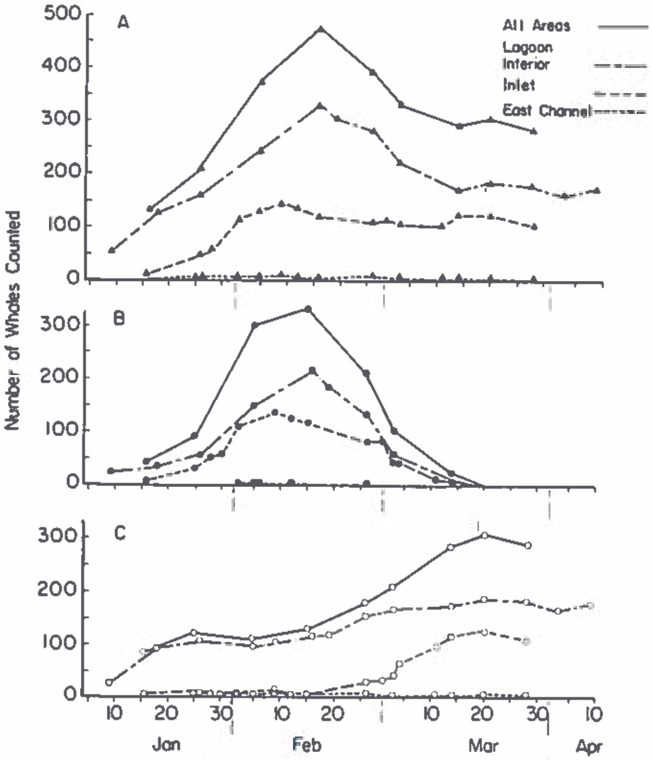

Fig. 4. *Total number of whales counted in the entire Laguna San Ignacio system in 1980. (A) Triangles are total adult whales. (B) Closed circles are single whales. (C) Open circles are female–calf pairs.*

The maximum single whale count of 351 animals also occurred on February 16, 1980. Thirty-nine percent of these animals were in the inlet, and 61% were in the lagoon interior. No single whales were in the east channel (Fig. 4B). By March 3, single whales in the inlet had declined to 26% of their maximum count for the entire lagoon system, and by March 14, only 3% remained.

In contrast to the single whales, at the maximum combined count only 8% of the 125 female–calf pairs counted were in the inlet, while 90% were in the lagoon interior, concentrated in the upper lagoon nursery area (Fig. 4C). The east channel, the smallest inner-lagoon area, never contained more than 2% of the lagoon whale population.

Following the departure of single whales from the lagoon, counts of female–calf pairs continued to increase and reached a maximum of 315 pairs on March 19. At this time, 40% were in the inlet, 59% were in the lagoon interior, and 1% was in the east channel. During the final aerial survey on March 28, 108 female–calf pairs were counted in the inlet. Local fishermen informed us that some females and their calves may be

[g] No single whales present.

seen in the surf areas of the inlet through April and May of some years, but they are rarely seen in June.

To illustrate the utilization of the inlet relative to the lagoon interior at the maximum combined count and at the maximum female–calf pair count, a more detailed breakdown of the number of whales utilizing the complete lagoon system is presented in Table I. The inlet was utilized extensively throughout the season and was clearly a major area. On the date of the maximum combined count, 39% of the single whales occupied the inlet at a density of 6.68 whales/km^2, while only 8% of the female–calf pairs were present in this area. Coinciding with the departure of single whales, however, the number of female–calf pairs gradually increased in the inlet and at their maximum count, the inlet contained 40% of these animals at a density of 12.29 whales/km^2, or double the density of single whales (female–calf pairs were counted as two animals for densities).

Lagoon Interior

To identify trends in gray whale abundance, distribution, and duration of season, the counts of whales were analyzed at two key time periods. The first period was the annual date of maximum combined counts, which coincided with the period of single whale maximum counts. For this time category, an overview of the total whale abundance and distribution in the lagoon is presented first. Then, the total whale population is subdivided into single whales and female–calf pairs and these two components are analyzed as separate but interacting groups. The second time period was the date of maximum female–calf pair counts which occurred after the departure of single whales from the lagoon each year. To determine whether whale abundance at the two time periods changed significantly among years, a least squares exponential regression line was fitted to the yearly maximum counts for each whale category (i.e., total whales, single whales, and female–calf pairs); the regression (significance of trend) and significance of slope (significance of increase or decrease) were evaluated with analysis of variance (ANOVA) (Sokal and Rohlf, 1981).

During the 1977 reconnaissance study, we learned that gray whales were distributed differentially within the lagoon. Whales occupied some areas throughout the season, while other areas were occupied only part of the winter. Therefore, to more precisely elucidate whale distribution, the lagoon interior was divided into three sections, the lower, middle and upper lagoon, based on our preliminary observations of whale distribution, and on the bathymetric features of the lagoon. The seasonal distribution of whales within each section was determined by subdividing the weekly censuses of the entire lagoon into the number of whales counted per area.

The dynamics of gray whale distribution in the lagoon interior was assessed by investigating three parameters: abundance, density, and the percentage of the total lagoon population that was within each area. We first tested for differences among lagoon areas, and then tested for changes within each area during the 5 years. A Kruskal–Wallis nonparametric test was used to evaluate differences in the three variables among the lower, middle, and upper lagoon areas. In the situation where the null hypothesis of the Kruskal–Wallis was rejected, nonparametric multiple comparisons

(Zar, 1974) were done to determine between which of the locations significant differences occurred.

Differences in the abundance of whales within each lagoon area over the 5 years were evaluated by using G-tests to compare each yearly count to the mean count for all years. Trends in abundance within each area were evaluated by fitting least squares, exponential regression lines to the counts for all years, and the significance of regression was evaluated with ANOVA.

To examine whether whale density (whales/km^2) varied significantly within each of the three areas, counts were analyzed with three separate Kolmogorov–Smirnov tests, where the expected frequency was the mean density in each location for the 5 years. In addition, least squares regression lines were fitted to the densities for each year and the significance of each regression was evaluated with ANOVA.

To determine whether there was a pattern to the whale distribution in the lagoon over the 5 years, the number of whales within each of the three areas was expressed as a percentage of the total number of whales in the lagoon, and changes in the proportion of the whales in each area were evaluated by calculating G-statistics for the log-likelihood ratios of observed percentages versus the mean percentage for each area.

Maximum Combined Counts. Gray whale counts from 60 boat transects, 10–14 each winter between 1978 and 1982, were used as an index of the weekly whale abundance within the lagoon interior. In all years, whales were present in low numbers when field work began. During the 1977–1978 season when transects were begun in December, the first count (5 single whales and 1 female–calf pair) on December 26, was only 2% of the eventual maximum count, and the second count (29 single whales and 2 female–calf pairs) on January 4, was 9% of the eventual maximum count for that year. In subsequent years, the first transects were conducted during the second week in January, and these counts averaged 20% (mean = 67 whales) of the annual maximum count.

The seasonal distribution of the overall whale population in the lagoon was bimodal: the major mode represented the maximum combined counts for each year and was composed primarily of single whales and some female–calf pairs (Fig. 5). Maximum combined counts occurred as early as February 2 in 1978 and as late as March 1 in 1979 with a mean day for the five winters of February 15 ± SE 3.9 days, and a 95% confidence interval of 21 days from February 5 to February 26. In 1978 and 1979, the dates of maximum combined counts were the most widely separated (27 days) and were significantly different from the mean day; the dates of maximum combined counts for the 1980 to 1982 seasons, however, were clustered about the mean day; these dates were February 16 in 1980, February 12 in 1981, and February 14 in 1982

Maximum combined counts increased significantly, 7.3% per year, from 300 adult whales in 1978 to 407 whales in 1982 [$F_{(1,3)} = 32.88$, $p < .025$, $r^2 = 0.916$] (Fig. 6). This increase was primarily attributable to greater counts of female–calf pairs each year. Counts of these whales increased significantly, 18.3% per year [$F_{(1,3)} = 16.13$, $p < .05$, $r^2 = 0.843$], from 65 pairs in 1978 to 137 pairs in 1982. In contrast, the 2.7% per year increase in the single whale counts was not significant [$F_{(1,3)} = 0.52$, $p > .50$, $r^2 = 0.147$].

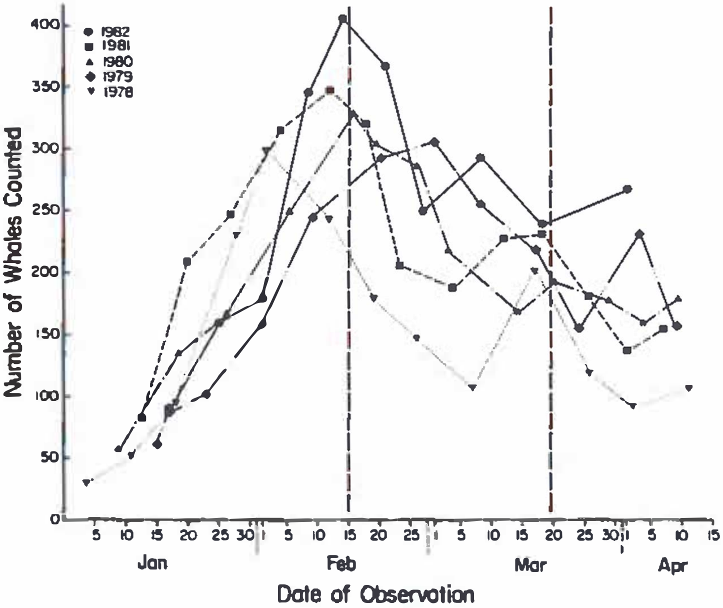

Fig. 5. *The number of whales (except calves) counted in 60 vessel transects of Laguna San Ignacio between 1978 and 1982. Broken vertical lines represent the mean date of combined maximum counts (February 15) and the mean date of maximum female–calf pair counts (March 19).*

The seasonal abundance and distribution of gray whales in the lower, middle, and upper lagoon areas between 1978 and 1982 are shown in Table II and in Figs. 7–9. A Kruskal–Wallis test of equality among lagoon areas revealed that whale abundance was not the same in all three areas [$X^2_{(2)} = 12.02$, $p < .01$]. The nonparametric multiple comparison test disclosed that abundance was significantly different in each lagoon area.

Whale abundance was greatest in the lower lagoon during all years. A G-test

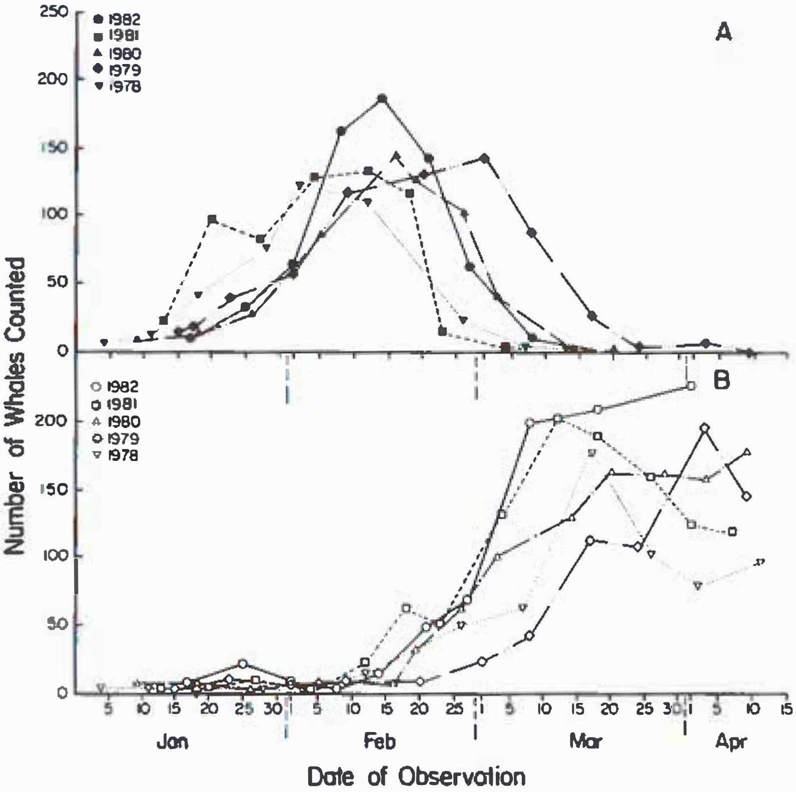

Fig. 7. *The number of single whales (A) and female–calf pairs (B) counted in 60 vessel transects of the lower lagoon between 1978 and 1982.*

indicated that the number of whales in this area at the date of maximum combined counts was significantly different each year [$G = 13.97 > X^2_{.05(4)} = 9.49$, $p < .01$] (Table II). The slope of the least squares, exponential regression line fitted to these counts indicated that the population in the lower lagoon increased 7.1% per year from 137 whales in 1978 to 202 in 1982, but, this increase was not statistically significant [$F_{(1,3)} = 4.97$, $p > .10$, $r^2 = 0.624$] (Fig. 10A, top). Thus, the heterogeneity in the counts among years was not explained by the regression.

The number of whales in the middle lagoon did not change significantly among years [$G = 5.63 < X^2_{.05(4)} = 9.49$, $p > .10$], and the 3.8% per year decrease in these counts from 73 in 1978 to 67 in 1982 was also not significant [$F_{(1,3)} = 0.03$, $p > .90$, $r^2 = 0.010$].

Finally, whale counts in the upper lagoon nursery did change significantly [$G = 14.15 > X^2_{.05(4)} = 9.47$, $p < .01$] showing a significant 8.9% per year increase from 92 in 1978 to 138 whales in 1982 [$F_{(1,3)} = 42.45$, $p < .01$, $r^2 = 0.934$]. Notably, the 7.3% per year overall increase in the whale population in the lagoon between 1978 and 1982 was

Female–calf pairs were counted as two animals in density calculations.*

seen primarily as an increase in the use of the upper lagoon area, while whale abundance in the lower and middle areas remained relatively unchanged.

As with whale abundance, densities of whales in the lower and middle lagoon areas did not change significantly between 1978 and 1982, and averaged 10.29 and 3.42 whales/km² respectively. The density of whales in the upper lagoon, however, did increase significantly from 3.16 whales/km² in 1978 to 5.25 whales/km² in 1982 [$F_{(1,3)} = 27.14$, $p < .02$, $r^2 = 0.900$].

The densities of whales within each area by year and the results of the Kolmogorov–Smirnov comparisons and ANOVAs for significance of regression are presented in Table III. The abundance and densities of whales per lagoon area and the least squares regression lines are shown in Figure 10A.

At the maximum combined count, the percentage of the total whale population in the lagoon that was present in each area did not change significantly between 1978 and 1982. These percentages and the results of the G-tests for significant differences within each area among years are summarized in Table IV. The lower lagoon contained an average of 48.3 ± SE 5% of the population, the middle lagoon contained an average of 20 ± SE 3.7%, and the upper lagoon contained an average of 32 ± SE 2.5% of the

	$\bar{X} \pm$ SE	32 ± 2	11 ± 2	80 ± 2	1 ± 0.6
	G	.69	8.31	1.39	9.32
	$P_{(G)}$	>.90	>.05	>.50	>.05

population. Thus, despite the significant annual increase in the abundance of whales in the upper lagoon, the proportion of the total yearly population that utilized each section of the lagoon remained nearly constant.

Following the maximum combined count each year, single whale abundance declined in all areas (see Single Whales), while female–calf pair abundance continued to increase, resulting in a second smaller peak in abundance around March 19, the minor mode of the population curves. At this time, the lagoon was occupied entirely by female–calf pairs (see Female and Calf Pairs).

Single Whales. Each year single whale counts increased rapidly during the 6-week period approximately from the last week in December through the second week in

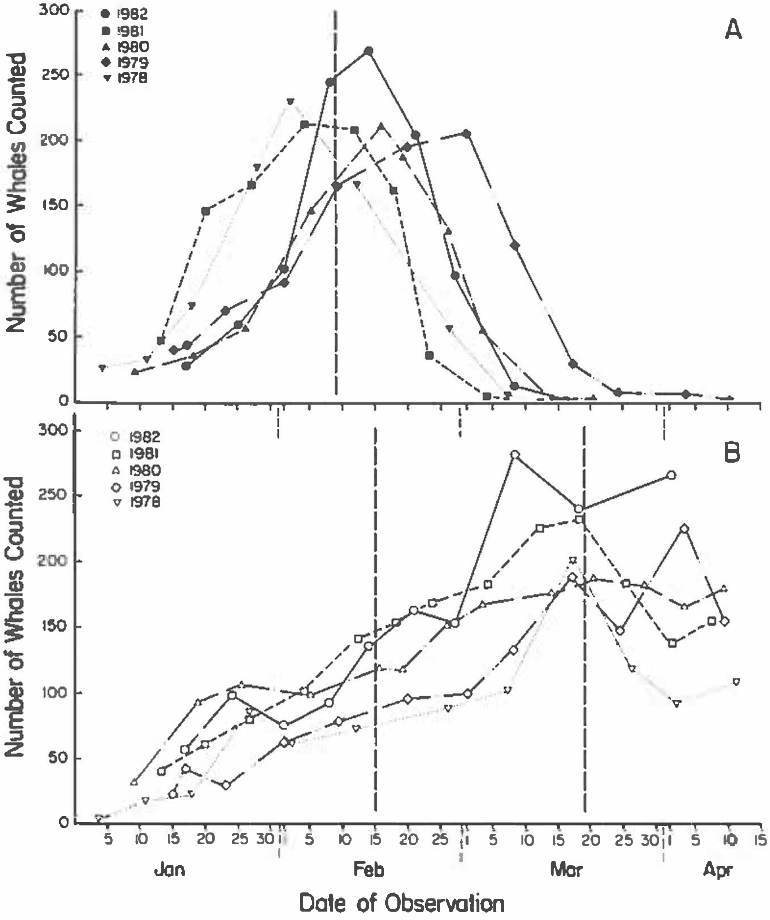

Fig. 11. *The number of single whales (A) and female–calf pairs (B) counted in 60 vessel transects of Laguna San Ignacio between 1978 and 1982. Broken vertical lines indicate the mean date of the maximum single whale counts on February 9 (A), the female–calf counts at the end of the birth period on February 15, and the mean date of maximum female–calf pair counts on March 19 (B).*

February (Fig. 11A). During our earliest census on December 26, 1977, five single whales or 2% of the eventual maximum single whale count for that year were already present. Single whale counts reached 50% of their eventual maximums as early as January 17 in 1981 and as late as February 2 in 1979 and 1982, with a mean date of January 27 ± SE 3 days.

The maximum single whale counts each year occurred on the same day as the combined maximum count; the average date of maximum single whale counts for all years was February 15 ± SE 3.9 days, with a range from February 2 in 1978 to March 1 in 1979 (Fig. 4). Both of these dates fell outside the 21-day 95% confidence interval for the mean date. Maximum single whale counts ranged from a low of 207 animals on February 12, 1981 to a high of 270 whales on February 14, 1982, with a mean maximum count of 227 whales. The slope of the exponential regression line fitted to these counts for all years indicated a 2.7% per year increase in single whale maximum counts, but this slope was not significantly different from 0, indicating there was no significant change in the abundance of single whales over the 5 years [$F_{(1,3)} = 0.516$, $p > .50$, $r^2 = .147$] (Fig. 6). Following peak abundance, single whale counts rapidly declined to 50% of their maximum counts on dates which ranged from February 19 in 1978 to March 11 in 1979, with a mean date of February 27 ± SE 3 days. Single whale counts had dropped further to 2–4% of their maximums as early as March 4 in 1981 and as late as March 24 in 1979, with a mean date of March 11 ± SE 3 days.

The duration of the single whale season was defined as the time elapsed between the first and last sighting of a single whale during the boat transects each year. We assumed that the single whale season began on December 26 each year (see p. 325). The weekly counts were scaled so that December 26 was equal to day one each year, rather than the calendar date.

Single whale seasons ranged from 76 days in 1981 to 104 days in 1979 with a mean duration of season of 84 days, and a 95% confidence interval of 72 to 97 days (Table V). Only the 1979 season of 104 days was significantly different from the mean length of season. That year, approximately seven whales, 3% of the maximum single whale count, remained in the lagoon 20 days longer than the overall mean season length. The mean length of the season for the four similar years was 79 ± SE 2.9 days, with a range of 6 days among years. The last day that single whales were counted in the boat transects ranged from March 12 in 1981 to April 9 in 1979 (Fig. 11). In summary, the length of the single whale season in Laguna San Ignacio averaged 11 weeks for the four similar years, but was 14.8 weeks in 1979.

To evaluate shifts in the timing of the single whale seasons, we calculated the mean day and its accompanying variance for each year and compared these among years (Reilly, 1981) (Table V). The mean day $\bar{j}$ is expressed as

$$\mu = \bar{j} = \frac{\Sigma j f_j}{n} \tag{4}$$

Table V
Summary of the Single Whale Seasonal Occupation of Laguna San Ignacio Between 1978 and 1982

Year	Number of transects	Maximum count day[a]	Duration of season	Mean day[a]	Variance of mean
1978	8	Feb 2	81	Feb 1	154.01
1979	9	Mar 1	104	Feb 16	292.74
1980	9	Feb 16	78	Feb 13	155.42

[a] Maximum count and mean days are scaled so that December 26 = day 1.

where $\bar{j}$ = the day of the season expressed with December 26 = day 1, f_j = the single whale count (as a proportion of the total count for the year), and n = the total number of days. The variance, (σ^2), is

$$\sigma^2 = \frac{\Sigma j f_j^2 - \dfrac{(\Sigma j f_j)^2}{n}}{n - 1} \qquad (5)$$

The mean days ranged from February 1 in 1978 to February 16 in 1979. A Bartlett's test indicated that the variances for each year were homoscedastic [$B_c = 2.71$, $p = .61$], and the ANOVA indicated the means were not significantly different [$F_{(4,39)} = 2.07$, $p < .05$], permitting the calculation of a pooled mean for all years of February 9. The 95% confidence interval for this pooled mean was 14 days, from February 2 to 16. The February 1, 1978 mean day was the only date to fall outside this confidence interval. The greatest shift in timing of the single whale season was 15 days between February 1, 1978 and February 16, 1979.

The seasonal distribution of single whales in the lower, middle, and upper lagoon areas between 1978 and 1982 are shown in Figs. 7A, 8A, and 9A. At their maximum counts, single whale abundance was not the same in the three lagoon locations [Kruskal–Wallis test: $X^2_{(4)} = 12.00$, $p < .01$]. Multiple comparison tests at $\alpha = .05$ confirmed that the abundance was unique in each area; moreover, counts of single whales were heterogeneous within each area over the 5 years, but did not show a significant increase or decrease. The G-tests of equality of abundance and ANOVAs for significance of regression in each area among years are summarized in Table II.

Single whales were most abundant in the lower lagoon, where their counts were different each year [$G = 13.61 > X^2_{.05(4)} = 9.49$, $p < .01$]. Maximum counts in the lower lagoon increased 6.7% per year from 129 in 1978 to 187 in 1982 (Fig. 7A); however, this increase was not statistically significant [$F_{(1,3)} = 3.43$, $p > .10$, $r^2 = .533$] (Fig. 10A, top).

Maximum counts of single whales in the middle lagoon were also significantly different each year [$G = 14.11 > X^2_{.05(4)} = 9.49$, $p < .01$] (Fig. 8A). The slope of the regression line fitted to these counts indicated a nonsignificant 5.3% per year decrease [$F_{(1,3)} = 3.90$, $p > .10$, $r^2 = .565$] (Fig. 10A, top).

Finally, single whales were least abundant in the upper lagoon nursery area where their counts were significantly different each year [$G = 22.24 > X^2_{.05(4)} = 9.49$, $p < .05$] (Fig. 9A).

In general, single whale maximum counts were heterogeneous in all areas in all years, and their slight increase in the lower lagoon and decrease in the middle and upper lagoon areas were not significant.

The density of single whales was homogeneous within each section of the lagoon; thus, the five yearly densities were pooled and a mean density calculated for each area (Table III). In the lower lagoon, single whale density averaged 8.46 ± SE 0.53 whales/km^2, in the middle lagoon it averaged 2.36 ± SE 0.23 whales/km^2, and in the upper lagoon single whales were least dense averaging 0.54 ± SE 0.09 whales/km^2 (Fig. 10A, bottom).

The Kruskal–Wallis test revealed that the proportion of single whales among areas was significantly different [$X^2_{(2)} = 12.29$, $p < .01$]. Single whales were distributed in a gradient each year being most abundant in the lower lagoon nearest the inlet and becoming less abundant toward the upper lagoon. As would be expected, since there were no significant changes in single whale abundance or density within each area during the 5 years, a G-test of the proportions of the total single whales that were within each area did not indicate any significant changes. An average of 65 ± SE 2% of the single whale population was in the lower lagoon, 24 ± SE 2% was in the middle lagoon, and 11 ± SE 2% was in the upper lagoon (Table IV).

In summary, the distribution of single whales at their maximum counts analyzed as abundance, density, and proportion of whales in each area did not change significantly between 1978 and 1982.

Female and Calf Pairs. The pattern of abundance and distribution of female–calf pairs in Laguna San Ignacio was more complex than that of single whales. Counts of female–calf pairs increased continuously between early January and late March or early April in all years (Fig. 11B). However, following approximately mid-February, the increase was not caused by continued births; rather, late season calves were judged by their size, color, and degree of barnacle infestation to be at least 1.5 to 3.0 months old. For this reason, the analysis of female–calf pairs was conducted in two stages.

The first stage was the time during which most births occurred and females with newborn calves occupied the lagoon. It is believed that most gray whale births occur during a period of at least 66 days from December 26 to March 1 (Swartz and Jones, 1983) with a mean birth date of about January 27, and that the majority of births have taken place by February 15 (Rice *et al.*, 1981). During 6 years we observed only two newborn calves after February 15; therefore, we assumed that late births were relatively rare events and that February 15 was best representative of the date by which a high percentage of the births had taken place. Counts of female–calf pairs on February 15 were used to estimate the number of females using Laguna San Ignacio as a nursery for newborn calves.

The second part of the analysis was the time of maximum female–calf pair counts. The increase in the number of female–calf pairs that utilized the lagoon after the birth period was representative of the number of whales that used the lagoon as a staging area (see below).

The Birth Period. The seasonal distributions of females with calves from January 4 to February 15 between 1978 and 1982 are shown in Fig. 11B. The number of female–calf pairs that occupied Laguna San Ignacio on February 15, the end of the birth period, increased significantly each winter. Female and calf counts rose from 81 pairs in 1978 to 137 pairs in 1982, a significant increase of 14.3% per year [$F_{(1,3)} = 33.56$, $p < .025$, $r^2 = .914$] (Fig. 12).

The significant increase in the number of female–calf pairs was accompanied by a significant increase in their abundance in one of the three lagoon areas. The seasonal distribution of females and calves in the lower, middle, and upper lagoon are shown in

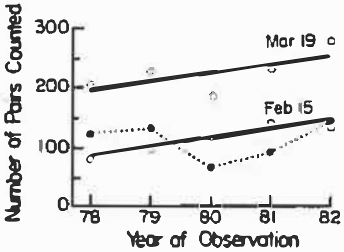

Fig. 12. *A comparison of the maximum female–calf pair counts (average date of March 19) and February 15 female–calf pair counts between 1978 and 1982 (open circles). Closed circles are the differences between these counts and represent minimum estimates of whales utilizing the lagoon as a staging area. Fitted lines are least square regression lines.*

Figures 7B, 8B, and 9B. A Kruskal–Wallis test revealed that the female–calf pair abundance was not the same in all three areas $[X^2_{(2)} = 9.555, p < .01]$; abundance in the upper and lower, and upper and middle lagoon areas was significantly different, but in the lower and middle lagoon it was not significantly different.

In all years, females with newborn calves were least numerous in the lower lagoon nearest the inlet. Counts were generally low, ranging from 8 pairs in 1978 to 24 pairs in 1979 and 1981, and were significantly different $[G = 15.54 > X^2_{.05(4)} = 9.49, p < .001]$ (Table II). The slope of the least squares regression line fitted to these counts indicated that female–calf pairs increased 32.2% per year, but this trend was not statistically significant $[F_{(1,3)} = 1.57, p > .10, r^2 = 0.345]$ (Fig. 10A, top).

Counts of female–calf pairs in the middle lagoon were also significantly different among years $[G = 11.76 > X^2_{.05(4)} = 9.49, p < .025]$ (Table II), but their 25.8% per year increase was not significant $[F_{(1,3)} = 2.43, p > .05, r^2 = .448]$ (Fig. 10A, top).

The increase in the annual female–calf pair counts was seen primarily as a significant positive rate of increase in their numbers in the upper lagoon nursery (Table II). Counts in this area were different each year $[G = 31.61 > X^2_{.05(4)} = 9.49, p < .001]$ increasing significantly 16.2% per year from 55 pairs in 1978 to 107 pairs in 1982 $[F_{(1,3)} = 14.96, p < .05, r^2 = .833]$ (Fig. 10A, top).

The densities of female and calf pairs within each area and the values for the Kolmogorov–Smirnov tests and ANOVAs are presented in Table II. Densities of female–calf pairs in the lower and middle lagoon did not change significantly among years and averaged 9.83 ± SE 0.72 and 1.06 ± SE 0.17 whales/km^2 respectively (Fig. 10A, bottom). For the upper lagoon, the Kolmogorov–Smirnov test suggested that the differences in whale densities among years were nonsignificant; nevertheless, the ANOVA for the least squares regression analysis of density showed that the steady increase in density from 2.36 whales/km^2 in 1978 to 4.59 whales/km^2 in 1982 was statistically significant $[F_{(1,3)} = 14.59, p < .05, r^2 = .829]$ (Fig. 10A, bottom). The conflicting results of the Kolmogrov–Smirnov test and the ANOVA can best be explained by the fact that the regression analysis is sensitive to the small but steady increase in density from year to year.

On February 15 each year, female–calf pairs were concentrated in the upper lagoon nursery area and became less abundant toward the inlet. In addition, the percentage of the total female–calf pairs in the lagoon that occupied each area remained essentially the same each year (Table IV). The percentage of female–calf pairs was smallest in the lower lagoon where they averaged 11 ± SE 2% of the total, the middle lagoon contained an average of 9 ± SE 9%, and the upper lagoon had the highest percentage of female–calf pairs, averaging 80 ± SE 2%. Although the number of female–calf pairs utilizing the upper lagoon increased significantly, the proportion of the population utilizing this area remained the same each year.

Maximum Female–Calf Pair Counts. The maximum count of female–calf pairs occurred late each season following the departure of single whales from the lagoon. After February 15, females and calves continued to increase steadily to their maximum counts that occurred as early as March 2 in 1982 and as late as April 3 in 1979, with a mean date of March 19 (Fig. 11B). The maximum counts increased approximately 6.9% per year from 202 pairs in 1978 to 281 pairs in 1982; however, this increase was not statistically significant [$F_{(1,3)} = 2.69$, $p > .25$, $r^2 = .473$] (Fig. 12).

To determine the degree to which Laguna San Ignacio was utilized as a staging area, we fitted a least squares regression line to the annual February 15 counts and the annual maximum female–calf counts and compared their slopes and elevations. There was no significant difference between the slopes of the lines [$t_{(6)} = 0.058$, $p > .80$], but the elevations were significantly different [$t_{(6)} = 13.17$, $p << .001$]. The difference between the elevations of the lines averaged 110 ± SE 0.7 female–calf pairs and represented a minimum estimate of the number of female–calf pairs that were gathering at Laguna San Ignacio late in the season and using it as a staging area. The maximum counts, the February 15 counts, and the difference between them are plotted in Fig. 12. The average difference was 111 ± SE 12 female–calf pairs and ranged from 67 in 1980 to 144 female–calf pairs in 1982. As mentioned previously, this late season increase included older calves and not newborn animals.

Following the combined maximum counts, single whales began to decrease and averaged only 3% of their maximum count by March 14. As the single whales departed, the female–calf pairs continued to increase and gradually shifted their distribution to the lower and middle lagoon (Figs. 7B and 8B); they were seen only rarely in the upper lagoon nursery after the third week in March (Fig. 9B). At their maximum counts, the abundance of females and calves was not the same in all three areas [Kruskal–Wallis test: $X^2_{(2)} = 10.86$, $p < .005$]. The multiple comparison tests of equality of abundance among years indicated that the lower and upper, and lower and middle lagoon areas were significantly different from each other, while the middle and upper areas were not significantly different.

In all years, females and calves were most abundant in the lower lagoon where their counts averaged 186 ± SE 6 pairs and did not change significantly (Table II; Fig. 10B, top).

In the middle lagoon, the number of female–calf pairs was significantly different each year [$G = 19.90 > X^2_{.05(4)} = 9.49$, $p < .001$], and their counts increased significantly 22.9% per year from 16 pairs in 1978 to 49 pairs in 1982 [$F_{(1,3)} = 11.80$, $p < .05$, $r^2 = .797$] (Table II; Fig. 10B, top).

Female–calf pairs were least abundant in the upper lagoon nursery area in late March each year (Fig. 9B). Here, counts ranged from no whales in 2 years to 33 pairs in 1982, and were significantly different each year [$G = 74.59 > X^2_{.05(4)} = 9.49$, $p < .001$] (Table II; Fig. 10B, top). The slope of the regression line fitted to the upper lagoon counts was not significantly different from zero [$F_{(1,3)} = 1.44$, $p > .50$, $r^2 = .324$].

Densities of female–calf pairs in the lower and upper lagoon areas did not change significantly between 1978 and 1982, averaging 21.3 ± SE 0.7 whales/km^2 and 0.4 ± SE 0.2 whales/km^2 respectively (Table II; Fig. 10B, bottom). As would be expected from the significant increase in abundance of female–calf pairs in the middle lagoon, the density of these whales also increased significantly in this area from 1.4 whales/km^2 in 1978 to 4.28 whales/km^2 in 1982 [$F_{(1,3)} = 11.88$, $p < .05$, $r^2 = .80$].

The percentage of the female and calf population in the lagoon that was in each area remained essentially the same (Table IV). The lower lagoon averaged 87.4 ± SE 6.0%, the middle lagoon contained 11.6 ± SE 1%, and the upper lagoon averaged 1.0 ± SE 0.6% of the population each year.

To summarize, at their maximum counts, female calf pairs were distributed in a gradient being most dense in the lower lagoon near the inlet and becoming less dense with increasing distance from the inlet. This gradient was consistent each year, as the abundance of female–calf pairs in each area and the percentage of the lagoon female–calf pair population that utilized each area remained the same.

Female and calf counts generally declined after mid-March, although a substantial number of female–calf pairs remained in the lagoon at the termination of our field work each April. The percentage of the maximum female–calf pair count remaining in the lagoon at the last transect each winter was 53% in 1978, 68% in 1979, 96% in 1980, 66% in 1981, and 96% in 1982.

Time limitations of field studies prevented us from documenting the entire female–calf pair occupation of the lagoon. Therefore, to estimate their minimum abundance and duration of season, we utilized late April and early May sightings of whales reported by other observers. J. Harvey and B. R. Mate (personal communication) reported that 25–35 female–calf pairs remained in Laguna San Ignacio and that an unknown number were outside the lagoon inlet in the breakers on April 26, 1980. In addition, Storro-Patterson (1982) reported that a few (no number specified) females and calves remained in the inlet in early May; and Mexican fishermen (Abreojos Fishing Cooperative, personal communication) indicated that gray whales could be found outside the lagoon in the inlet as late as early June of some years. The earliest arrival of female–calf pairs in Laguna San Ignacio during our study was December 26. The combination of our early season observations with these late season sightings yielded an estimate of a 4- to 4.5-month (16- to 18-week) duration of season for female–calf pairs in Laguna San Ignacio. This was 1–1.5 months longer than single whales that arrived at approximately the same time, but departed from the lagoon by mid-March.

Table VI

Summary of Length Measurements and Sex Composition of Dead Gray Whale Calves in Four Breeding Areas, 1954–1983

MORTALITY

The basic unit of the mortality section is the Laguna San Ignacio data from 1977 to 1982. In brief, we give a general account of mortality and then examine four aspects of mortality, (1) the number of dead whales, (2) whale lengths, (3) age class composition, and (4) the calf mortality rate. In addition, data on natural mortality from 1954 to 1983 which were available for Laguna Guerrero Negro, Laguna Ojo de Liebre, and the Boca de Soledad area of the Bahia Magdalena complex are compared and integrated with the Laguna San Ignacio information to determine (1) the age class composition of dead whales, (2) the proportion of carcasses in each age class among years, (3) the mean length of dead calves for comparison with the length of near-term fetuses, and (4) the sex ratio of calves and all whales combined. A summary of calf mortality is presented in Table VI, and immature and adult mortality is shown in Table VII.

Age frequencies were determined by grouping the carcasses into three broadly defined categories—calves, immatures, and adults. Animals between 3 and 8.99 m were considered to be calves of the year, those measuring 9–10.99 m were regarded as immatures, and whales 11 m and larger were classified as adults (based on Rice and Wolman, 1971; Zimushko and Ivashin, 1980; and Chapter 21, this volume).

[a] No dead immature or adult gray whales were sighted in Boca de Soledad in 1982.
[b] A = adult, I = immature.
[c] M = male, F = female, and U = sex unknown.
[d] Isla Arena separates the inlets of Guerrero Negro and Laguna Ojo de Liebre lagoons.

Thirty-two recently dead gray whales including 25 calves, 6 immatures, and 1 adult were examined in Laguna San Ignacio. The cause of death was not determined for any of these whales; however, it appeared that one immature died as the result of a killer whale (*Orcinus orca*) attack and that many calves were stillborn or had died shortly after birth as evidenced by intact umbilical cords or bleeding umbilical wounds that had not healed prior to death. In addition, the 23 calves that were discovered in January and February lacked epizoic barnacles compared to 2 stranded calves discovered in March which possessed these parasites.

The minimum calf mortality rate for each 97-day season in Laguna San Ignacio from 1978 to 1982 was estimated by dividing the number of dead calves discovered per season by the estimated gross calf production per season (i.e., the number of living calves at the maximum combined count + the number of dead calves per season) (Caughley, 1966, 1977). The calf mortality rate was 5.81% in 1978, 4.00% in 1979, 3.25% in 1980, 2.78% in 1981, and 2.84% in 1982.

The average, minimum, calf mortality rate for the 5-year period was calculated as the sum of the dead calves discovered in all years divided by the sum of the estimated gross production for all 5 years, or

$$\frac{21}{573 + 21} \approx 0.0354 \tag{6}$$

A G-test indicated that the seasonal calf mortality rates were not significantly different from the mean rate for all five seasons [$G_{(4)} = 3.67 < X^2_{.05(4)} = 9.49$, $p > .25$].

To determine whether the number of dead calves, immatures, and adults discovered per year in Laguna San Ignacio was the same over the 5 years, each age category was tested for heterogeneity by computing a G-statistic of the difference between the observed mortality per year and the mean number of carcasses per class. All categories were homogenous among years; the number of dead calves ranged from 4 to 5 per year and averaged 4.17 whales per year [$G = 0.15 < X^2_{.05(4)} = 9.49$, $p > .99$] (Table VI). The number of immatures ranged from 0 to 2 per year with a mean of 0.67 whales per year [$G = 1.64 < X^2_{.05} = 9.49$, $p > .75$]. And finally, the number of dead adults ranged from 0 to 1 with a mean of 0.17 whales per year [$G = 3.49 < X^2_{.05(4)} = 9.49$, $p > .10$] (Table VII). Because the frequency of carcasses within each category was not significantly different during the 5 years, we pooled the frequencies per class, and calculated the percentage of the total sample that was in each age class. Seventy-eight percent were calves, 19.5% were immatures, and 2.5% were adults.

In order to compare age class frequencies of dead whales from different breeding areas in which there was unequal search effort within years, we converted the total number of whales in each category to a percent of the total number of whales counted in each area. For each age class, we pooled the percentages from all areas, including Laguna San Ignacio, and calculated a mean percentage. These means were used as the expected frequencies in three separate G-tests of the null hypothesis of equality between the mean proportion and the observed proportion per class for each area. The percentages of calves among areas were homogeneous, ranging from 78 to 100% with a mean of 91.4% [$G = 3.13 < X^2_{.05(4)} = 9.49$, $p > .50$]. The percentages of immatures, however, were significantly different in each area, and ranged from 0 to 19.5% [$G = 42.07 > X^2_{.05(4)} = 9.49$, $p < .001$]. The percentages of dead adults were also significantly different in each area, ranging from 0 to 5% [$G = 12.73 > X^2_{.05(4)} = 9.49$, $p < .025$]. Due to the small sample sizes for dead immatures and adults, these estimates may not be representative.

Sex was determined for 101 of the 194 dead gray whales reported from all the lagoons. These included 57 males and 44 females (Tables VI and VII). The sex ratio of calves, immatures, and adult whales combined was 56.4% males to 43.6% females. A G-test with a William's correction (Sokal and Rohlf, 1981) indicated that the observed ratio of dead male to female whales was not significantly different from 1:1. Here, the expected sex ratio was 1:1, as reported by Rice and Wolman (1971, p. 118).

To determine whether male and female calves died in equal numbers, we tested for a difference in the sex ratio of these animals. Of the 125 calves from all areas combined, sex was determined for 97. The ratio of 55 males (56.7%) to 42 females (43.3%) was not significantly different from unity [$G_{adj}(1) = 1.747 < X^2_{.05(1)} = 3.841$, $.10 < p < .20$]. This suggests that the slight preponderance of male calves was not indicative of differential mortality between the sexes.

Sample sizes of the immature and adult age classes were too small to evaluate the significance of their observed sex ratios.

A Bartlett's test for homoscedasticity of calf carcass lengths for samples among years from Laguna San Ignacio between 1977 and 1983 indicated that the variances were not significantly different [$B_c = 6.99 < X^2_{.05(6)} = 12.59$, $p = .32$]. The ANOVA disclosed that the mean lengths for each year were also not significantly different [$F_{(6,22)} = 0.866 < F_{.05(6,22)} = 2.55$, $p = .53$]. This permitted the calculation of a pooled mean for calf carcass lengths in Laguna San Ignacio which was 4.47 ± SE 0.086 m. The mean calf lengths per year are shown in Table VI.

The lengths of dead whales in different breeding areas were tested for significant differences. A Bartlett's test revealed that the samples from each breeding area were highly heteroscedastic [$B_{(c)} = 200 >> X^2_{.05(4)} = 12.59$, $p < .001$]; but, the Kruskal–Wallis test of the null hypothesis that the "location" of the sample populations were the same was not rejected. Therefore, we concluded that the lengths of the dead calves from each area were not significantly different [$H_c = 4.79 < X^2_{.05(4)} = 9.49$, $p > .25$]. The grand mean of the lengths of dead calves for all areas was 4.43 ± SE 0.06 m.

The lengths of dead calves have been used as indicators of gray whale calf length at birth (Rice and Wolman, 1971; Rice *et al.*, 1981; Rice, 1983). To determine the validity of extrapolating the mean length of calves at birth from dead calf data, we compared the lengths of dead calves reported from the lagoons to lengths of near-term fetuses.

The series of length measurements for near-term fetuses reported by Rice and Wolman (1971) was the only sample presently available that was large enough to provide statistically reliable data for comparison with the sample of length measurements of recently born, dead calves from the breeding lagoons. Other data on lengths of near-term fetuses taken from females in the Korean or California populations were reported by Scammon (1874), Townsend (1887), Andrews (1914), Risting (1928) and Mizue (1951). These accounts, however, were of limited use because many of the calf lengths were estimated and not actually measured, ranges of lengths were often given rather than individual lengths, and the collection dates of individual whales were frequently not reported.

Rice and Wolman (1971) measured 55 near-term fetuses taken from female gray whales collected off San Francisco during a 38-day period from December 15 to January 20 from 1959 to 1969. These ranged in length from 3.60 to 5.31 m with a mean of 4.62 ± SE 0.007 m. To ascertain whether the "location" of the calf lengths from the lagoons was significantly different from the length of near-term fetuses, we tested the null hypothesis that the lengths of dead gray whale calves in the southern range were greater than or equal to the length of near-term fetuses collected during migration. A one-tailed Mann–Whitney U-test failed to accept the null hypothesis $[Z = 3.819 > t_{.05(1),\infty} = 1.96, p < .005]$. Therefore, we concluded that the mean length of 4.43 m for dead neonates from the southern range in January and February was highly significantly smaller than the mean length of 4.62 m for near-term fetuses collected during migration.

Seven (78%) of the nine immature whales measured in three breeding areas fell into the yearling (8.2 to 9.6 m) age category, suggesting that next to calves, yearlings had the second highest mortality rate. The lengths of immatures ranged from 7.4 to 10.41 m with a mean length of 8.20 ± SE 0.43 m (Table VII).

The analysis of the lengths of some immatures was problematic. According to Rice and Wolman (1971), Zimushko and Ivashin (1980), and Blokhin (Chapter 21, this volume), the length of a gray whale at 1 year of age should range from 8.2 to 9.6 m; but, four of the seven dead immatures in Laguna San Ignacio were too small to be classified as yearlings and two were too large to be classified as calves of the year (>7.3m). All of these carcasses were infested with adult barnacles, further suggesting they were yearlings, as newborn calves do not develop adult parasites while in the breeding lagoons.

Only one dead adult whale was discovered in the lagoon. In addition to the whale mortality in Laguna San Ignacio, five adult and three immature carcasses were reported from other lagoon areas, and all are summarized in Table VII. Sample sizes of these whales were too small for statistical comparisons.

WHALE-WATCHING ACTIVITIES

Nature of Human Activities

Human activities within Laguna San Ignacio during the winter included local fishing, U.S. based overland and seagoing commercial whale-watching excursions, and visitation in private yachts.

Local Mexican fishermen operated 4- to 6-m fiberglass and wood pongas powered by 40- to 65-hp outboard engines throughout each winter, but their numbers and working days fluctuated with the condition of the fisheries and the weather. During the winters of 1978 and 1979, six to eight pongas operated approximately 5 days each week in the lower lagoon. Following the designation of the lagoon as a refuge in 1979, only three pongas operated in the lower lagoon between 1980 and 1981. In 1982, again only three pongas regularly operated in the lower lagoon; however, between 15 and 18 pongas with hooka-assisted divers operated in the middle and upper lagoon areas in response to an emergent bay-scallop (*Pectin* sp.) fishery in the shallow eelgrass beds north of Punta Piedra.

Individuals aboard private yachts continued to visit the lagoon following its designation as a refuge, averaging six visits each winter lasting from 1 to 10 days each.

Between 1977 and 1979, three or four land-based whale-watching excursions visited Laguna San Ignacio, but these companies ceased operation when the refuge was established in 1979 because the regulations prevented their access to the lower lagoon whale-watching area which can only be reached by boat.

Seagoing whale-watching excursions based in San Diego, California accounted for 90% or more of the human activities within the lagoon each winter. These excursions were conducted aboard 100-ton vessels that carried an average of 25 passengers each and typically spent 2½ days (3 days and 2 nights) or approximately 60 hr in the lagoon each visit. These vessels are powered by two or three diesel engines (V-12 to V-16, 550 to 965 hp range) with two 60- to 100-kW diesel generators (Fig. 13). During a typical visit to the lagoon, these vessels were underway with their main engines running approximately 1.5 hr (2% of 60 hr) and moved around the lagoon at speeds between 5 and 8

Fig. 13. *Typical whale-watching excursion vessel in Laguna San Ignacio. Note gray whale spyhopping in foreground.*

knots; total running time within the lagoon included entry (30 min), at least one change of anchorage (30 min), and their departure (30 min). The remainder of the time (97.5% of 60 hr) these vessels were at anchor with only their power generators operating. While underway they produced broadband waterborne noise ranging from 125 Hz to 20 kHz at source levels ranging from 124 to 170 dB *re.* μPa at 1 m depending upon hull construction and engine type (Dahlheim, 1984; Chapter 22, this volume).

Each excursion vessel launched three or four inflatable, wooden, or aluminum 4- to 5-m skiffs powered by 20-hp outboard engines to take their passengers whale watching and to visit various places of interest within the lagoon. These skiffs normally operated 8 hr per day between 07:00 and 16:00 hr for approximately 24 running hr per visit (40% of 60 hr); during the remaining 36 hr the skiffs were not in operation. Besides the presence of vessels at anchor (generators on), whales did not have to contend with skiff activity at night. Therefore, whales were followed less than 50% of the day. While whale watching at idle speeds, skiff waterborne noise source levels ranged from 75 to 120 dB *re.* μPa at 1 m, and while motoring at half throttle, source levels ranged from 105 to 120 dB *re.* μPa at 1 m (Dahlheim, 1984; Chapter 22, this volume).

Whale-Watching Excursion Visitation

The number of whale-watching excursions that called at Laguna San Ignacio during the 97-day period from January 5 to April 15 between 1978 and 1982 is summarized in Fig. 14.

In 1978, 28 commercial whale-watching excursions visited Laguna San Ignacio during 50 days (51%) of the 97-day winter season. The number of these excursions increased 28% in 1979 to 36 excursions visiting during 56 days (58%) of the winter, and in 1980 they increased another 5.5% to 38 excursions during 72 days (73%) of the winter.

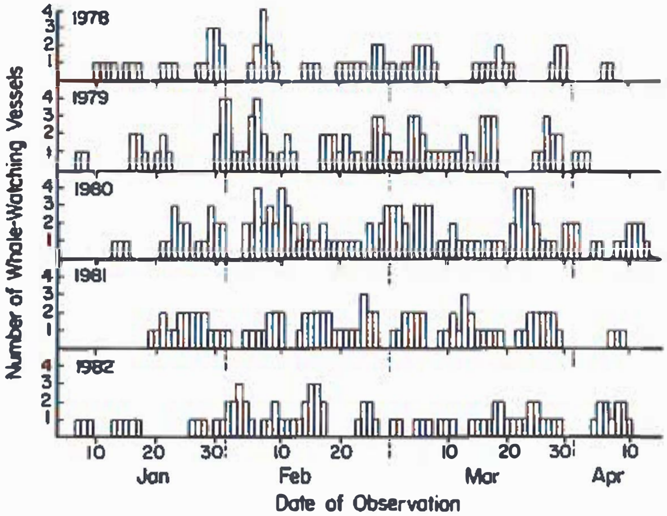

Fig. 14. *The number of whale-watching excursion vessels that visited Laguna San Ignacio from January 5 to April 12 between 1978 and 1982.*

Table VIII
Whale-Watching Excursion Vessel Visitations to Laguna San Ignacio during each 97-day[a] Winter Season between January 5 and April 12 for the Years 1978 to 1982

		Vessel days		Number of vessels per vessel day				Vessels with engines engaged[b]		Vessels at anchor[c]		Skiffs operating[d]	
Year	Number of trips/passengers	Number	% season	1	2	3	4	hr/season	% season	hr/season	% season	hr/season	% season
1978	28/700	50	51	36	11	2	1	42	1.8	800	34	400	17
1979	36/900	56	58	29	15	9	3	54	2.3	896	38	448	19
1980	38/950	72	73	34	23	10	5	57	2.4	1152	49	576	25
1981	28/700	60	62	31	27	2	0	42	1.8	960	41	480	21

Average	32/800	60	62	35	18	5	2	45	2.0	963	41	514	22

[a] Ninety-seven days = 2328 hr.
[b] Engines engaged based on 1.5 hr per trip.
[c] At anchor with generators running based on 16 hr per vessel day.
[d] Skiffs in operation based on 8 hr per vessel day.

In 1981, the number of whale-watching excursions declined by 28% (primarily in response to a 125% fare increase from 1978) to 28 excursions visiting during 60 days (62%) of the winter and then increased slightly in 1982 to 30 excursions visiting during 63 days (65%). The number of days without vessel activity within the lagoon declined from 49% in 1978 to 27% in 1980 and increased to 35% in 1982. Between 1978 and 1982, the number of excursion vessels within the lagoon at any one time averaged one vessel during 35 days (40%), two vessels during 18 days (20%), three vessels during 5 days (5%), four vessels during 2 days (2%), and no vessels in the lagoon the remaining 33% of the time (Table VIII).

Although the Mexican refuge regulations and commercial vessel permits allow only two commercial vessels in the lagoon at any time, three to four vessels occupied the lagoon together on 32 days over the 5 years. Because of the extensive shoals and strong currents at the lagoon inlet, multiple entries and exits occurred when one vessel followed another into or out of the lagoon, particularly if one operator was more familiar with the inlet channels. At these times excursion trips overlapped and when a third or fourth vessel arrived on the day that another vessel was scheduled to depart. This overlap resulted in three to four vessels occupying the lagoon simultaneously for approximately ½ day. On other occasions more than two vessels occupied the lagoon for one to three days. In both situations, there was a concomitant cumulative increase in the noise disturbance.

Ambient noise in the lagoon comes from both biological and nonbiological sources. Dahlheim *et al.* (Chapter 22, this volume) reported that levels of biological noise were lowest below 2 kHz, increased to high levels between 2 and 5 kHz, and declined gradually through 20 kHz. The average ambient noise levels attributable to biological sources (excluding cetaceans) ranged from 94 to 110 dB *re* μPa. The amount of nonbiological waterborne noise of human origin introduced into the lagoon habitat each season was dependent upon the number of hours that vessels were in the lagoon, the class of the vessel, and the amount of time each vessel or skiff was engaged in various activities.

One-hundred-ton class excursion vessels while underway produced the greatest levels of noise; however, on the average, these vessels ran their main engines only 48 hr of each 2328 hr- (97-day) season or approximately 2.0% of the winter. While at anchor, with only their power generators running, excursion vessels produced noise levels of 70 to 110 dB re. μPa at 1 m (Chapter 22, this volume) for approximately 963 hr or 41% of each winter. Outboard-powered skiffs were active an average of 514 hr or 22% of each winter season (Table VIII) and produced noise levels between 75 and 120 dB re. μPa at 1 m (Chapter 22, this volume).

In 1978, excursion vessels introduced noise distrubance during 51.5% (50 days) of the 97-day winter season. By 1980 these trips were introducing noise during 73% (72 days) of the winter, but the noise disturbance declined to 65% (63 days) by 1982. The 22.5% increase in the amount of time vessel noise was present in the lagoon between 1978 and 1980 represented a substantial change in the acoustical environment of the lagoon, particularly in the low-frequency range characteristically used by gray whales to communicate (Dahlheim, 1984). The 1980 winter saw the greatest amount of visitation and the greatest amount of nonbiological noise introduced into the lagoon.

Vessel Versus Nonvessel Day Comparison

Our goal of comparing gray whale abundance and distribution during control and experimental conditions was not fully realized. Almost continuous vessel visitation in some years combined with unstable winter weather severely hindered the opportunity to obtain data for pairwise comparisons between consecutive days with and without whale-watching activity. Only seven pairs of days were satisfactory for analysis.

To evaluate the short-term impact of whale-watching disturbance on gray whale demography in Laguna San Ignacio, we tested the hypotheses that gray whale abundance and distribution on days with and without tour vessel activity remained the same in the lagoon as a whole, in the lower lagoon where whales and human activities occurred simultaneously, and in the upper lagoon nursery area.

There was no evidence that gray whales moved out of the lagoon on days during the presence of whale-watching activities. In our three samples of paired-days prior to and following the arrival of a vessel, lagoon whale abundance increased in two instances and declined in one. In four samples of paired-days prior to and following the departure of a vessel, whale abundance decreased three times and increased only once. A Wilcoxon's paired-sample test (Sokal and Rohlf, 1981) of the nonvessel control days

Table IX
Comparison of Whale Abundance on Paired Days with and without Vessel Activity in Laguna San Ignacio, 1978–1982

Test comparison days	Date	Number of vessels	Number of whales		
			Entire lagoon	Lower lagoon	Upper lagoon
Preceeding vessel arrival versus vessel present	Jan 15	0	64	18	28
	Jan 16	2	86	24	43
	Mar 24	0	155	113	15
	Mar 25	1	139	92	15
	Apr 1	0	219	174	—
	Apr 2	2	234	205	—
Vessel present versus following vessel departure	Feb 1	2	129	64	45
	Feb 2	0	138	54	41
	Feb 9	1	245	126	61
	Feb 10	0	235	92	53
	Feb 26	2	137	74	23
	Feb 27	0	108	50	19
	Mar 7	1	107	66	10
	Mar 8	0	82	56	11
Wilcoxon's paired-sample test			$T_s = 5$ $p > .20$ $n = 7$	$T_s = 4$ $.10 < p < .20$ $n = 7$	$T_s = 1$ $.05 < p < .10$ $n = 6$

versus the vessel disturbance, experimental days revealed that the observed differences were not statistically significant [$T_s = 5 > t_{.05(2)7} = 2$, $.10 < p < .20$] (Table IX).

We suspected that any change in gray whale abundance in the area designated for vessel activity might be local, possibly masked, and not detected when the overall lagoon abundance was used as an estimator. We therefore repeated the above analysis using whale abundance data for only the lower lagoon. Whales were slightly more abundant in the lower lagoon while vessels were present. With the arrival of a vessel in the lower lagoon, whale abundance increased twice and decreased once. Following the departure of a vessel from the lower lagoon, whale abundance decreased in four instances; however, these differences in abundance were not significant [$T_s = 4 > t_{.05(2)7} = 2$, $.10 < p < .20$].

Finally, there was no conclusive evidence of an alteration in abundance or distribution of whales in the nursery area relative to the presence or absence of vessel activity in the lower lagoon. In two samples of paired days prior to and following the arrival of a vessel, whale abundance increased once and was unchanged once. In four samples of days prior to and following the departure of a vessel, female-calf pair abundance decreased in three instances and increased only once. The Wilcoxon's test revealed these changes were not significant [$T_s = 1 > t_{.05(2)7} = 0$, $.05 < p < .10$].

Friendly Whales

One of the unexpected effects of commercial whale watching in Laguna San Ignacio was the appearance of curious or "friendly whales." Friendly whales, as nicknamed by Gilmore, were first described for Laguna San Ignacio in 1975–1976 by Gilmore (1976), Wolfson (1976), and B. Cauble (personal communication), who reported that a few gray whales were soliciting human attention by deliberately approaching tour boats and whale-watching skiffs and allowing the passengers to pet them (Fig. 15).

During the course of this study, the friendly whale phenomenon rapidly expanded. In 1977–1978 friendly or curious whale behavior was a rare event involving a small number of individual whales (Swartz and Cummings, 1978; Larsen, 1978). But, by 1982 the incidence of this behavior had increased dramatically such that we personally had encounters with at least 200 friendly whales during 70 days of our 97-day field season. Moreover, virtually all whale-watching excursions that visited the lagoon between 1980 and 1982 have had encounters with friendly whales. For instance, in 1981, 26 of the 28 excursion vessels had contacts with curious whales, and nearly all 700 passengers were able to "pet a whale." Similarly, in 1982, each of the 30 excursions had repeated encounters with friendly whales (Swartz and Jones, 1981; Jones and Swartz, 1984).

Reports by investigators working in other areas indicate that friendly whale behavior has spread and is no longer unique to Laguna San Ignacio. At La Entrada (Bahia Magdalena) in 1979, Norris *et al.* (1983) reported two instances of friendly whale behavior when whales approached their research vessel, the *Regina Maris*, while she lay at anchor. In 1982, a chronic friendly whale that had been photographed for four consecutive winters in Laguna San Ignacio was encountered by researchers working in Laguna Guerrero Negro (Chapter 15, this volume). During the same year in Laguna Ojo

Fig. 15. *Friendly gray whale calf allowing whale watchers to pet it on the head. Note the tip of the mother whale's rostrum below and between calf and skiff.*

de Liebre, a team of Mexican scientists reported an encounter with a "curious" whale (Anonymous, 1983[5]). Similarly, in 1983, Lawson (1983) encountered a friendly whale in the Boca de Soledad area of Bahia Magdalena that nudged and rubbed against the skiffs tied astern a large excursion vessel. Most recently, a gray whale that was feeding along the west coast of Vancouver Island, British Columbia approached a skiff and exhibited friendly behavior (Hudnall, 1983). This whale remained in the area for a week or more where it was "friendly" to numerous vessels (J. D. Darling personal communication). Lastly, while recording gray whale vocalizations on the Bering Sea feeding grounds in July of 1982, M. Dahlheim (personal communication), who has experienced friendly whales in Laguna San Ignacio (Chapter 21, this volume), encountered a friendly whale that followed her boat for approximately 20 min.

Salient features of friendly whale behavior in Laguna San Ignacio have included: (1) participation by whales of all sex–age classes, (i.e., females and calves, males, females, groups of adults and immatures, and single individuals, (2) a seeming attraction toward a skiff with its engine idling in neutral gear, (3) frequent approaches to skiffs from astern, as though curious about the source of the engine sound, (4) frequent departures when the engines were shut off, (5) blowing large bubble bursts under and around the skiffs,

---

[5] Cetacean workshop discussion, VIII Reunion Internacional Sobre Mamiferos Marinos de Baja California, La Paz, Baja California Sur, Mexico.

(6) producing airborne "Bronx cheer" sounds from slightly pursed blowholes, (7) allowing physical contact (patting, rubbing, stroking, etc.) by passengers, (8) probing and frequently lifting the skiff, (9) occasionally jostling skiffs hard enough to knock a passenger overboard, (10) approaching and remaining near or directly alongside excursion vessels at anchor, (11) an accumulative effect where the presence of a single curious whale or female–calf pair appeared to attract additional passing whales creating groups of friendly whales of up to 20 individuals, (12) whales leaving the company of others to follow a skiff, (13) chronic curious behavior from some individual whales which continued throughout an entire day, and from week to week, month to month, and year to year for up to 6 years, (14) following slow moving whale-watching skiffs for up to 5 km and resuming friendly behavior when the skiffs stopped, (15) following skiffs attempting to leave an area, even at speeds in excess of 11 km/hr (6 knots).

The large majority of curious whale encounters have occurred without incident. Most friendly whales were cautious to the point of being timid. Whales when first making contact, generally probed the skiffs with the tip of their rostrum. We discovered that the whales were very sensitive to the slightest touch and often flinched if touched unexpectedly before they made the initial contact with the boat. On occasion, however, energetic "friendlies" have prodded skiffs with sufficient force to cause concern for the safety of the passengers. During six encounters, whales bumped whale-watching skiffs hard enough to knock six people overboard and cause slight damage to one of the skiffs and outboard engines. Skiff operators reported that the initial behavior of these whales toward the boats was gentle, but over time became increasingly rambunctious. In no instance, however, did this behavior appear as either aggressive or defensive behavior as described by Scammon (1874), Norris and Gentry (1974), or Norris *et al.*, (1977). On subsequent encounters with the same whales, the more forceful behavior was pronounced throughout and the whales did not revert to the formerly gentle contact. In addition, twice during curious encounters adult whales were observed breaching and lob-tailing within a distance of less than one body length from the skiffs, sending a cascade of water over the occupants. Furthermore, instances of near collisions with whales surfacing directly in the path of skiffs underway were observed.

Discussion

ABUNDANCE, DISTRIBUTION, AND OCCUPATION TIMETABLE

The demographic study of gray whales in Laguna San Ignacio provides a detailed picture of whale abundance and use of this breeding area between 1978 and 1982. An important finding is that the Laguna San Ignacio whale population at maximum combined counts has increased moderately at a statistically significant rate of 7.3% per year over the 5 years. This increase was chiefly due to significantly greater numbers of females and calves that primarily occupied the upper lagoon nursery during the birth period. The 18.3% per year increase in their counts indicated that greater numbers of females were either utilizing Laguna San Ignacio for parturition or were entering the lagoon with newborn calves. This increase, however, was not accompanied by a change in the timetable of female–calf pair occupation or their duration of stay, which remained the same each year. In contrast to the female–calf pairs, our results provide good evidence that the demography and phenology of the single whale population has remained essentially stable since 1978. There were no significant changes in the maximum abundance, distribution, or density of single whales, and, with the exception of one season, their timetable of occupation remained the same.

Prior to our research, mid-February aerial surveys of gray whale abundance in Laguna San Ignacio were conducted between 1947 and 1965 by Hubbs and Hubbs (1967) and later by Gilmore (1960). A second series of aerial counts was conducted by Gard (1978) between 1974 and 1976. Although all of these investigators attempted 100% coverage, each utilized unstandardized procedures and transect track lines; consequently, their results preclude quantitative comparisons. These early surveys are valuable, however, because they provide an index of gray whale abundance in Laguna San Ignacio over the past 35 years. An exponential curve fit to the counts since 1947 along with our boat counts between 1978 and 1982 suggests that the number of gray whales utilizing the lagoon has increased at least 7.9% per year [$F_{(1,18)} = 97.01$, $p < < .001$, $r^2 = .851$] (Fig. 16). This rate of increase agrees closely with the 7.3% per year rate of increase of our maximum combined counts between 1978 and 1982; however, it also suggests an annual rate of increase for the lagoon in excess of the population growth. The best estimate for the annual rate of increase of the California–Chukotka gray whale population is 2.5% per year, based on Reilly's (1981) analysis of 13 years of shore censuses of the fall migration past Monterey, California between 1968 and 1980; this was concurrent with an annual exploitation of 1.2% per year, yielding a 3.7% per year net realized rate of increase. During our 5-year study, then, gray whale counts in the lagoon increased approximately 4.8% per year above the growth rate of the population itself. At the beginning of our study in 1977–1978, the size of the gray whale herd was estimated to be 14,811 ± SD 2,272 whales and would have increased to approximately 16,000 by 1982 (Reilly *et al*., 1983).

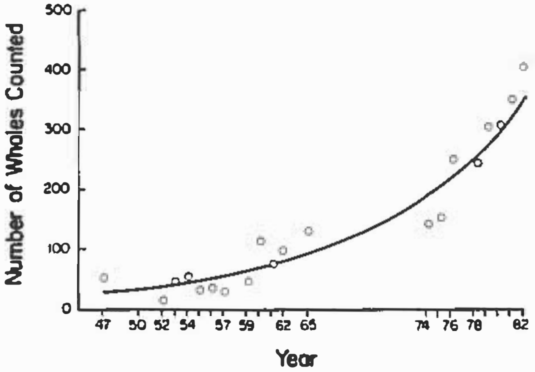

Fig. 16. *Gray whale abundance counts in Laguna San Ignacio from surveys conducted between 1947 and 1982. Aerial surveys were flown between 1947 and 1976 by Gilmore (1960), Hubbs and Hubbs (1967), and Gard (1978). Boat counts between 1978 and 1982 were conducted by the authors. Black line is a least squares exponential regression line fitted to the counts.*

There are at least two possible explanations for the overall increase in whale abundance in Laguna San Ignacio between 1978 and 1982. The first is that the gray whale herd is continuing to grow following its recovery from exploitation, and, therefore, counts in the lagoons continue to increase. An alternate explanation is that the higher overall whale counts could be due to a larger fraction of the total herd utilizing this lagoon. With the exception of Laguna Guerrero Negro, where whale counts did not increase significantly between 1980 and 1982 (Chapter 15, this volume), we do not know if increases in abundance occurred in other breeding areas, or whether Laguna San Ignacio is unique in attracting larger numbers of whales per year.

Notably, Laguna San Ignacio supports the second largest number of whales of all the major winter breeding areas. This is demonstrated by the results of boat surveys of gray whales (not including calves) reported from other breeding areas during the same time period (Fig. 17). Total adult whales in Laguna Ojo de Liebre reached a maximum of 829 animals on February 1, 1980 (Rice *et al.*, 1981); in Laguna San Ignacio the maximum count was 407 whales on February 14, 1982; in Boca de Soledad the maximum count was 225 adults on February 8, 1982 (Lawson, 1983); and maximum counts ranged from 120 to 207 whales between 1980 and 1982 in Laguna Guerrero Negro (Chapter 15, this volume). In addition, Rice *et al.* (1981), who conducted extensive aerial surveys of the west coast of Baja California, showed that two other areas were utilized by substantial numbers of adult grays; their unadjusted counts revealed that 170 whales were in San Juanico Bight on February 4, 1980, and 139 whales were in Bahia Almejas on February 5, 1980.

A main difference in the composition of the whale population in Laguna San Ignacio compared with other lagoons is that Laguna San Ignacio, at the time of maximum combined counts, is a single-whale-dominated system, whereas female–calf pairs predominate in the other lagoons during the same time period. For example, single whales averaged 70% of the population in Laguna San Ignacio at maximum combined counts, compared to 44% in Laguna Ojo de Liebre, 32% in Boca de Soledad, and an average of 19% in Laguna Guerrero Negro. Thus, Laguna San Ignacio supports a relatively small proportion of female–calf pairs while these animals outnumber single whales in the other areas at maximum combined counts.

To evaluate the relative importance of Laguna San Ignacio as a calving area for females and as a breeding area for single whales, we compared maximum counts of both groups in Laguna San Ignacio with maximum counts of these whales in other breeding areas. In terms of overall female–calf pair usage, Laguna San Ignacio appears to host the second highest number of females and calves with a maximum of 281 counted on March 8, 1982 (Fig. 17). The area with the greatest abundance of female–calf pairs was clearly Laguna Ojo de Liebre with 571 pairs counted there on February 4, 1980 (Rice *et al.*, 1981). One hundred and fifty-four mothers and calves were counted in Boca de Soledad on February 4, 1982, making it the third largest female–calf area (Lawson, 1983). Finally, Laguna Guerrero Negro contained the least number of these whales, averaging 127 pairs between 1980 and 1982 (Chapter 15, this volume). Laguna San Ignacio also appears to host the second greatest number of single whales, with an average maximum count of 227 (Fig. 17). Again, this is second only to Laguna Ojo de

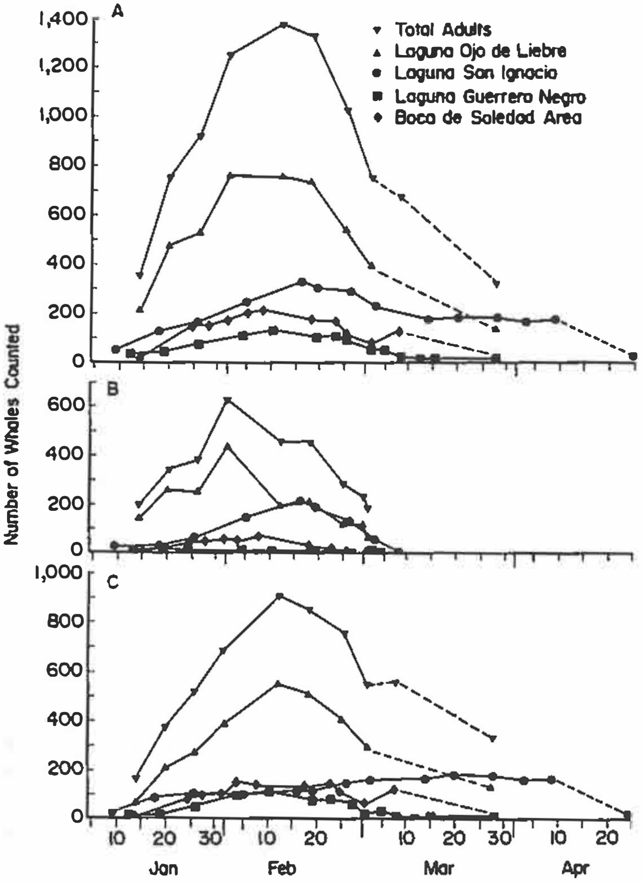

Fig. 17. *The number of gray whales (excluding calves) counted in four major breeding areas:* ▼, *total adults;* ▲, *Laguna Ojo de Liebre (Rice* et al., *1981);* ●, *Laguna San Ignacio (Swartz and Jones, 1981);* ■, *Laguna Guerrero Negro (Chapter 15, this volume);* ◆, *Boca de Soledad area (Lawson, 1983). All counts are for the 1980 winter except the data for Boca de Soledad which are from the 1983 season. (A) Total whales for all areas, (B) single whales, (C) female–calf pairs. Counts connected by solid lines are from boat surveys; those connected by broken lines are from 100% aerial surveys (see text for explanation).*

Liebre which contained 438 single whales at their maximum count on February 1, 1980 (Rice *et al.*, 1981). Boca de Soledad contained the third largest number of single whales, with 75 on February 8, 1982 (Lawson, 1983), and Laguna Guerrero Negro supported the smallest number of single whales of all these areas; single whale counts in this lagoon ranged from 19 to 43 in mid-February between 1980 and 1982 (Chapter 15, this volume).

We cannot explain why the single whale maximum abundance remained the same each year rather than increasing significantly; however, we believe that the total number of single whales using Laguna San Ignacio during a winter season is far greater than the number counted in the lagoon at maximum combined counts. The boat surveys provide an index of the minimum number of whales in the lagoon at specific points in time throughout a season; but, we do not mean to imply that the population is a static group or that the same individuals are being counted repeatedly each week as the number of whales builds to its maximum each year. In other words, we suspect that single whales have a high turnover rate in the lagoon. Evidence supporting the notion of a relatively continuous exchange of whales through the lagoon during each season comes from our photographic identification study between 1977 and 1982, and our shore-based observations of the main entry channel of the lagoon inlet in 1982. Photographic identification results revealed that 81% of the single whales photographed in Laguna San Ignacio had a duration of stay of 1 week or less. In addition, the fact that two single whales photographed by D. Withrow (personal communication) in Laguna Oje de Liebre were resighted approximately 1 week later in Laguna San Ignacio during the same season suggests the possibility of a relatively rapid circulation of whales between breeding areas as well (Jones, 1984). Finally, our census of whale movement through the inlet demonstrated that substantial numbers of single whales enter and exit the lagoon every day. For example, at the time of the maximum combined count in 1982, when 270 whales were counted within the lagoon, a minimum of 341 others entered and 185 exited the lagoon during a 7-hr. period. Because the majority of the singles present in the inlet throughout the season were actively transiting and their movement was independent of the tide, counts of these whales through the inlet were indicative of a real exchange of animals rather than being repeat counts of the same individuals passively moving into and out of the lagoon with the tide (Jones and Swartz, 1984).

The duration of the single whale season in Laguna San Ignacio was statistically consistent during 4 of the 5 years when it averaged 79 days (11 weeks). In 1979, however, the season was significantly longer, as seven whales (3% of the maximum count) remained in the lagoon approximately 2 weeks longer that usual. Since the number of whales present during the tail end of the deviant year was small, we think that the 4 year average is the best estimate for the single whale duration of stay in Laguna San Ignacio between 1978 and 1982. Nevertheless, there are two obvious reasons why this estimate may be somewhat biased toward overestimating the actual length of the single whale season. First, late-pregnant females are believed to be the first animals to arrive at the lagoons (Rice and Wolman, 1971), and because these females are indistinguishable from single whales until they give birth to their calves, census counts early in the winter probably extend the length of the single whale season beyond its actual length. Similarly, whale counts late in the season may include some females that lost their calves and would be counted as single whales.

The durations of stay of single whales were nearly the same in Laguna San Ignacio, Laguna Ojo de Liebre, and Boca de Soledad, and each of these areas hosted single whales longer than Laguna Guerrero Negro. In Laguna Ojo de Liebre, the minimum length of the single whale season in 1980 was 75 days (10.7 weeks). This period is based on an estimated beginning date for the season of December 20 which Rice *et al.* (1981) extrapolated from the timing of the southbound migration past Point Loma, California, and from the date of their last lagoon boat census on March 3. Because their final count included 67 single whales, and our March 28 aerial survey of the same area revealed no single whales, we suspect that the season probably extended to at least March 10, 1980 and, therefore, was at least 80 days (11.4 weeks) in duration. Single whales were present in Boca de Soledad for a minimum of 78 days (11.1 weeks) from January 9 to March 28, 1982 (Lawson, 1983). Lawson stated that approximately 15 whales were already present at the beginning of her study, thus, the duration of the season was probably a few days longer. Lastly, Bryant *et al.* (Chapter 15, this volume) reported that the single whale season in Laguna Guerrero Negro began on approximately January 3 and usually ended by March 10 for the 3 years from 1980 to 1982. This yields a 66-day (9.4-week) duration of single whale season, which is approximately 2 weeks shorter than that reported for any of the other breeding areas. This shorter single whale season may be related to Bryant *et al.*'s (Chapter 15, this volume) finding that Laguna Guerrero Negro consistently hosted only a small number of single whales that averaged 16.2% of the total adult whales. In summary, the period of lagoon occupation for single whales in these areas ranged from 9.4 to 11.4 weeks, beginning in late December or early January and ending by approximately mid-March. Their departure from these lagoons occurred approximately 1 month before the departure of female–calf pairs.

Knowledge of the duration of a behavior contributes to the understanding of an animal's time budget. In the case of the gray whale, the duration of stay in the lagoons has important implications in terms of the whales' energy requirements. Because single whales leave the breeding areas approximately 1 month earlier than many of the female–calf pairs, they presumably arrive on the summer feeding grounds earlier and spend more time there than females that give birth to calves during the same year (Rice and Wolman, 1971). Given that females normally reproduce biennially, this suggests that adult females would alternate between a longer period on the summer range when newly pregnant and a shorter period on the summer range when lactating. Males, however, would be able to spend the same amount of time feeding on the summer range each year. For newly pregnant females, this extra summer feeding time is of obvious energetic significance related to their need to acquire more fat reserves for the gestation of a calf and a 7-month lactation period.

The variation in the timing of the single whale seasonal occupation of Laguna San Ignacio is best expressed as differences between the mean day per season, rather than as changes in the dates of the maximum counts. The timing of maximum counts may be more a function of the weekly sampling schedule than of actual variations in the timing of single whale abundance. For example, the dates of single whale maximum counts in Laguna San Ignacio differed as much as 27 days between winters and were significantly different, whereas the mean days differed by 15 days and were not significantly different from one another or the pooled mean day. For predictive purposes, the pooled mean day of February 9 is the best estimate of the midpoint of the single whale season between 1978 and 1982. The variation in the seasonal timing, expressed as differences between mean days, may occur as a result of environmental factors such as changes in the timing of the advance of the Arctic ice sheet (Chapter 10, this volume) or extremely favorable or unfavorable weather in the summer range and along the migratory route.

Estimates of the mean day of the single whale season are not available for other breeding areas. At present, the timing of peak abundance of single whales among breeding areas can only be evaluated by comparing the dates of maximum counts. A comparison of the 5-year average day of maximum counts in Laguna San Ignacio with the date of maximum counts in other areas indicated that the timing of single whale maximum counts is variable among breeding areas. Peak counts coincided in the northernmost lagoon of Guerrero Negro and the southernmost lagoon of Bahia Magdalena, but occurred a few days earlier than in Laguna San Ignacio; for example, in Laguna Guerrero Negro maximum counts were obtained between February 8 and 10 during the period 1980 to 1982 (Chapter 15, this volume), and in Boca de Soledad they occurred on February 8, 1982 (Lawson, 1983). In Laguna Ojo de Liebre maximum counts were obtained on February 1, 1980 (Rice *et al.*, 1981), 2 weeks earlier than in Laguna San Ignacio. The variation among the different areas may be the result of real changes in the single whale season or of the survey schedules employed in the various breeding areas. Clearly though, the timing of single whale counts from these lagoons is not suggestive of a sequential occupation of areas from north to south (Norris *et al.*, 1983); rather, the timing of the occupation appears to be independent of geographical location.

The pattern of temporal distribution of female–calf pairs in Laguna San Ignacio was virtually the same each year, but was strikingly different from that in other lagoons. In Laguna San Ignacio, the number of females with calves increased steadily throughout the birth period from late December through mid-February, and reached peak numbers in late March or early April. At maximum counts, abundance was nearly double that in mid-February and averaged 226 pairs compared to 116 pairs. In Laguna Guerrero Negro, Laguna Ojo de Liebre, and Boca de Soledad, however, maximum counts of females and calves occurred much earlier. In these areas, counts increased in early January to maximums in mid-February and then decreased. For instance, maximum counts of female–calf pairs were obtained between February 8 and 10 between 1980 and 1982 in Laguna Guerrero Negro (Chapter 15, this volume), on February 12, 1980 in Laguna Ojo de Liebre (Rice *et al.*, 1981), and on February 4, 1982 in Boca de Soledad (Lawson, 1983).

One explanation for the difference in timing of female and calf peak counts between Laguna San Ignacio and the other areas is that this lagoon serves as a staging area for female–calf pairs prior to their departure from the southern range. There are two sources of evidence supporting this idea. First is the observation that the late season influx is not due to continued births; rather, these late season females have calves that are approximately 2 to 3 months old (Swartz and Jones, 1981). Second, the results of our 6-year photographic identification study, in combination with a 3-year program in Laguna Guerrero Negro by Bryant and co-workers and a 1-year project in Boca de Soledad by Lawson, revealed that some females with older calves were immigrating to Laguna San Ignacio after leaving these breeding areas. Prior to the extension of photographic identification studies to other breeding areas, we and other investigators had speculated that the late season influx of whales consisted of females with calves that were moving northward from Bahia Magdalena (Swartz and Jones, 1978; Rice *et al.*, 1981). But this is only partly true. In addition to northbound immigrants, some females with calves photographed early in the season in more northerly lagoons, vacated these areas and moved south to Laguna San Ignacio late in the season (Jones, 1984).

Recently, a late season influx of female–calf pairs was reported for Boca de

Soledad; however, this influx occurred on March 8 and was preceded by a decrease in abundance from their maximum count on February 4, rather than showing the continual increase seen in Laguna San Ignacio (Lawson, 1983). Lawson speculates that this late season influx in Boca de Soledad consists of whales moving north from the main bay of Bahia Magdalena or from the Gulf of California. Additional observations will be required to determine if this influx is an annual event in Boca de Soledad.

The reason why females and their calves are attracted to Laguna San Ignacio late in the season is unknown, but may be related to a combination of factors. For example, females may utilize potential food resources in Laguna San Ignacio, as there is a growing body of direct and indirect evidence indicating that a subgroup of gray whales, particularly females with calves, may opportunistically consume appreciable amounts of prey within the lagoon and its nearshore waters (Swartz and Jones, 1981; Jones and Swartz, 1984). Another possibility is that this aggregation of whales is related to the social structure of the herd or to the "socialization" of older calves. Gray whales have been characterized as being unsocial animals, partly because of the solitary nature of mothers and calves during the early part of the winter (Gilmore, 1960). However, the contention that these gatherings may have a social function is supported by the observation that in the latter part of the season in Laguna San Ignacio when calves are older, mothers and young frequently join to form large groups characterized by intense physical contact (Swartz and Jones, 1981). Group members cavort, rolling and rubbing against each other, wheeling and diving at the surface and below. Multiple bubble bursts frequently mark their location while submerged. The size and duration of these groups vary, but can involve up to 20 mother–calf pairs at a time, and can last from a few minutes to over 3 hours. The groups are fluid, with pairs coalescing and exchanging continually (Jones and Swartz, 1984). Another hypothesis is related to the physical development of the calves; that is, Laguna San Ignacio may serve as a resting area where females stop over to rest and nurse their growing young after periods of oceanic swimming. Additional study will be required to evaluate the validity of these tentative hypotheses.

A major objective of the study was to learn how gray whales use Laguna San Ignacio. This lagoon is an important calving and breeding area for single whales and female–calf pairs, and during our study, the whales exhibited a regular distribution that did not vary significantly over the 5 years. During the period from late December to late February, when single whales and females with calves occupied the lagoon jointly, 50% of the total whale population was distributed in the lower lagoon, 20% in the middle, and 30% in the upper lagoon. However, there was a consistent separation between the calving and breeding portions of the lagoon population. Females with calves and single whales utilized the lagoon quite differently. As whales entered the lagoon, the population became segregated spatially and temporally such that the distribution, gross movement, and timetable of occupation differed for each group. Single whales were dispersed in a gradient being most dense near the inlet and becoming less dense with increasing distance from the inlet, while most female–calf pairs were concentrated in the upper lagoon nursery farthest from the inlet. To illustrate, at the date of combined maximum counts each year, the average distribution of single whales was 65% in the lower lagoon, 24% in the middle, and 11% in the upper lagoon. In contrast, the average female–calf pair distribution at the same time was 11% in the lower lagoon, 9% in the middle, and 80% in the upper lagoon nursery.

The single whales' definite preference for the lower lagoon may be related to access to the relatively deep and wide channel, which is unrestricted even at low tide, or to close proximity to the inlet and open ocean areas, or both. While in this area, single whales are predominantly engaged in social activities associated with courtship and mating. The lower lagoon is 2–4 times deeper than the middle and upper lagoon respectively, and may be more conducive to sexual behavior by allowing the whales greater mobility.

The localization of single whales in the inlet and lower lagoon region of Laguna San Ignacio is a feature of lagoon use by single whales that also occurs in other breeding areas. Gilmore (1960) reported that lone adults, courting adults, and immatures also predominate at the entrances to Laguna Ojo de Liebre and Bahia Magdalena, and suggested that courting and mating are the primary activities of the whales in these areas. In addition, Samaras (1974) stated that adult male and female grays use the inlet of Laguna Ojo de Liebre as a staging area for precopulatory behavior, while pregnant females occupy the inner lagoon calving area. Norris *et al.* (1983), who studied lagoon entrance aggregations of gray whales at La Entrada, the main entrance to Bahia Magdalena, and Canal Rehusa, the entrance of the southernmost calving lagoons at Bahias Almejas and Santa Maria, reported that the entrance aggregations were composed entirely of males, nonparturient females, and juveniles whose primary behaviors appeared to be courtship, mating, and possibly feeding. On the other hand, Bryant *et al.* (Chapter 15, this volume) described Laguna Guerrero Negro as hosting very few single whales and they did not appear to aggregate in the area nearest the inlet. They also noted, however, that this lagoon does not have any deep-water areas comparable to those in the larger breeding lagoons, but further remarked that a large number of singles have been observed in the deep-water area just offshore. This finding, then, is reminiscent of the pattern of single whale distribution in other breeding areas.

The predominance of female–calf pairs in the upper lagoon nursery area of Laguna San Ignacio is undoubtedly related to a number of features that are conducive to the rearing of very young calves. First, the upper lagoon area is relatively shallow and least affected by tidal currents, but the area available to the whales is greatly reduced at low tide. Evidently, these inner lagoon features are attractive to females with newborn calves since they consistently utilize the innermost areas when single whales are present in the lagoon. Mothers and calves in the upper lagoon are primarily engaged in the more tranquil activities of resting, nursing, and moving about with the changing tides. Moreover, it is generally accepted that the nursery area furthest from the inlet provides an area of relative solitude for the females following parturition and during early calf development. In addition, we feel that harassment by courting whales is probably a major factor in the segregation of females and calves away from single whales inhabiting the outer lagoon areas. Females with calves avoid courting groups; despite their avoidance of single whales, they are occasionally pursued by groups of single whales that appear to harass and attempt to mate with these females (Swartz and Jones, 1981; Jones and Swartz, 1984). Mating bouts appear to be very disruptive events and may involve as many as 15 individual whales thrashing at the surface and throwing their flukes and flippers about as they jocky for mating position. It is certainly reasonable to think that a calf might be separated from its mother or could sustain injuries or even be killed in these circumstances. We agree with Norris *et al.* (1977) that "courting–mating aggregations are almost certainly disruptive places for mother–calf pairs."

The pattern of female–calf pair distribution in Laguna San Ignacio during the first half of each winter is consistent with the findings of investigators working in other lagoons who report that the uppermost lagoon areas farthest from the open sea are utilized extensively by female gray whales with newborn calves (Scammon, 1874; Gilmore, 1960; Rice and Wolman, 1971; Samaras, 1974; Gard, 1974; White, 1975; Norris *et al.*, 1977). The dynamics of female–calf pair distribution in Laguna Guerrero Negro appears to correspond to that observed in the upper portions of the larger breeding areas of Laguna Ojo de Liebre, Laguna San Ignacio, and Bahia Magdalena; that is, the duration of female–calf pair occupation in Laguna Guerrero Negro and in the upper regions of these areas begins and ends at approximately the same time, their periods of peak abundance coincide, and very few single whales are found in these areas.

The middle lagoon consistently hosted the lowest density of whales early in the season. One explanation for the decrease in single whales in the middle lagoon and nursery is that the significantly larger numbers of female–calf pairs using these areas, in effect, may have displaced single whales. In addition, this region may serve as a "buffer" between courting single whales and females with their newborn calves. Norris *et al.* (1983) commented that an almost whale-free "buffer-zone" existed at Bahia Magdalena between single whales in the area nearest the inlet and the female–calf pairs deepest within the lagoon interior.

Following the period of combined maximum counts, and with the gradual departure of single whales from Laguna San Ignacio, female–calf counts continued to increase to their maximum counts and these whales gradually shifted their distribution to the lower lagoon and inlet, essentially abandoning the upper lagoon nursery. Thus, throughout each season, gray whales are most numerous in the lower lagoon and inlet. The average distribution of female–calf pairs at this time is: 87% in the lower lagoon, 12% in the middle lagoon, and 1% in the upper lagoon.

The trend for female–calf pairs to occupy the area nearest the sea following the end of the birth period and the departure of single whales from the lagoon was prevalent during all winters in Laguna San Ignacio, and suggests that females prefer the inlet and lower lagoon over other areas when their calves are 2–3 months old. We conducted aerial surveys (100% counts) of Lagunas Guerrero Negro and Ojo de Liebre on March 28, 1980 and found that female–calf pairs had abandoned the innermost regions of these lagoons as well and were concentrated in the lower lagoon and inlet areas; in Laguna Guerrero Negro, we counted 17 mother–calf pairs in the lower lagoon entry channel and 73 pairs in the inlet, and in Laguna Ojo de Liebre we counted 22 pairs in the upper portion of the lagoon, 83 pairs in the lower portion, and 121 pairs in the inlet, indicating that a late-season shift in the distribution of female–calf pairs toward the inlet also occurs in these lagoons. The tendency for whales to shift their distribution from the inner regions of the breeding areas to the lower and inlet areas is also seen in Boca de

Soledad (Lawson, 1983) and Bahia Magdalena (Norris *et al.*, 1983). Scammon (1874) and Norris *et al.* (1977) interpreted this shift as being the first stage of the migration preparatory to leaving the lagoons.

MORTALITY

Age-specific mortality is a vital parameter in any demographic study. The pattern of gray whale mortality in the winter range that emerged from the evaluation of mortality data in Laguna San Ignacio, Laguna Guerrero Negro, Laguna Ojo de Liebre, and Boca de Soledad between 1954 and 1983 can be characterized by three age-class components: (1) a very high proportion of calves, consistent in all areas, that averaged 91.4% of the total dead whales, (2) a relatively high, but unstable proportion of immatures that ranged from 0–19.5% among areas, and (3) a consistently low, but unstable proportion of adults ranging from 0 to 5% between areas.

This mortality pattern supports both the contention that calves are more susceptible than adults to fatal strandings in the lagoons and the idea that calf and yearling mortality is higher than that of adults (Eberhardt and Norris, 1964; Gard and Gard, 1972; Gard, 1976) and further implies that gray whale age specific mortality is typically mammalian. That is, in most mammal species, young and immatures have higher mortality rates in relationship to older individuals, whose mortality rates remain relatively constant following maturity (Allen, 1981). Caughley (1977) states that mammal mortality rates typically follow a U-shaped trend with age, where prepubertal mortality varies greatly compared to adult mortality rates which remain less variable with age. Gray whale mortality appears to fit such a trend, with calf and immature mortality rates significantly greater than that of adults. Since the gray whale population is changing demographically as it continues to grow, records of strandings, particularly calf mortality, are valuable for monitoring changes in age-specific mortality and will provide a more accurate profile of the population age structure.

The preponderance of dead gray whale calves discovered in the breeding areas in all years suggests that the period including birth and the time immediately following birth within and near the breeding lagoons is critical for the survival of the young. Calf carcasses were commonly discovered in the lagoons throughout the birth period from January 5 to February 15, but were infrequently encountered in March and April, suggesting that the probability of dying is greatest for a calf just after birth and decreases with time.

The mean calf mortality rate of 3.54% calculated for whales in Laguna San Ignacio (1978–1982) is comparable to the 2.5% mean rate for calves in Laguna Guerrero Negro (1980–1982) and the 2.9% rate in Laguna Ojo de Liebre in 1980 (Swartz and Jones, 1983). Unfortunately, data on calf mortality prior to the exploitation and subsequent depletion of gray whales are nonexistent, making it impossible to determine whether the mortality rates for Laguna San Ignacio and the other areas are high, low, or typical for the species. Counts of dead calves undoubtedly underestimate actual calf mortality because not all carcasses are discovered: some dead whales are washed out to sea with the tides, some are consumed by scavengers, others strand on beaches not visited by investigators, and still others are missed by researchers altogether. Nonetheless, mortality rates based on dead whales are useful as minimum estimates.

From our analysis of the body size of dead calves stranded in Boca de Soledad, and Guerrero Negro, Ojo de Liebre, and San Ignacio lagoons, we concluded that the mean lengths of the calves in all these areas were consistent and together averaged 4.43 m. It has been generally assumed that the lengths of dead calves in the lagoons are representative of the lengths of gray whales at birth (Rice and Wolman, 1971; Rice *et al.*, 1971; Rice, 1983). However, our comparison of the lengths of dead calves from the breeding areas with the lengths of near-term gray whale fetuses collected by Rice and Wolman (1971) clearly indicated that the dead neonates were significantly shorter than the fetuses (4.43 to 4.62 m respectively) and suggests that the typical length at birth of most viable gray whale calves would be longer than the lengths of the dead lagoon calves. Presumably, had the fetuses developed to full term, only a small percentage of them, equal to the calf mortality rate in the lagoons, would be expected to die, and we would expect the lengths of *these* calves to be similar to the lengths of dead neonates from the lagoons.

Rice *et al.* (1981) also noted the smaller size of dead neonates in the breeding lagoons compared to near-term fetuses, and proposed that ". . . the body length shrinks after birth, possibly due to compression of the intervertebral disks." An alternate explanation for the dead neonates being shorter is that they might be premature, and as premature animals their lengths would not be representative of full term neonates. The fact that they are dead, also suggests that these whales are abnormal and not representative of normally developed young. Another possibility is that neonatal mortality is higher for smaller calves. It is generally known that among mammal species, the bigger the offspring, the better are its chances of survival (Ralls, 1976), and that for humans and some species of nonhuman primates and some ungulates, small offspring have higher mortality than larger individuals. Although we have no hard evidence to support any of these ideas for gray whale neonate mortality, we feel that the deaths of these smaller whales are probably related in some way to reduced fitness at birth.

Theoretically, gray whale yearlings should attain a length of about 8.2–9.6 m by the time they make their first return trip to the southern range. The dead immatures from Laguna San Ignacio that were either too small to be yearlings or too large to be calves of the year, perhaps, were animals that became ill before or following separation from their mothers, or failed to learn how to forage for themselves, or did not spend their first summer in a suitable feeding area with the result that their growth was stunted. These "runt" animals could then have followed the fall migration of the population to the southern range where they died as undersized yearlings.

Most population biologists agree that accurate aging of animals is important because knowledge of the dynamics of a population depends heavily on the ability to age individuals (Caughley, 1977). Many also agree that errors are inevitable especially when the criterion of age is a morphological feature, like body size, that changes continuously with age. In the case of gray whales where body length is used to age individuals, the problem of correctly categorizing small gray whales as yearlings rather than calves points out an obvious bias with this or any fixed length–age interval classification scheme. Alternative methods of aging small whales are limited primarily because small whale carcasses decompose rapidly (Eberhardt and Norris, 1964), and short-term clues as to their age, such as the presence of adult barnacles, are lost relatively soon after death. Thus, small yearlings could be misidentified by age as calves of the year. One important effect of this error is that calf mortality rates might be biased upward. In this instance, it would be important to know what proportion of dead calves is actually undersized yearlings. A second effect is that yearling lengths misclassified with calf lengths would contribute error when these data are used to assess calf growth rates (i.e., it would bias calf growth rates upward). In the future, it will be valuable to know how often the gray whale age classification index leads to error, so that researchers can reduce bias in their results and better evaluate the significance of age-specific mortality in this species.

Sex Ratio

The 1:1 sex ratio of dead gray whale calves, immatures, and adults combined reported from the four breeding lagoons is in agreement with the findings of Rice and Wolman (1971), who report that gray whales have an equal sex ratio at all age classes. Based on the sex ratio of gray whales collected during migration, Rice and Wolman (1971) state that ". . . there is probably little sex difference in mortality rate, a conclusion further supported by the essentially equal sex ratio at all ages." While this may be true for gray whale calves, the sample of dead immatures and adult whales from the lagoon was too small to permit the evaluation of differential mortality between males and females of these age classes. If gray whale mortality is typically mammalian, we would expect proportionately greater male mortality in older age classes (Caughley, 1966; Ralls *et al*., 1980). However, additional data are needed to clarify this issue.

WHALE-WATCHING ACTIVITIES

Concern about the potential detrimental consequences of the intrusion of human activities into the breeding lagoons of the gray whale has been widespread since whale-watching excursions began to visit these areas in the early 1970s. Gard (1974) and Villa-Ramirez (1975) maintained that the presence of people seeking to view the whales close-up displaces gray whales from their preferred breeding areas, but they provided no conclusive evidence. Rice (1975) stated that "considerable harassment is caused by commercial cruise boats which take people into the calving lagoons to see the whales." Additional speculation came from Gilmore (1978) who wrote that the "entry of man with his industrial or recreational activities into the calving and courting lagoons . . . , could only have an adverse effect on the reproduction and survival of the newborn [whales]."

In seeking a biological basis for the argument that whale-watching excursion vessels pose a significant threat to breeding gray whales in Laguna San Ignacio, we attempted to assess the long and short-term demographic effects on gray whales including changes in abundance, distribution, and mortality that may occur as the result of repeated encounters with excursion vessels and their related activities. To our surprise, none of the adverse consequences that we proposed might result from exposure to human activities were substantiated. Rather, our findings to date suggest that the gray whales possess sufficient resiliency to tolerate the physical presence and activities of whale-watching vessels and skiffs and the noise produced by this level of activity without major disruption.

Gray whales did not shift their distribution from Laguna San Ignacio in response to human activities. They continued to return to the lagoon, and there was no decrease in whale abundance concurrent with the growth of the thriving whale-watching industry within the lagoon. In fact, the whale population in Laguna San Ignacio has steadily increased since whale-watching activities began in 1974, as demonstrated by the comparison of previous aerial surveys over the past 35 years with our 5 years of abundance counts. Moreover, the increase in gray whale abundance in the lagoon each year exceeded the estimated rate of growth of the population, suggesting that gray whales were preferentially utilizing this lagoon even with the presence of whale-watching activity. Further evidence of the grays' apparent tolerance of whale-watching disturbance, which is of major importance to their reproductive success, is the fact that the number of female–calf pairs inhabiting the lagoon during the birth period also increased significantly at a rate approximately 10% per year above the population growth between 1978 and 1982. We feel that a key factor responsible for maintaining the stability of the whale population in Laguna San Ignacio was the establishment of the gray whale refuge in the lagoon, which serves to regulate the number of vessels operating in the lagoon and provide an area free of all vessel activity as a sanctuary for the use of the whales (particularly females with calves) (Vargas, 1981).

Our index of whale abundance in all regions of the lagoon throughout the season revealed that patterns of use of the three lagoon interior areas have been essentially the same in all years despite increased levels of tourism. The upper lagoon and the lower lagoon merit special consideration. For instance, the number of females and calves that utilized the upper lagoon nursery area showed a significant increase, indicating that human activities in the constriction of the main entry channel at Punta Piedra did not impede their access to and from the upper area or prevent them from entering the lagoon. If tranquility within the lagoon is important to females with calves, then perhaps containment of whale-watching activities in the lower lagoon has had a beneficial influence on the whales in that the closed middle and upper lagoon nursery areas provide a refuge where females with calves remain relatively undisturbed.

In the lower lagoon, gray whales have continued to co-exist next to whale-watching activities. The whale population has made no detectable shift away from the lower lagoon toward areas of less human contact. Although the lower lagoon is the smallest of the three lagoon sections, it was the region most heavily utilized by the whales. This area consistently contained 65% of the single whales during the first half of each winter, and later was occupied by 87% of the female–calf pairs. In fact, each year, whale density was greatest in this area when female–calf pairs occupied it exclusively during the last half of each season. Thus, it is reasonable to conclude that the single whales and female–calf pairs have not been displaced from their preferred habitat as a result of whale-watching activities in the lower lagoon from 1978 to 1982.

The whales' continued utilization of the lower lagoon during the presence of whale-watching activities may be related to the fact that whale-watching skiffs were operated only during 8 daylight hours, or approximately 33% of each day that they were present in the lagoon, while the remaining 66% of the day, the whales were free to move about the lower lagoon unencumbered by interruptions caused by whale-watching skiff activity. On a seasonal basis, in fact, skiffs were only in use during approximately 22% of the time. Similarly, excursion vessels were underway only during daylight hours, and operated their main engines (which produced the greatest amount of waterborne noise) for only 2% of each season. If night movement is an important element in the gray whale's winter life cycle, then the lessened vessel traffic during this time is likely to contribute to their apparent ability to tolerate vessel activity within the lagoon. Indeed, there is some evidence from behavioral observations in Laguna San Ignacio which demonstrates that the whales are active at night. For instance, from nighttime observations with a starlight scope, Swartz and Jones (1981) determined that there were no outstanding differences in the types of behaviors exhibited by females and calves, lone single whales, and groups of single whales during the night and the day in Laguna San Ignacio. At night, whales jumped out of the water (breached), held their heads above the surface (spy-hopped), moved around the lagoon as singles or in groups, rolled at the surface, or remained motionless, drifting with the current (Swartz and Cummings, 1978). Furthermore, Mate and Harvey (1981) and Harvey and Mate (Chapter 24, this volume) reported that "radio-tagged whales generally left the lagoon during the night and returned in the morning hours."

Another factor that may contribute to the continued use of the lower lagoon by gray whales is the method of whale-watching employed by the skiff operators. The primary objective of the whale-watching excursions is to provide an opportunity for the passengers to view free-ranging gray whales in their natural habitat. Paying passengers and crew generally show a genuine respect for the whales and a desire to minimize their disturbance (Gilmore, 1976). Most skiff operators have had years of experience at operating skiffs around whales and have learned that gray whales are not seen by forceful pursuit (Storro-Patterson, 1981). Thus, practices that overtly disrupt whale behavior or cause the whales to flee from whale-watching skiffs are not generally employed. On the contrary, when following whales, skiff operators typically move at slow speeds, usually following a whale for only a short distance or remaining stationary with the engine running in neutral waiting for whales to pass by. It is to their advantage not to "run" a female with a newborn calf or to "spook" the whales and cause them to leave the whale-watching area. Additionally, because gray whales are so numerous in Laguna San Ignacio, if one individual shows avoidance behavior, many other whales are available for skiff operators to follow instead.

It is also possible that because of their continued exposure to boat noise and whale watching at the controlled level observed during our study, gray whales may have, to some degree, become habituated to the vessel activity in the lower lagoon. In other words, gray whales may be growing accustomed to the presence of tourist vessels in this lagoon. A finding that lends support to this idea is the widespread increase in the incidence of friendly whales in this lagoon. Previously, Gilmore (1976) remarked that friendly whale behavior "suggests that sport-fishing [i.e., whale-watching] boats and their skiffs have not been harassing the whales, disturbing their calving, nursing, and courting, as have been contended." Likewise, Reeves (1977, p. 20) quotes Hubbs (in litt.) as stating that the San Ignacio whales "have shown very definite indications of becoming accustomed to the party boats [i.e., whale-watching vessels] and the small craft, and have actually, in some instances, given every indication of inviting attention and even physical, friendly contact." At the time these encounters were first reported, one could argue that the friendly whale phenomenon was aberrant behavior by a few animals. During our project, however, we witnessed the incidence of friendly whale behavior grow from a few isolated encounters each season to a commonplace event that involved numerous whales and was experienced by nearly every whale watcher aboard the whale-watching excursions to the lagoon.

Finally, we obtained no conclusive evidence that whales move out of the general area of whale-watching activities during or on the day following human disturbance, which further suggests that whale-watching did not significantly disturb gray whales in the lagoon. Support for this comes from the pairwise comparison of the whale abundance on days with and without the presence of excursion vessels. These activities did not seem to alter the overall distribution of whales in the lagoon or change the distribution of whales in the area of chronic disturbance. Gray whale demography in the upper and lower lagoon, and in the lagoon as a whole did not change significantly with the arrival or departure of excursion vessels in the lower lagoon. Unfortunately our sample size of paired days with and without disturbance was relatively small and, therefore, may not be sufficiently representative to allow the formulation of a conclusion regarding the short-term cause–effect relationship between the whales and whale-watching activities. Given the small sample size, caution should be used when interpreting these results as additional data will be required to fully evaluate the short-term significance of vessel disturbance on whales in the lagoon.

A very important consequence of the disruption of gray whales by whale-watching activities in the lagoon as a whole would be the potential for increased mortality of calves, either as the direct result of collisions with vessels or separation from their mothers, or as the indirect result of severe vessel-induced stress. Reeves (1977) speculated that whale-watching activity may cause calves to be separated from their mothers and possibly abandoned, which would result in the death of the abandoned calf. From our findings in Laguna San Ignacio, it does not appear that whale-watching activity has caused an increase in calf mortality. Calf mortality was highly consistent at four dead calves per year during five winters and five calves in one winter between 1977 and 1982. There was no indication that vessel activity contributed to any of these deaths. Additional evidence indicating that the effects of whale watching on calf mortality in Laguna San Ignacio must not be too severe is the finding that calf mortality in this lagoon was proportionately the same as calf mortality in three breeding areas not visited by significant numbers of whale-watching excursions.

There have been several studies in recent years which suggest that grays and other species of whales are able to accommodate to various kinds of human disturbance. Reeves (1977), who investigated the problem of whale harrassment at the breeding lagoons, stated that the continued high level use of Laguna Ojo de Liebre by gray whales following relocation of commercial salt shipping operations from Laguna Guerrero Negro to Laguna Ojo de Liebre after 1967, suggests that the movement of salt barges "may not be such a nuisance to them." Laguna Ojo de Liebre is, by far, the largest and perhaps the most important single breeding area of the gray whale, and Reeves contends that because it is a large area, "the whales there simply may have been able to 'move-over' and co-exist next to the barges." Based on his aerial surveys of this lagoon in the 1970s, Storro-Patterson (1981) agrees that the whale distribution in Laguna Ojo de Liebre seems to be only minimally effected by salt barge traffic. A similar apparent accomodation to vessel disturbance was reported by Fraker *et al.* (1982) who concluded that bowhead whales (*Balaena mysticetus*) did not permanently vacate areas where they had been exposed to short-term noise from seismic surveys, dredges, and vessel disturbance and that "flight" response seemed brief in duration and was usually followed by a return to normal activities. Watkins and Schevill (1979) reported that feeding humpback whales (*Megaptera novaeangliae*) were not disrupted by the passage of an oil tanker to within 800 m of the animals. Humpback whales wintering off Maui, Hawaii also appear to habituate to routine vessel traffic activity associated with the harbor (Darling, 1983).

On the other hand, although the current levels of whale-watching activity in Laguna San Ignacio do not appear to be having a detrimental effect on the demography of gray whales in this lagoon, there is some evidence from other geographical areas that gray whales and other mysticetes are sensitive to and may be displaced by human disturbance under different circumstances. For example, during the gray whales' recent recovery from depletion, their utilization of Laguna Guerrero Negro has varied widely (Storro-Patterson, 1981). By 1967, the evaporative salt works located in the town of Guerrero Negro was shipping approximately 3 million tons of salt per year out of the lagoon. Prior to the growth of the salt industry, Gard (1974) stated that the number of gray whales using Laguna Guerrero Negro had increased steadily during the 1950s. As salt-barge traffic and dredging activities increased with the growth of the salt industry, Gard's aerial counts of gray whales decreased to zero by 1964. Following the relocation of the salt works to Laguna Ojo de Liebre in 1967, salt shipping ceased in Laguna Guerrero Negro and counts of whales increased to 104 animals by 1973. Gard speculates that the "shipping of salt from this lagoon between 1957 and 1967 apparently drove out the whales, but they reinvaded the lagoon in substantial numbers after shipping was eliminated." In assessing the effects of human activities on the whales, however, it has been very difficult to determine whether salt shipping was entirely responsible for the whales abandonment of the lagoon. Concurrent dredging operations to maintain the channel of the lagoon, natural variations in water temperature or chemistry in the habitat, or biological changes within the population itself may have also contributed to the changes in lagoon use (Storro-Patterson, 1981). In the case of humpback whales, it has been proposed that the apparent sudden abandonment of Glacier Bay, Alaska, by humpback whales in 1978 may be due to a dramatic increase in whale watching and other fishing and recreational vessel traffic within the confines of the bay, suggesting that the whales' tolerance for vessel activity had been exceeded (U.S. Marine Mammal Commission, 1980; Baker *et al.*, 1982).

During the course of this study from 1978 to 1982 we have accrued no statistically significant evidence to substantiate the contention that whale watching has had a detrimental effect on the demography of gray whales in Laguna San Ignacio. However, it may well be that human activities in the lagoon, if they negatively impact the whales, do so in an indirect manner. For instance, the cumulative effects of continual exposure to increased water-borne noise, visual stimuli, restriction of space available to whales, or stress associated with vessels being in and passing through whale areas could have serious biological implications if, for example, gray whale reproductive fitness is reduced over the long term (U.S. Marine Mammal Commission, 1980). Studies of other species of large mammals suggest that stress may have distinct physiological and population effects (Geraci and St. Aubin, 1980; Eisenberg, 1981), and that significantly loud noise could mask important environmental noise and/or interfere with communication between whales (Davis *et al.*, 1983). Clearly, the degree to which the gray whale is affected over the long term by habitual exposure to human activities will require continuous evaluation of their abundance, distribution, and productivity. The breeding lagoons provide an excellent opportunity to continue to obtain this information.

In conclusion, to date, whale-watching activity in Laguna San Ignacio does not seem to pose a serious threat to the gray whales, but its potential for becoming one should be acknowledged so that future developments can be monitored carefully for the benefit of whales and for humans.

Friendly Whales

The apparent interest in human activities exhibited by friendly whales in Laguna San Ignacio confounds the argument that whale-watching activity harasses gray whales. The friendly whale phenomenon has also given rise to many important questions. For instance, if whale-watching activity is not benign and seriously disturbs gray whales, why has curious behavior developed? Why has this behavior persisted year after year? And, are recent reports of friendly whale behavior outside Laguna San Ignacio indicative of the spread of this behavior throughout the gray whale's range? The interaction involving calves is perhaps the single most astounding case, as calf participation contradicts most previous beliefs about maternal protection. Friendly mother gray whales seemingly do not perceive the interaction between the boats and their calves as a threatening situation.

Speculation as to why whales appear to demonstrate curiosity is widespread among the scientific and lay communities alike. In a letter to the editor of *Science Magazine*, Wolfson (1976) suggested that the present gray whale population, recovering from near depletion, and composed of primarily young animals, has never been severely harassed by the whaling industry, and therefore has never become conditioned to avoid boats.

Gilmore (1976) proposed that the whales are curious about the small boats that hover over them in the lagoons. He felt that continued exposure to boat noise has probably conditioned most gray whales to tolerate the vessels and has encouraged some whales to approach and even explore whale-watching skiffs.

Storro-Patterson (1981) commented that this behavior may be the result of the method of whale-watching employed by the skiff operators in the lagoon. In his opinion, the skiff operators do not forcefully pursue the whales, but instead "almost seem to 'tease' the whales by refusing to follow them for more than 20–50 yards. They move at very slow speeds or stay in one place waiting, but always with the motor running, often in neutral."

Finally, it is widely accepted that the acoustical sense of cetaceans is their most important sensory process, and we believe that gray whales are initially attracted to some sounds of the outboard engines. They appear to show an interest in the submerged portion of the outboard engine running in neutral, such as the nonrevolving propeller and exhaust ports from which sound emanates. Some whales repeatedly bumped the still propeller of the engine with their rostrum and even took it into their open mouth. The whales avoided Mexican fishing boats with 40-hp engines running at high speed. However, they approached and even followed 20-hp engines running at moderate or low speed. Curious whales usually left the vicinity of idling outboard engines when they were shut down, and they also avoided nonmotorized vessels including kayaks, canoes, and small sail boats. Many of the sounds from gray whales fall within the frequency range of slow-running (or idling) outboard engines (Swartz and Cummings, 1978; Chapter 22, this volume). We agree with Dahlheim *et al.* (Chapter 22, this volume) that in addition to engine sounds, other factors may be involved in maintaining the friendly behavior once the whales physically contact the boat. We suspect that tactile stimulation from rubbing against the boat and from the "strokes" of the passengers act in concert with engine sounds and other stimuli to reinforce curious behavior over the long term.

To determine whether gray whales had displayed this behavior before the 1975–1976 reports from Laguna San Ignacio, we and our assistant Mike Bursk searched the literature and spoke to individuals that had worked in the breeding lagoons prior to 1975. There were no reports of friendly whale behavior in the literature prior to 1975, and investigators that had studied gray whales in the lagoons had not experienced these animals (R. M. Gilmore, C. L. Hubbs, K. S. Norris, T. J. Walker, and others, personal communications). At the San Diego Natural History Museum, we found a chart of Laguna Ojo de Liebre made by Jim Mills, a Santa Barbara Pharmacist. The chart, dated in the early 1960s, noted "curious and friendly whales" in the lagoon. Captain Bill Lang, an excursion vessel operator, spoke of a few experiences with curious gray whales while running whale-watching trips to Laguna Ojo de Liebre in the late 1960s. Captain Lang recalled that small whales lingered behind the excursion vessel, apparently inspecting the empty skiffs tied astern. And, occasionally whales approached the skiffs filled with whale watchers, as they cruised about in the lagoon (Swartz and Bursk, 1979). But, at this time, gray whales were not to be trusted. From the days of commercial whaling, the whales, particularly females with calves, held a notorious reputation for inflicting violent attacks on pursuers. The name "devilfish" was well earned; and, consequently, close contact with whales was avoided. Perhaps the forerunners of friendly whales were in

Laguna Ojo de Liebre, but cautious skiff operators were hesitant to let any whale get too close to his skiff full of passengers.

With the closing of Laguna Ojo de Liebre, attention focused on Laguna San Ignacio as the prime whale-watching location. Because Laguna Ojo de Liebre was closer and easily accessible for U.S.-based excursions operators, Laguna San Ignacio had received few visitors; thus, we found no records of past expeditions. We spoke to the residents of La Laguna, a San Ignacio fishing village, and none were familiar with friendly whales. However, for these people any whale encounter was unlikely because the local fishermen avoid all contact with them. When traveling across the lagoon, the fishermen usually motor their pongas over sand bars to minimize the risk of colliding with a whale. While crossing deep channels, they pound on the hulls of their boats and sing loudly as if to alert the whales (Swartz and Bursk, 1979). The first bonafide reports of friendly whales in Laguna San Ignacio, then, were the encounters during the 1975–1976 winter.

In summary, the phenomenon of friendly gray whales in Laguna San Ignacio between 1975 and 1982 suggests that not all interactions with boats are necessarily disturbing to the whales. The bottom line that virtually all whale watchers have agreeded upon is that whether or not a whale exhibits curious behavior is entirely up to the animal; in other words, friendly whales find you, you don't find them. The educational, recreational, and economic importance of carefully controlled whale-watching activities is evident; however, the observation that grays occasionally jostle boats or appear to act rambunctiously (Swartz and Jones, 1981) signifies that there can be some degree of potential threat to humans as well as harassment of whales. As noted by Baker *et al.* (1982), the increased incidence of "jostling" of boats by gray whales "may indicate aggressive behavior or may only reflect the actions of the laws of probability: that accidental contact is increasingly more likely with increased human use of the whale habitat." In any event, it is imperative that the whale-watching community be reminded that gray whales are wild and immensely powerful animals and need to be treated with great caution.

Acknowledgments

Field research on free-ranging cetaceans and the analysis of the results requires the help of many hands and many minds for long periods. We were exceptionally fortunate to have had the assistance of many talented people and agencies throughout this project. In particular we wish to thank our full-time field assistants (in order of appearance) Mike Bursk, Gayle Dana, Debbie Miller, Dennis Miller, Bruce Reitherman, Jim Sumich, and Mike Symons. Special thanks are due the Mexican biologists Geriminal Marcet, Carlos Maya, and Ricardo Sanchez who participated in the study. We wish to offer our sincere appreciation to Raymond M. Gilmore of the San Diego Society of Natural History and to Laura and Carl Hubbs of Scripps Institution of Oceanography for sharing their extensive knowledge of gray whales in the breeding lagoons and for their continuous and enthusiastic support of this study. Scientific research permits were issued by the Secretaria de Pesca de Mexico. The work was funded by the American Cetacean Society, Hubbs–Sea World Research Institute, the International Union for the Conservation of Nature, the International Whaling Commission, the Committee for Research and Exploration of the National Geographic Society, the National Marine Mammal Laboratory of the National Marine Fisheries Service, the U.S. Marine Mammal Commission, and the World Wildlife Fund—U.S. Cetacean Research Associates of San Diego, California administrated this program. Our heartfelt thanks to all.

Gray Whale (*Eschrichtius robustus*) Calf Production and Mortality in the Winter Range

Steven L. Swartz and Mary Lou Jones

Cetacean Research Associates, 1592 Sunset Cliffs Boulevard, San Diego, California 92107

ABSTRACT

Annual gray whale (*Eschrichtius robustus*) calf production and mortality were empirically estimated from data collected in Laguna Guerrero Negro, Laguna Ojo de Liebre, and Laguna San Ignacio, Baja California Sur, Mexico between 1980 and 1982. A gross annual production of 1,185 calves with a 5.4% mortality based on lagoon strandings yielded a net production of 1,121 calves. This represents a 7.0% annual rate of production based on the best estimate of the current population size of 15,942 gray whales. By comparison, the proportion of calves passing Pt. Piedras Blancas, California in 1980 and 1981 was 4.3% (679) and 4.8% (769) respectively, suggesting a 31% calf decrease may occur between the lagoons and central California. Two periods critical to calf survival are postulated; the first period immediately follows birth, and the second corresponds to the calves departure from the lagoons and the beginning of the northward migration.

INTRODUCTION

Empirical data on calf production and mortality are not available for most cetacean species. Recent studies within the breeding and calving lagoons, and along the migratory route of the gray whale (*Eschrichtius robustus*) provide an opportunity to examine newborn calf gross production, mortality, and net calf production during the winter breeding season. This information is useful for analyzing gray whale population growth and recovery from depletion, and it may be useful in understanding other depleted cetacean populations. This paper will:

1. Estimate maximum theoretical calf production based on current gray whale population estimates, proportion of breeding females in the population, and pregnancy rates.
2. Examine empirical data on gray whale calf production and calf mortality in breeding lagoons.
3. Compare observed net calf production within lagoons with calf population estimates from shore counts of the northward spring migration.

ESTIMATED MAXIMUM ANNUAL GRAY WHALE CALF PRODUCTION

Population estimates for gray whales based on shore censuses of the fall migration at Monterey, California between 1968 and 1981 indicated an annual 2.25% rate of increase (Reilly *et al.*, 1980a). The 'best estimate' from a regression of thirteen annual counts was 15,587 for 1980 (Reilly *et al.*, 1980b), and at the above rate of increase would be 15,942 in 1981 and 16,304 in 1982. Additional studies supporting population estimates of this size include an age structured simulation of gray whale population history using Monterey data which yielded a 1980 population of 15,400 (Reilly, 1981), and two years of shore censuses of the northward migration from Pt. Piedras Blancas, California resulting in population estimates of 15,725 for 1980 and 16,140 in 1981 (Poole, 1981). These population size estimates are further supported by earlier independent estimates of 14,400 for 1976 (Hall, 1977), and 15,099 for 1977 (Rugh and Braham, 1979) from fall counts of southward migrating gray whales passing through Unimak Pass, Alaska.

Rice and Wolman (1971) proposed that the maximum theoretical rate of gray whale calf production was 12.8% based on an equal sex ratio (50:50), an adult breeding proportion of 56%, and an annual female pregnancy rate of 46%. Based on the current population estimates given above (Reilly *et al.*, 1980b), the maximum expected number of calves produced assuming a 12.8% rate of increase would be 2,072 for 1981, and 2,119 for 1982.

CALF COUNTS IN THE BREEDING LAGOONS

Gray whales give birth during a 66 day period approximately from 26 December to 1 March (Jones and Swartz, 1983) with a mean birth date of 27 January (Rice *et al.*, 1982). Evidence supporting this proposed calving period comes from studies of the passage of southbound late-pregnant females past San Francisco, California in December and January (Rice and Wolman, 1971), the peak counts of cow/calf pairs in Laguna Ojo de Liebre (Rice *et al.*, 1982) and Laguna Guerrero Negro (Bryant and Lafferty, 1983), and the range of birth dates observed in Laguna San Ignacio (Jones and Swartz, 1983). In Laguna San Ignacio the number of cow/calf pairs counted continued to increase after mid-February. This increase did not include newborn calves; rather, these calves were judged by their size, coloration, and extent of barnacle encrustation to be 1–2 months old and presumably emigrated from areas outside Laguna San Ignacio (Swartz and Jones, 1980; 1981; Jones and Swartz, 1983). Annual calving, then, appears to be near completion by mid-February, and calf counts made during this period would best represent gross calf production in each respective lagoon or coastal area.

Aerial surveys in the breeding lagoons and along the near-shore waters of Baja California, Mexico tend to underestimate abundance of gray whale calves when compared to simultaneous vessel surveys (Fleischer, 1980; Bryant and Lafferty, 1980; Rice *et al.*, 1982; Swartz and Jones, 1981; Storro-Patterson, 1982). Results of aerial surveys by various researchers, although available, are difficult to compare because of differences in survey dates, aircraft census techniques, and environmental sea state. Vessel surveys utilizing the same techniques were conducted in mid-February for three seasons in Laguna Guerrero Negro (Bryant and Lafferty, 1980, 1983), one season in Laguna Ojo de Liebre (Rice *et al.*, 1982), and for three seasons Laguna San Ignacio (Swartz and Jones, 1980; 1981; Jones and Swartz, 1983); therefore, we have elected to use only the results of vessel surveys in the following analysis. These surveys were limited to lagoon interiors because high surf conditions preclude vessel surveys of lagoon inlets and adjacent near-shore waters even though these areas are utilized by a significant proportion of whales throughout the winter (Swartz and Jones, 1980; Storro-Patterson, 1982; and Norris *et al.*, 1983).

The number of calves counted during vessel surveys, and the number of dead calves discovered in the three breeding lagoons of Laguna Guerrero Negro, Laguna Ojo de Liebre, and Laguna San Ignacio between 1980 and 1982 are summarized in Table 1. The average mid-February calf count in Laguna Guerrero Negro was 129.7. This number of calves, combined with the average of 3.3 dead calves/year, suggests an average annual gross calf production of 133 individuals. Similarly, for Laguna San Ignacio, an average count of 132 calves/year plus four dead calves/year yields an annual gross calf production of 136 animals. Data are available for only one season in Laguna Ojo de Liebre: in 1980 557 calves were counted in mid-February, 12–16 dead calves counted within the lagoon and 23 stranded on the ocean side of the barrier island. This makes an annual gross production at Laguna Ojo de Liebre of 573 if 16 dead calves are added to the 557 living calves counted.

There was no significant difference in the yearly stranded calf and calf counts for Laguna Guerrero Negro, Laguna Ojo de Liebre, and Laguna San Ignacio (chi-square = 0.148, p = 0.9287); thus, these data from within the lagoons were combined to yield a grand average mid-February calf count of 818.7, an average stranded calf count of 23.3, which give a combined gross calf production of 842 calves. Because bloated calf carcasses are known to move about and even out of lagoon interiors with the winds and tides (Swartz and Jones, 1978; Rice *et al.*, 1982), we strongly suspect that 23 calves found stranded on the beach between Laguna Guerrero Negro and Laguna Ojo de Liebre belonged to this lagoon system. If these 23 calves are not included, calf mortality and gross production would be underestimated. Adding these calves to the combined totals the gross calf production becomes 842 + 23 = 865 calves for all three lagoons.

LAGOON CALF MORTALITY RATE

Minimum calf mortality may be estimated from the number of dead calves discovered divided by the estimated gross annual calf production. The combined annual mortality for all three lagoons (Laguna Guerrero Negro, Laguna Ojo de Liebre, and Laguna San Ignacio) of 23.3 calves divided by the total estimated gross production of 842 gives an annual lagoon calf mortality rate of 2.8% (Table 1). If the 23 calves found stranded outside of Laguna Guerrero Negro and Laguna Ojo de Liebre are included, the mortality rate becomes 46.3/865 = 5.4%.

ESTIMATED TOTAL ANNUAL CALF PRODUCTION

Aerial surveys by Rice *et al.* (1982) examined major gray whale calving areas and ranked them by the proportion of the total calves counted within each area. These surveys were conducted in mid-February using the same observers and were flown during sea states of Beaufort No. 3 or less, at a constant altitude and air speed. We assume that the bias toward underestimation of calf abundance (as discussed earlier) was uniform during all surveys and the proportions of calves counted in each area are good estimates of actual distributions. The results of these surveys suggest that Laguna Guerrero Negro contained 9%, Laguna Ojo de Liebre 53%, and Laguna San Ignacio 11% of all the calves born that year, or 73% of all the calves produced in a given year. The remaining 27% of the calves were in the Bahia Magdalena lagoon complex and along the Pacific coast of the Baja Peninsula.

If the rates of production and mortality are

Table 1

Gray whale mortality and production in three breeding/calving lagoons between 1980 and 1982.

Lagoon	Year	Stranded calves	Mid-Feb. calf counts	Gross calf production	Mortality rate
Guerrero Negro	1980	4	115	119	0.034
	1981	4	161	165	0.024
	1982	2	113	115	0.017
Average		3.3	129.7	133	0.025
Ojo de Liebre	1980	16	557	573	0.029
Outer Beach LGN & LOL	1980	23	—	—	—
San Ignacio	1980	4	119	123	0.033
	1981	4	140	144	0.028
	1982	4	137	141	0.028
Average		4	132	136	0.029
Grand average (all 3 lagoons)		23.3	818.7	842	0.028
Grand average (including outer beach count)		46.3	818.7	865	0.054

equivalent for all the breeding/calving areas, including Bahia Magdalena and the coastline between lagoons, then the total expected gray whale gross calf production extrapolated from the above proportions would be 865/0.73 = 1,185 calves. The expected total annual calf mortality would be 5.4% of the total gross production, or approximately 64 calves. Thus, the net annual production would be 818.7/0.73 = 1,121 calves.

CALF ABUNDANCE ESTIMATES FROM MIGRATION COUNTS

The 1981 population estimate of 15,942 gray whales (Reilly *et al.*, 1980b) and the estimated net lagoon production of 1,121 calves generated above combine to suggest a 7% annual rate of production, compared with the theoretical maximum rate of 12.8% calculated by Rice and Wolman (1971) (Table 2).

Proportions of calves to adults observed during two short censuses of the spring northward migration are available for comparison with the estimated net annual lagoon production. Poole (1981) utilized Reilly's (1981) model to estimate that 15,725 gray whales passed Pt. Piedras Blancas, California in 1980, and 16,140 passed in 1981; of these 679 (4.3%) in 1980, and 769 (4.8%) in 1981 were calves. The difference between Poole's 1981 calf abundance estimate and the estimated annual net calf production (1,121 − 769 = 352) suggests a calf attrition or loss of up to 31% between the lagoons and central California.

A calf loss of 31% may be the result of an underestimate of northward migrating whales; however, Poole's gray whale population estimates of 15,725 for 1980 and 16,140 for 1981 agree with other independent estimates (Hall, 1977; Rugh and Braham, 1979; Reilly, 1981), and the increase between both years of 415 whales (2.6%) is consistent with the 2.25% annual rate of increase established for gray whales (Reilly *et al.*, 1980a). Unfortunately, estimates of the variance of these calf estimates are not available. Poole states that during the period corresponding to the northward spring migration of cow/calf pairs (from mid-April to the end of May), of 1,790 whales passing Piedras Blancas 264 (15%) were not cow/calf pairs, but may have been postpartum females that had lost their calves. These whales were almost always observed travelling in the presence of a cow/calf pair rather than alone.

If we add 264 to Poole's 1981 estimate of 769 calves to compensate for females that presumably lost their calves, we can account for 1,033 calves which is within 88 calves (8%) of our estimated net annual lagoon production of 1,121. This corroborates our estimated 31% loss rate of calves. If the missing calves do not die but disperse below central California, we would expect approximately 352 gray whales per year to be detected somewhere in the southern range. Except for two verified sightings of gray whale calves unattended by adults off Isla Guadalupe, Baja California, Mexico in April of 1973 and June of 1974 (Leatherwood, pers. comm.), a 13 meter long gray whale in Bahia de San Quintin, Baja California Norte in July 1977 (Aguayo, 1980), and a handful of unsubstantiated reports over the past 15 years, there is no evidence that gray whales in the numbers calculated above remain in the southern range.

DISCUSSION

The best available data suggest approximately 5.4% of the gray whale calves produced annually die within the breeding/calving lagoon areas and that an additional 31% decrease (presumed mortality) of the net lagoon production occurs during the first leg of their northward migration before reaching central California.

The strength of this analysis lies in the accuracy of data from the lagoons and the abundance estimates extrapolated from shore-based migration counts. Estimates of lagoon calf production and mortality are minimum estimates based on counts of cow/calf pairs and of dead calves found within the lagoons during the same time periods. Estimates of calves migrating past central California and estimates of gray whale population size are extrapolated from daytime shore-based counts corrected for whales missed due to poor visibility, whales missed before the first and following the last day of the census, whales that passed during the night time, and whales not sighted as a function of their distance from shore (Reilly *et al.*, 1980b). Although the majority of cow/calf pair sightings are well inshore, we cannot discount the possibility that a few pairs may migrate offshore beyond the sight of coastal census stations. Between 1969 and 1972 Leatherwood (1974) reports five cow/calf pairs migrated northward offshore through the Southern California bight. Similarly, in his 1982 aerial survey off central California, Poole (In Press) observed one cow/calf pair (4%, n = 24) 10.4 km offshore, while all other pairs sighted were within 1.2 km of the beach.

Evidence exists that the tail-end of the cow/calf northward migration may not have passed central California when Poole ceased his observations at the end of May. J. Harvey and B. R. Mate (pers. comm.)[1] reported 25 to 35 cow/calf pairs remained in Laguna San Ignacio and an unknown number were outside the lagoon inlet in the breakers on 26 April 1980. Throughout April and May sportfishing vessel operators sailing between San Diego and Baja California Sur report sightings of gray whale females with their calves moving northerly along kelpbeds and up to a few kilometers offshore (pers. comms)[2]. Storro-Patterson (1982) reports a few females and their calves remain at the lagoon inlets into May, and local

Table 2

Summary of gray whale calf production estimates based on the 1981 population estimate of 15,942 whales (Reilly, 1980b).

		No. calves	Source
Maximum theoretical rate of production	0.128	2,072	Rice & Wolman, 1971
Observed net production in lagoons	0.07	1,121	This paper
Pt. Piedras Blancas estimate	0.043 (1980)	679	Poole, 1982
	0.048 (1981)	769	

Mexican fishermen (pers. comms)[3] indicate gray whales may be found outside the lagoons as late as early June of some years. These observations imply that an unknown number of cow/calf pairs were not included in the central California abundance estimate, and if included they would reduce the disparity between estimated lagoon calf production and estimated calf abundance during the migration.

The frequency of dead gray whale calves found in the lagoons and the apparent loss of calves between the lagoons and central California suggest that two periods critical to the survival of calves occur during the first few months of a gray whale's life. The first period includes birth and the time immediately following birth. The physical appearance and condition of stranded gray whale calves examined in the lagoons indicate some are under-sized and may have been stillborn, while others drowned during birth or died within a few days after birth (Rice and Wolman, 1971; Rice *et al.*, 1981; Jones and Swartz, 1983). Because the gray whale population is recovering from very low levels, we would expect it to include a higher proportion of young females (perhaps first time mothers) than when the population reaches a stable age distribution, and that these females may not be as successful at reproducing as older females that have bred previously. Dead newborn calves are discovered throughout the birthing period (26 December to 1 March), but they are found only infrequently later in the season, suggesting that the probability of dying is greatest just after birth and decreases with time.

The second critical period of calf mortality would correspond to the cow/calf pairs' departure from the lagoon areas and their northward migration. It is reasonable to think some calves are unable to withstand the rigors of coastal migration, fall prey to sharks and killer whales (*Orcinus orca*), or become lost, disoriented, and ultimately separated from their mothers prior to weaning. Killer whale harassment of gray whales is well documented (Rice and Wolman, 1971; Baldridge, 1972; Poole, 1982; Norris, pers. comm.) and probably contributes significantly to the deaths of very young gray whales. Calves of the year comprised 43% of 97 gray whale strandings reported along their migratory route between 1950 and 1981, suggesting that calves die in significantly higher proportion to other gray whale age classes (Jones and Swartz, 1983).

In the present context, caution must be used in drawing strong conclusions about gray whale calf mortality and production in the breeding/calving lagoons because the data are incomplete as follows:

1. Estimates of the variance of the calf estimates from shore censuses, the variance of the population rate of increase, and the variance for the estimated lagoon calf production are not available and are necessary to assess the significance of these numbers.
2. Not all dead whales are discovered; some carcasses strand on beaches not visited by investigators, are lost at sea, or are consumed by scavengers. These data tend to underestimate mortality.
3. Not all calves born each year are detected; census counts represent minimum estimates of annual gross calf production. These data tend to underestimate calf production.
4. Census counts from different sites made at different times and seasons cannot be assumed to be independent; there may be mixing of gray whales (and calves) between lagoons, particularly just prior to northward migration. Census data should be collected simultaneously from all areas to be compared.
5. Lagoon censuses do not include the near-shore waters adjacent to lagoon inlets. These areas are utilized extensively by significant numbers of whales throughout the breeding season (Swartz and Jones, 1980; Norris *et al.*, 1983). Additional cow/calf pairs counted outside the lagoons would decrease the mortality rate but consequently increase the discrepancy between observed net calf production within lagoon areas and calf population estimates from shore counts of the northward migration.
6. Data are not available for all birthing areas; however, we must assume the rate of production and mortality observed in the three lagoons studied is representative of all areas. Additional data from these and other areas is needed.

ACKNOWLEDGEMENTS

We are grateful to David Bain, Jeffery M. Breiwick, Steven G. Hoffman, J. Stephen Leatherwood, Edward D. Mitchell, Kenneth S. Norris, Stephen B. Reilly, Dale W. Rice, Dave R. Rugh, and Dave Withrow for their advice, encouragement, and review of this manuscript.

GRAY WHALE MORTALITY AT OJO DE LIEBRE AND GUERRERO NEGRO LAGOONS, BAJA CALIFORNIA SUR, MEXICO: 1984–1995

Gray whales migrate annually from their northern feeding grounds in the Bering and Chukchi Seas to their winter breeding and calving grounds along the coast of Baja California, Mexico. Swartz and Jones (1983) estimated that 5.4% of gray whale calves of the year die near or in the lagoons, and an additional 31% of calf mortality occurs by the time they reach central California in the first part of their northward migration. This increase in calf mortality outside the lagoons emphasizes the apparent advantage of the coastal lagoon habitats to reproductive success of this species. Calf survival may be enhanced by the combination of factors found in the breeding and calving lagoons (Rice and Wolman 1971, Jones and Swartz 1984, Sanchez 1991).

The objectives of this study were to (1) identify stranding locations within and adjacent to the lagoons, (2) determine periods of peak mortality during the winter reproductive season, (3) determine the sex ratio of stranded whales, (4) determine the age and sex class of stranded whales, and (5) identify and describe key factors that may influence the mortality of gray whales in and adjacent to the lagoons.

The outer coasts from the southern end of the entrance to Ojo de Liebre Lagoon north along Arena Island to the northernmost portion of Manuela Lagoon were surveyed each winter from 1984 to 1995 except for 1986 and 1994. We photographed, measured, sexed and noted the location of each dead whale encountered. In addition, we estimated date of death from the state of the decomposing carcass, location on the shore, and time elapsed since our previous search. Any unique markings or scars were noted. Each carcass was marked with a line tied around a flipper to prevent double counting.

A total of 191 whales were found. Length was determined for 176 whales, sex was determined for 146, and time of death was estimated for 117.

The southwest coast of Arena Island had the highest incidence (34%) of stranded dead whales (Fig. 1). Interactions among ocean currents, prevailing northwest winds, and tidal flow into and out of the lagoon are likely responsible for depositing floating carcasses in the area. Similar abundance of stranded whales at this same location was noted by Rice *et al.* (1981). These authors

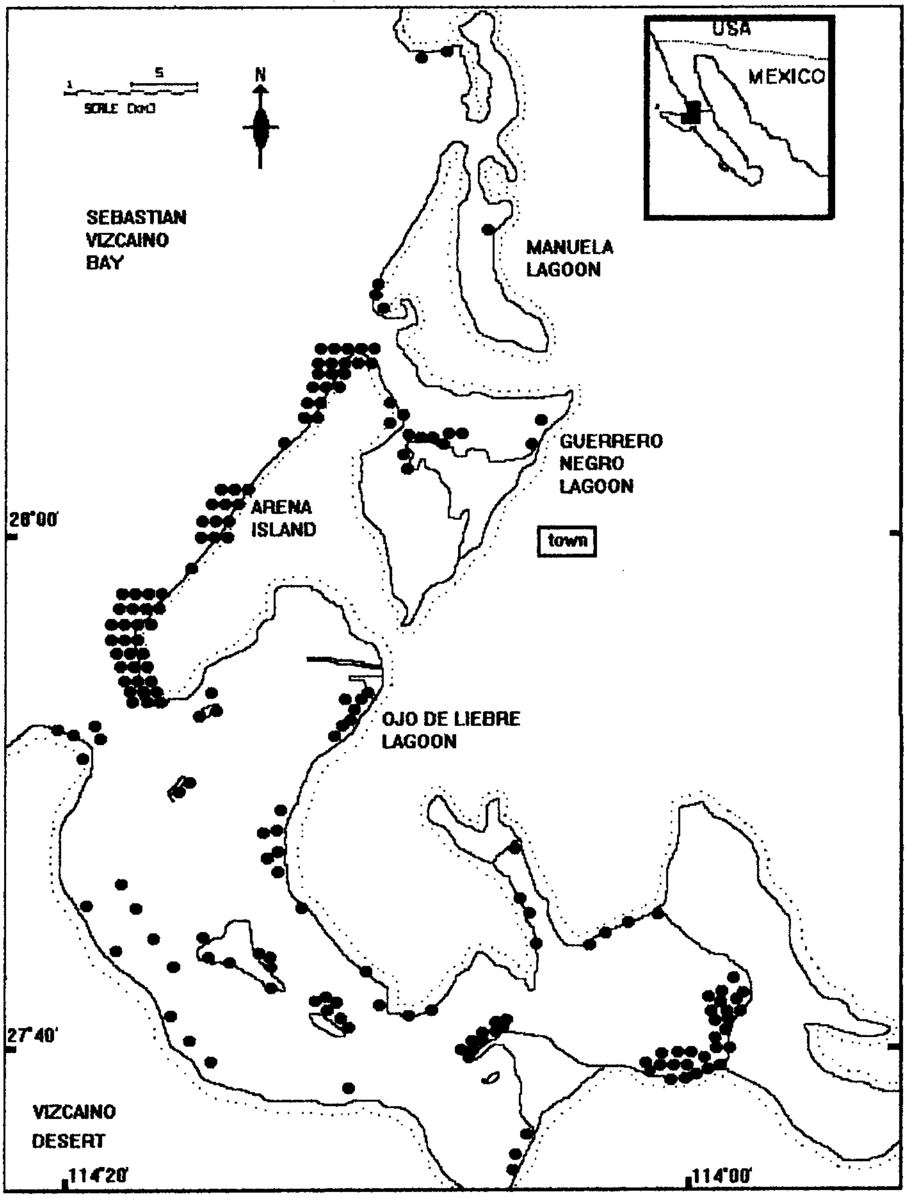

Figure 1. Stranding locations of gray whales (1984–1995).

stated that it could not be determined if calves found on this outer beach died inside or outside the lagoon. As they suggest, if the latter were true, it would support the contention that the lagoon interior offers conditions that contribute to increased survival of neonates.

The earliest calves of the season were observed in Ojo de Liebre and Guerrero Negro Lagoons on 27 December. The earliest that dead newborn calves

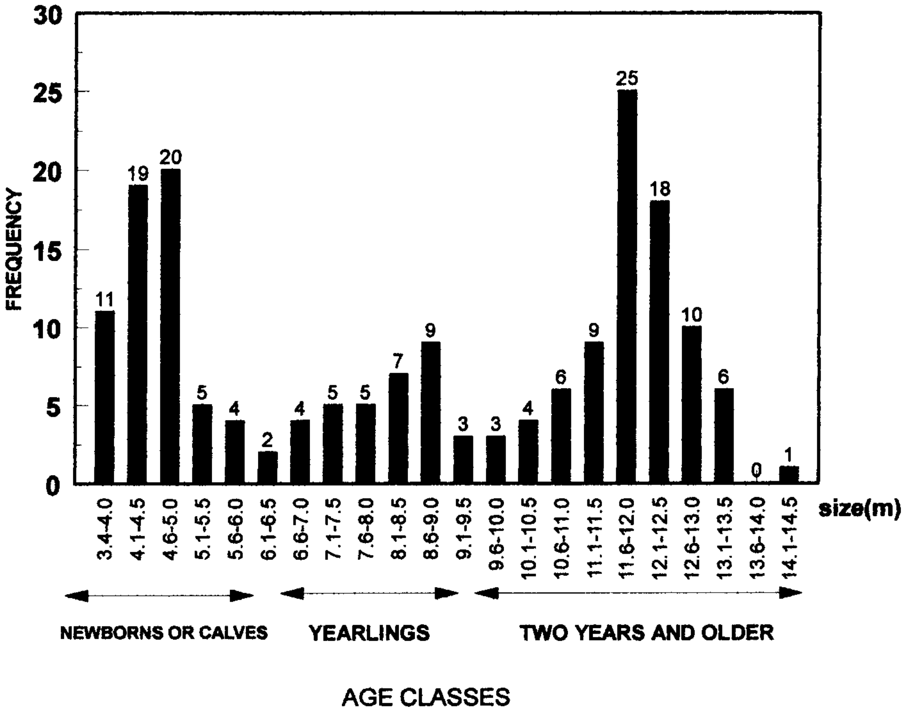

Figure 2. Size frequency of dead gray whales at Ojo de Liebre and Guerrero Negro Lagoons (1984–1995).

were found was 4 January and the latest was 9 March. This range of dates suggests a calving season of 73 d. Mean mortality date for calves was estimated at 2 February ($n = 39$, SD = 14.9), which is approximately one week later than the mean birth date of 26 January described by Rice (1983).

Fifty percent of the calves found were estimated to have died between 24 January and 10 February, and 77% between 15 January and 15 February. After the first half of February, the number of dead calves discovered declined, which suggests a higher survival rate for calves older than two weeks and/or a decline in the number of births during this period.

Only six calves between 5.6 and 6.2 m long were found. Sumich (1986) predicted a mean length of 5.69 m (range 5.35–6.03 m) at three months. This could mean that at this size/age range, calves leave the area or that survival chances are better so that fewer, more mature calves are found dead.

We found that 44.8% of whales larger than 6.0 m died between 1 and 28 February. The average mortality date for these whales was estimated at 15 February ($n = 78$, SD = 22.0), which is close to the peak of whale abundance in Ojo de Liebre Lagoon of 12 February reported by Rice *et al.* (1981) and Sanchez (1991).

The stranded whales can be divided into three size/age classes based on the frequency distribution of their lengths (Fig. 2). As Sumich (1986) proposed, the first class can be delimited by the low frequency of stranded whales measuring 6.1–6.5 m, which appears to separate the calf and yearling age classes. The average size of newborn calves was 4.63 m (n = 61, SD = 0.62, range 3.4–6.2 m). Our results are similar to the average calf length reported by Jones and Swartz (1984) (4.47 m), Rice (1983) (4.57 m), and Sumich (1986) (4.58 m). Whales measuring 3.4–6.5 m accounted for 34.6% of all the stranded whales measured. This supports the findings of Swartz and Jones (1983) and Sumich and Harvey (1986) that the most critical survival period with the highest calf mortality rate occurs during the first few weeks following birth.

Determining the limits for whales in the second size/age class was more difficult. Jones and Swartz (1984) observed, based on the growth rate of symbiotic barnacles in the breeding lagoons, that gray whale calves do not display adult barnacles during the season in which they are born, and it is only after at least one year that adult barnacles are observed on whales. The smallest stranded whale observed in this study with barnacles was 7.3 m long. We used this individual to set the lower size limit for this age class. The upper size limit for this class was set at 9.5 based on the low frequency of individuals between 9.1 and 10.0 m (Fig. 2). Whales measuring 6.6–9.5 m were considered yearlings. This age class had a mean length of 8.13 m (n = 33, SD = 0.82) which corresponds to other published ranges for yearlings by Jones and Swartz (1984) (9.0–10.0 m), Rice *et al.* (1981) (8.2–9.6 m) and Sumich (1986) (8.0 m). Whales in this size class accounted for 18.7% of all stranded whales measured.

The third size class includes whales larger than 9.6 m, which were all estimated to be two years and older. Mean length for whales in this class was 11.94 m (n = 82, SD = 0.86). Whales of this size class represented 46.5% of all stranded whales measured, compared to only 2.5% reported for San Ignacio Lagoon between 1977 and 1982 (Jones and Swartz 1984). Prior to 1988 it was rare to find a stranded whale longer than 9.0 m in the study area, but in 1990, 1991, and 1992, 79.5% of the stranded whales were 9.6 m long or longer (Table 1). The predominance of larger whales during this period follows an event during the 1989 winter in which an unusually large number of gray whales was observed inside the Gulf of California and as many as 54 whales, including a calf, were seen in Bahia de La Paz, Baja California Sur (Fleischer and Maravilla 1990).

Differences in the average lengths between female and male neonates and yearlings (Table 2) were not statistically significant (t-test; α = 0.05). For whales estimated to be two years and older, females were significantly longer (34 cm on average). This supports the conclusions of Rice and Wolman (1971) who found that female gray whales overall are longer than males.

The 1:1.3 ratio (61 to 84) of stranded females to males suggests that females have a higher probability of surviving in these areas or that males were more abundant than females in certain years, as was found in 1990, 1991, and 1992 (22 females, 55 males). This difference is particularly noticeable for stranded whales of the third size category ($\leq$ 9.6 m), where the female to male ratio was 1:2.1 (25 to 52).

The stomach contents of three stranded adult gray whales were examined. The first was from a whale longer than 7.0 m, believed to be a male. The stomach contained about 3 kg of pebbles averaging 0.6 cm in diameter. Other than a reddish paste, no evidence of animal or plant material was contained in the stomach. The second stomach examined was from a 13.3-m female and was essentially empty except for some fragments of eel grass and a gray-green liquid. The intestines contained a dark gray paste in the anterior portion. The third stomach examined was from a 12.4-m female; it contained only small amounts of a dark greenish paste. These findings are consistent with the conclusion of Rice and Wolman (1971) that feeding does not occur on the winter breeding grounds.

Although it was not possible to determine the exact cause of death for the stranded whales, we observed some activities that could have contributed to their mortality. Calves were often observed being severely struck by adult whales that were involved in mating groups, and these blows could have resulted in fatalities. It is also possible that calves may become separated from their mothers by males, strong currents, or vessels and, once separated, become disoriented, exhausted, and die. In 1985 we observed a probable yearling (8.75 m) in Guerrero Negro Lagoon that appeared to be disoriented and unable to

2 yr and older	25	12.16	1.07	52	11.81	0.64

find the channel to the lagoon entrance. It was observed on several occasions about to strand and was finally found dead along the shore. Five of the stranded whales examined had distinct shark bites, but none of these appeared severe enough to cause injury to vital areas or death. It is more likely that sharks feed on the carcasses before they strand, as suggested by Eberhardt and Norris (1964). With regard to human activities, one stranded whale had propeller cuts deep enough to cause severe bleeding and perhaps death. Three whales exhibited rope scars on their caudal peduncles, and one whale had an entire fishing net wrapped around it.

Three of the stranded calves were discovered alive, but two of these were later found dead from undetermined causes within 5 and 30 h from stranding, respectively. The third was pushed into deep water and was not seen again.

ACKNOWLEDGMENTS

Judith Llampallas, Marcelino Agüero, and Fernando Hool provided assistance in the field. Antonio Aviles (former director of C.E.T. del Mar) provided field equipment. Marilyn Dahlheim, Steven Swartz, and Bruce Mate provided encouragement and comments on the draft manuscript. Sergio Flores and Jose de la Cruz helped with the statistical analyses. Exportadora de Sal, S.A. of Guerrero Negro, and especially the Director Sr. Juan Bremer, provided support in the field and equipment. This research was conducted in coordination with and support from the Secretaria de Desarrollo Urbano y Ecologia, Secretaria de Desarrollo Social, Delegacion Baja California Sur as part of the gray whale research program of the "Reserva de la Biosfera El Vizcaino."

LONG-TERM ASSOCIATION OF AN INDIVIDUAL LONG-FINNED PILOT WHALE AND ATLANTIC WHITE-SIDED DOLPHINS

Multispecies associations range from congeneric to interordinal and occur across a wide range of taxa. They have been described for numerous mammalian species, including cetaceans (references below). The nature of these associations is not always clear, and they may be of temporal or spatial happenstance without direct interaction, or more dynamic with direct interactions and coordinated activities. Although they typically involve groups of individuals from the associating species, occasionally a single animal will join a group of heterospecifics. Most multispecies associations appear to be relatively brief, and associations across years are quite rare. Bearzi (in press) reported seeing the same common dolphin (*Delphinus delphis*) with bottlenose dolphins (*Tursiops truncatus*) in two different years, and M. Poole (personal communication) has observed an individual spinner dolphin (*Stenella longirostris*) with bottlenose dolphins over four years. There are no other documented accounts of relationships of such duration. The association described here, of an individually identified long-finned pilot whale (*Globicephala melas*) with Atlantic white-sided dolphins (*Lagenorhynchus acutus*) over six consecutive years is thus highly unusual.

On twelve days between 1991 and 1996, a single long-finned pilot whale was observed 16 times with variably sized groups of Atlantic white-sided dolphins. Two of these days (13 June 1992 and 22 September 1993) included multiple sightings over several hours. Fourteen of the sightings were off the Massachusetts coast in the southern Gulf of Maine and one (4 July 1993) was in the northern Gulf of Maine, approximately 20 nautical miles east of Mt. Desert Rock, Maine (Table 1). No other pilot whales were observed in the vicinity of any of these encounters. The pilot whale was photographed in each case. GRAY WHALES BORN NORTH OF MEXICO: INDICATOR OF RECOVERY OR CONSEQUENCE OF REGIME SHIFT?

KIM E. W. SHELDEN,[1,3] DAVID J. RUGH,[1] AND ALISA SCHULMAN-JANIGER[2]

[1]*National Marine Mammal Laboratory, Alaska Fisheries Science Center, NOAA, 7600 Sand Point Way NE, Seattle, Washington 98115-6349 USA*
[2]*American Cetacean Society, Los Angeles Chapter, P.O. Box 1208, San Pedro, California 90733-1208 USA*

Abstract. Every winter, most gray whales (*Eschrichtius robustus*) of the eastern North Pacific stock migrate from feeding areas in the Arctic to warm, shallow lagoons in Mexico, covering a distance of 15 000–20 000 km roundtrip. It is hypothesized that this migration to warmer climes is undertaken to reduce the whales' thermoregulatory energy requirement during winter when food resources are low. Calves are particularly vulnerable as they have yet to acquire a thick layer of blubber. Prior to the mid-1970s, newborn calves were seen primarily in Mexico's lagoons. However, since 1980, shore-based observers have reported increased numbers of calf sightings north of Mexico. Calves were greatly under-represented in the shore-based records as rarely did more than one independent observer at a time recognize the presence of a calf and a strong nearshore preference was not evident from the aerial data. Although cows with calves were difficult to detect, significant increases in average annual calf counts occurred at two counting stations in California, USA; counts increased in the late 1970s at a station near San Diego (southern California) and in the mid-1980s at a station near Carmel (central California). This trend is probably more than an increased emphasis on reporting calf sightings over the years for two reasons: (1) The first reports of calves stranding north of Mexico during the southbound migration occurred after 1976; and (2) calves were absent during many of the earlier censuses, and when they were seen, most appeared near the end of each migration. In subsequent years, calf sightings spread through the respective seasons, first at the southern stations (sometime after 1969) and then farther north (sometime after 1980). Increased calf counts at the northern stations were strongly correlated with warmer sea surface temperature anomalies. The interannual increase in calf sightings may be related to the increased abundance of the population, to changes in ocean climate, or to both factors. A one-week shift in the timing of the southbound migration since 1980 placed the mean passage date for pregnant females near Carmel at 8 or 9 January, coinciding with earlier estimates of median calving date (10–13 January). Assuming the median parturition date has not changed, this would mean that nearly half of the calving now occurs north of Carmel.

Key words: birth; calf; California; calving lagoons; counting stations; Eschrichtius robustus; *gray whale; Mexico; migration; recovery.*

INTRODUCTION

During late autumn each year, pregnant gray whales (*Eschrichtius robustus*) of the eastern North Pacific stock lead a migration from their feeding grounds in the Arctic south to wintering areas in or near lagoons of Baja California, Mexico (Rice and Wolman 1971, Rugh et al. 2001). Presumably as food resources dwindle, gray whales seek warmer climes where their thermo-energetic needs are minimized (Rice and Wolman 1971). During the winter they only feed opportunistically, relying on fat reserves until the following spring when they return to northern feeding areas (Nerini 1984, Dunham and Duffus 2001). In particular, newborn whales are vulnerable to heat loss because they have yet to acquire a sufficient layer of blubber (Rice and Wolman 1971). Besides providing an escape from the cold arctic seas, the warm, shallow lagoons of Baja California have been described as sites for breeding, calving, and nursing (Norris et al. 1977, Rice et al. 1981, Swartz 1986).

The assumption that gray whale calving does not, or rarely, occurs north of Mexico pervades much of the literature (e.g., Rice and Wolman 1971, Sund 1975, Rice et al. 1981, 1984, Sumich 1983, Swartz and Jones 1983, Sumich and Harvey 1986). Previous studies indicate that calving occurs from the coastal waters of San Diego, California, USA (Gilmore 1960, Hubbs 1960), south to the lagoons of Baja California (Scammon 1874, Hubbs 1959, Rice et al. 1981, Swartz and Jones 1983) and lagoons on the mainland of Mexico (Findley and Vidal 2002). San Diego Bay has been described as the northernmost calving site (Gilmore 1960), although Henderson (1972, 1984) did not believe this was an effective calving area.

† Seventeen sightings made during strip-transect surveys plus three during nearshore surveys.

‡ Calculated from transect data only.

§ Seven on-transect sightings and four off-transect sightings (including a calf attacked and killed by killer whales).

Prior to the 1990s, there were only a few published accounts of gray whale calf sightings north of Mexico during the southbound migration (Leatherwood and Beach 1975, Sund 1975), and these papers described a single observation of a mother with calf. However, multiple calf sightings have been noted in a number of unpublished reports dating back to the 1970s (Table 1). Often authors of these earlier accounts (e.g., Leatherwood and Beach 1975, Sund 1975) suggested that calves born during the migration were premature because the birth occurred north of what was considered to be the calving grounds. Rice and Wolman (1971) examined gray whales collected near San Francisco during southbound migrations from 1959 to 1969. They found 26 females carrying near-term fetuses, but no recently postpartum females or calves. This seemed to confirm that calving did not occur during the southbound migration, at least not north of San Francisco. The unpublished accounts of large numbers of calves off Monterey and the Channel Islands in the mid-1980s (Table 1) prompted us to review and analyze datasets maintained by the National Marine Mammal Laboratory (NMML) and the American Cetacean Society (ACS) for gray whale calf sightings.

METHODS

Survey sites

Over the last 50 years, gray whale counts have been conducted during the southbound migration from shore stations near San Diego, Los Angeles, and Carmel, California, USA. Data from the following long-term studies were reviewed for gray whale calf sightings:

1) Census operations conducted by the National Marine Mammal Laboratory (NMML) and its predecessors were designed to monitor gray whale abundance from shore-based survey sites. Censuses were conducted near San Diego intermittently from 1952 to 1978 at Point Loma (32°42′ N) on a cliff 130–156 m above sea level and at La Jolla (32°30′ N) from a lookout 23 m above sea level (Fig. 1; Gilmore 1960, Reilly 1984). However, an undetermined number of gray whales migrated beyond the view of observers at the southernmost station at Point Loma, some as far as 200 km offshore from the mainland (Rice 1965). From 1967 to 2002, there were 22 censuses conducted near Carmel, initially at Yankee Point (36°29′30″ N) at a site 23 m above sea level, and then, starting in 1974, at Granite Canyon (36°26′41″ N) from the edge of a cliff 21 m above sea level (Reilly 1984, Rugh et al. 2001). During whale marking cruises conducted near Yankee Point in the 1960s, it was determined that few whales migrated beyond the visual range of observers on shore (Rice and Wolman 1971). This was confirmed in 1973, when five flights were conducted to test the width of the migration corridor (Sund and O'Connor 1974). Results indicated that 96% of the whales passed within 4.8 km of shore (94% within 1.6 km). This offshore distribution was also documented during aerial surveys at the Granite Canyon station, where fewer than 2% of the whales migrate beyond the sighting range of shore observers (Shelden and Laake 2002).

2) The American Cetacean Society (ACS) chapter in Los Angeles has maintained records of all marine mammals seen throughout daylight hours for nearly half of each year since 1979, except for the winters of 1981–1982 and 1982–1983. This project has operated from Long Point or Point Vicente (33°44′ N, 118°24′ W) on the edge of a cliff 38 m above sea level (Fig. 1). During 1984–1987, parallel stations also operated near the west end of Santa Catalina Island (33°28′43″ N, 118°36′18″ W; 206 m elevation) and at Cavern Point on Santa Cruz Island (34°03′13″ N, 119°33′47″ W; 96 m elevation). South of Point Conception (34°27′ N), as gray whales enter the Southern California Bight, the migration route spreads out with many animals going directly south through the Channel Islands, while others continue to follow the coastline (Fig. 1; Jones and Swartz 1987*a*). Because most gray whales use offshore

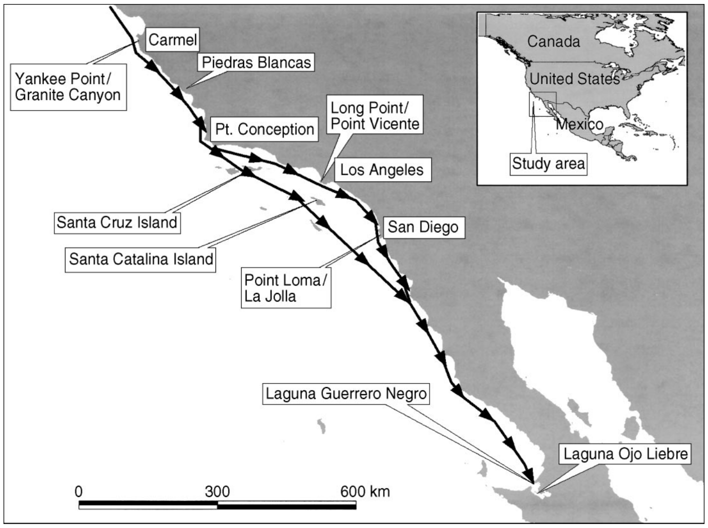

FIG. 1. Map of gray whale census sites located along the California, USA, coast and place names mentioned in the text. Arrows indicate the migration path of southbound whales.

migratory routes through the California Bight, especially on the southbound migration, the ACS project near Los Angeles has focused on ascertaining seasonal usage of the nearshore migratory path and documenting trends over time.

Data collection

Data collection procedures during censuses conducted by NMML and its predecessors have been fairly consistent since shore-based counts began in 1952 (detailed in Rugh et al. 1993). Throughout most daylight hours, observers maintained independent searches for whales, hand recording sighting and related effort and environmental data (referred to as standard watch). Prior to 1987, generally only two observers conducted the census throughout the entire field season (from mid-December to mid-February), each working five hours per day. Observers scanned a 130-degree field of view, confirmed identifications and recorded the number of animals in each pod (using 7 × 50 binoculars), with emphasis on careful and repeated observations. Distances of animals from shore were estimated in increments of 0.25 nautical miles (nmi; 0.463 km). Sightings of calves were recorded, although there were no explicit instructions on calf identification and observation methods.

After 1987, the 9-h daylight period was broken into three 3-h watches in order to minimize fatigue. Replacement observers were rotated into the schedule, so that rarely did any one observer need to stay for the entire survey season. The primary search area was reduced from 130 degrees to 60 degrees to concentrate the effort in a zone near and north of the beamline (Fig. 2). Binoculars (7 × 50) with reticles (marks etched into the binocular optics) were used to measure the angle of a sighting below the horizon, providing a more accurate calculation of distance from shore. Calves were systematically recorded in a dedicated column and described in the comment section of the data form. Starting in 1986, during a portion of each field season, a second observer did a paired, independent search, providing a test of the repeatability of the observational record (Rugh et al. 1990, 1993). Since 1995, tests of the observers were also made by conducting simultaneous watches through fix-mounted, 25× binoculars (Rugh et al. 2002). This provided improved sighting conditions at greater distances and precise records of whale sightings, but within a limited field of view. Aerial surveys were conducted in conjunction with the land-based surveys at Carmel in January of 1979, 1980 (Reilly et al. 1983), 1988, 1993, 1994 (Withrow 1990, Withrow et al. 1993, 1994), and 1996 (Shelden and Laake 2002) to document the offshore distribution of gray whales in the viewing area of the shore-based observers and to circle some whale groups for determining group size as a means of calibrating observer's estimates (Shelden and Laake 2002). These aerial surveys provided a more accurate assessment of the proportion of calves to adults and the distribution of sightings relative to shore.

During the ACS census near Los Angeles, volunteers search for whales each year from 1 December through 15 May throughout all daylight hours, seven days a week. All participants use binoculars (most recently with reticles), and spotting scopes were available to confirm and detail sightings. Weather data, including visibility and sea conditions, are recorded at least hourly. Observers identify and record various marine mammals and their behaviors, focusing on gray whales.

Identifying calves

Often synchronized blows of a pair of whales traveling close together, one distinctly smaller than the other, provided the first cue to shore-based observers. However, blow size alone did not indicate the size of a whale. Even large whales may make small blows at

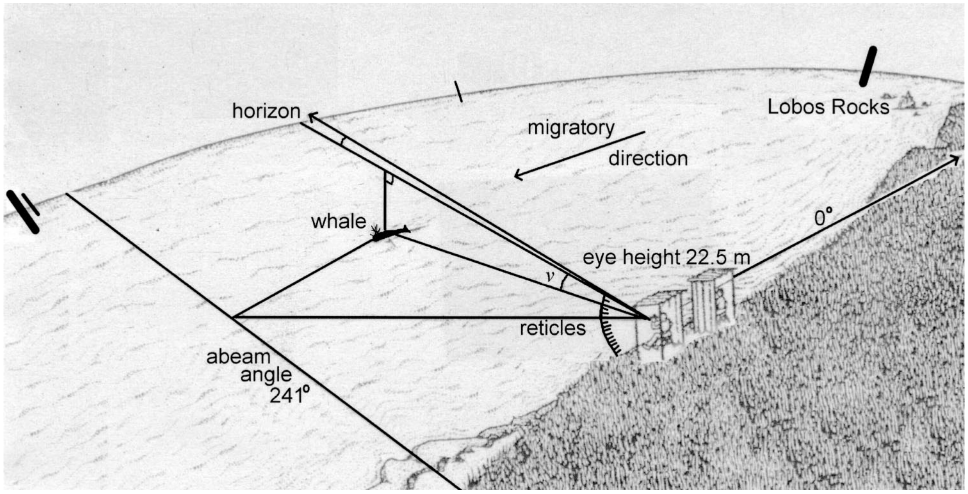

FIG. 2. Diagram of observer field of view at the Granite Canyon station near Carmel, California, where paired observers independently record whale sightings. Vertical angle to a sighting (v) is established relative to the horizon by using reticles in the binoculars (the horizon is 0.15° below true horizontal). Horizontal angles are magnetic bearings; 241° is perpendicular to the shoreline. Small tick marks on the horizon indicate a 60° field of view as used in recent years; broader tick marks represent the 130° field of view used in previous years.

times, and in some instances, the two blowholes of one whale may make different-sized blows. Although cows and calves have more or less synchronized diving intervals, the calves need to surface more often, and they spend less time at the surface than adults.

Calves often swim along the flank of the adult, usually on the left or right, but sometimes changing sides (Fig. 3). Shore-based observers notice the dorsal ridge more than any other part of the calf. The ridge on a calf is extremely narrow compared to an adult's, and the height of the ridge above the water is usually much lower for the calf than for an adult. Although the amount of back exposed during a surfacing changes rapidly through the surfacing, a calf's back is clearly smaller than an adult's. Flukes on a calf are tiny compared to the accompanying adult. Very young calves sometimes lift their entire head out of the water when they surface to breathe, instead of exposing little more than their blowholes as adults do. Gray whale calves do not have the pronounced markings of the adult caused by ectoparasites, especially barnacles; the skin of calves appears relatively clean and dark (Fig. 3a). Even so, calves do have some natural pigment patterns and may appear to have some mottling. Calves were

identified during NMML aerial surveys based on a combination of three characteristics: their size (usually one-third the length of the companion whale), coloration (pale and lacking barnacle clusters), and position (usually swimming beside the peduncle of the larger whale) (Fig. 3b).

Data analyses

Original data records were not available for shore-based censuses conducted between 1952 and 1956, therefore survey effort and gray whale counts were obtained from Gilmore (1955, 1960). Counts of whales observed during San Diego censuses from 1957 to 1978 were obtained from Rice (1981; National Marine Fisheries Service [NMFS], *unpublished data*). Computer database summaries provided tallies of total number of whales for the Carmel stations (1967 to 2002), but only identified calves in comment entries until 1987 (this meant reviewing the original data forms for calf sightings). Northbound whales were not included in the analyses. Calf counts were tabulated from raw data collected from 1959 to 1986, while computer database summaries provided these numbers for the NMML surveys conducted from 1987 to 2002. A calf sighting was considered valid when three independent reviewers agreed with the identification. A sighting was considered questionable, but still listed as a possible calf sighting, when discrepancies between the reviewers occurred. These questionable sightings were not included in the ratios of calves to whales. Calf counts and total number of whales observed were obtained for the aerial surveys conducted in January 1988, 1993, 1994, and 1996 (no calf sightings were reported in the 1979–1980 surveys).

During shore-based surveys near Los Angeles, the first three seasons (1979–1981) from Long Point and Santa Catalina Island were quite truncated, and though some calves were seen (Table 1), there were no special efforts made to identify and record calves. Since 1984, more attention was given to gray whale calf sightings during both the southbound and northbound migration. The intent was to improve the tracking of trends in calf recruitment. The number of southbound calves and whales was tabulated from the computer database maintained by the ACS-Los Angeles Chapter.

The proportions of calves relative to all gray whale sightings recorded each season at the respective stations was calculated based on raw counts of calves divided by the total count of gray whales, including calves. Census season dates were truncated on figure axes to simplify comparisons across years (e.g., 2001 refers to the 2000/2001 season). Calf counts were graphed and tested for changes in average annual counts over time. Log-transformed counts from each station were tested for potential trends over time using regression analyses. The seasonal distribution of calf sightings was graphed for each research site and compared across decades. Median passage dates were calculated for years with adequate samples (i.e., >2 calf sightings). Correlations between calf numbers and climatic variables were also explored.

Repeatability of calf sightings was tested by comparing records when independent, concurrent shore-based watches occurred at the NMML Granite Canyon station (i.e., paired, independent standard watches; paired searches through two 25× binoculars; and searches through 25× binoculars compared to the standard watch; see Plate 1). Records of individual pods observed during concurrent aerial and shore-based surveys in 1993 and 1994 were reviewed to determine the ability to see calves from shore relative to sightings from the air.

Offshore distances in kilometers were computed from reticle distances (Lerczak and Hobbs 1998) for those years in which binoculars with reticles were used during the standard watch (1987–2002) near Carmel. These distances were compared with the offshore distances of calf sighting made during aerial surveys (obtained by interpolating distances relative to time of sighting on the trackline [dead-reckoning] or global positioning system [GPS] locations) and using 25×

binoculars (with reticles etched on the optics). To determine where calves occurred within the migratory corridor, a comparison was made of distance data from the full field season of shore-based counts in 1993/1994 and 1995/1996 to aerial records collected during January 1994 and 1996.

RESULTS

The first calf sightings reported north of lagoons in Mexico occurred during the 1955/1956 census near San Diego (Table 2). There were no other reports until the 1968/1969 census, when a single confirmed and an additional unconfirmed sighting were recorded. However, the last three censuses near San Diego (1975/1976, 1976/1977, and 1977/1978) each reported multiple calf sightings with a peak of 11 sightings during 1977/1978 (Fig. 4). Calf sighting rates ranged from 0.001 to 0.003 calves/whale during these three censuses. In contrast to the increased sighting rates in the late 1970s near San Diego, the initial 13 censuses conducted near Carmel (645 km north of San Diego) from 1967 to 1980 had only five confirmed calf sightings (corresponding to $\leq$0.001 calves/whale), only two of which occurred during the late 1970s (Table 2, Fig. 5). The difference in calf sighting rates at the two sites was significant ($X^2 = 19.9$, df = 3, $P = 0.0002$). During the more recent 11 censuses that were conducted near Carmel from 1985 to 2002, proportions of calves increased to an average of 0.005 calves/whale, ranging up to 0.015 calves/whale (Table 2, Fig. 5), but no comparable re-

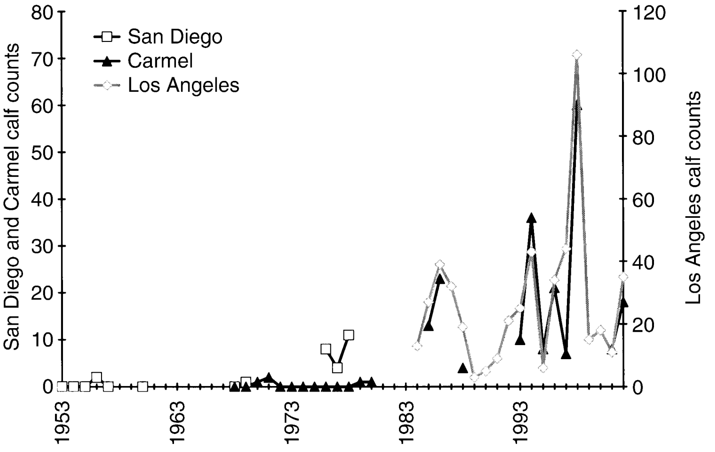

FIG. 4. Counts of gray whale calves observed during the southbound migration at counting stations near San Diego, Los Angeles, and Carmel, California.

cords were available from San Diego after 1978. During the same period, data from Los Angeles showed an average of 0.034 calves/whale, with annual values ranging from 0.005 to 0.086 calves/whale (Table 3, Fig. 5). The last three field seasons (1997/1998, 2000/2001, and 2001/2002) produced the first northbound calf sightings near Carmel (on 22 February 1998, 28 February 2001, 1 March 2001, 26 February 2002, 1 March 2002, and 5 March 2002). Northbound sightings were not included in analyses involving relative numbers of calf sightings.

Seasonal distribution of sightings

At the southernmost counting stations based in San Diego, calves were absent during many of the censuses prior to the 1970s, and when present, were observed only near the end of the southbound migration (Fig. 6). By the late 1970s, calf sightings near San Diego were scattered throughout the season (as early as 17 December and as late as 16 February). However, near Carmel, calves were absent during most of the censuses in the 1970s, and, when calves were observed, sightings were in the middle or the end of the migration (Fig. 7). In the 1980s, calves began appearing several weeks before the peak of the migration off Carmel (median date = 16 January; Rugh et al. 2001). A similar pattern was also observed during the 1990s. By the end of this study, sightings near Carmel were occurring throughout the season, as early as 25 December in the 1997/1998 season and as late as 1 March in 2001/2002 (Fig. 7). Near San Diego, 65% of the sightings occurred in January (26% in December), while at the Los Angeles and Carmel stations, most of the southbound calf sightings occurred in January (90% and 95%, respectively; Figs. 6–8). For these three stations, median calf sighting dates were similar (15–17 January; see asterisk symbols on Figs. 6–8), indicating that, during the southbound migration through the southern half of California, gray whale calves are more likely seen in mid-January.

The distribution of calf sightings at the Carmel station prior to and after the mid-1980s was compared to the median passage dates for all gray whales (Table 4). Before 1980, the few calves that were seen appeared well after the main migration had passed the site. After 1980, observations of calves before the migration peak (which was one week later than the pre-1980 period; Rugh et al. 2001) resulted in a median date of all calf

sightings that was not significantly different from the median passage date for all gray whales ($t = -0.659$, $P = 0.52$).

Unobserved calves

Many calves were missed by shore-based observers. During independent, concurrent standard watches conducted near Carmel, there were 76 instances in which at least one observer recorded a sighting of a cow–calf pair, but 80% of the time the other observer entirely missed the pod or did not see a calf next to the adult. When observers were compared on independent searches through 25× binoculars, 11 calves were seen, but none were seen by more than one observer at a time. Among all of the records from watches through 25× binoculars, whether or not a second, independent search through similar binoculars was underway, there were 28 calves seen, but only four were also seen by observers on the standard watch. During experiments where the aerial crew directed shore-based observers to specific pods to test estimates of pod size, shore-based observers were able to locate only four of eight cows and never saw the associated calf. It was often noted in the sighting record that cows with calves were cryptic (i.e., barely breaking the surface to breathe and exhaling without casting a distinctive V-shaped blow). No corrections for calves missed by observers on the standard watch were included in calf counts in Table 2.

The distance cows with calves traveled from shore may have also contributed to the number of calves missed by the shore-based observers. The median distance calves were detected during a standard watch

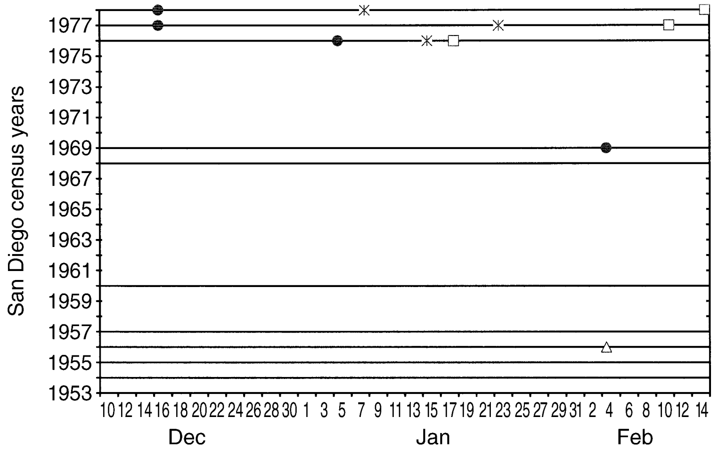

FIG. 6. Seasonal distribution of gray whale calf sightings at the southernmost counting stations near San Diego, California. Solid circles indicate first sighting of the season, stars (⁎) indicate median date, and open squares indicate last sighting. The open triangle in February 1956 represents two calf sightings for which observation dates were not provided (see Gilmore 1960).

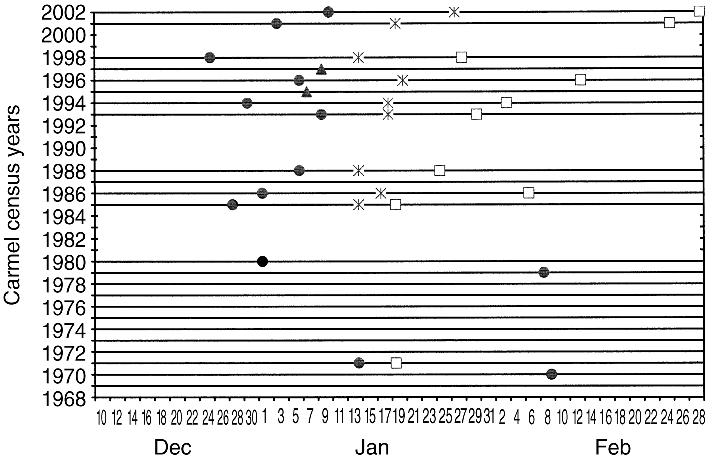

FIG. 7. Seasonal distribution of gray whale calf sightings at the northernmost counting stations near Carmel, California. Solid triangles in 1995 and 1997 indicate first sighting for a truncated field season.

was, in general, closer to shore than the distances reported using 25× binoculars or during aerial surveys (Table 5). About 99% of the southbound population passes within the shore-based observers' visual range of 5.6 km (Shelden and Laake 2002). Of the 1.28% (n = 18 pods) observed beyond 5.6 km during aerial surveys (Shelden and Laake 2002), only three were cows with calves (at 9.4, 14.3, and 33.9 km), representing ~10% of the calves observed during aerial surveys (n = 29; Table 5). However, if shore-based observers had difficulty identifying cows with calves beyond 2.6 km (the maximum distance calves were seen during the standard watch; Table 5), then 28% of the calves migrating past the site may have been missed due to distance alone based on the aerial survey data.

The proportion of calves to total number of gray whales seen from the air (0.022) was 6.3 times greater than the proportion seen from shore (0.003) when sampled during January (Table 6). The ratio of these proportions for aerial and shore sightings (6.3:1) gave an approximation of how many calves were missed from shore (i.e., shore observers saw only 16% of the calves in the viewing area). Recomputing the aerial ratios (Table 6) using only those sightings where offshore distances were available (n = 29) and excluding sightings beyond the shore-based observers' visual range of 2.6 km (n = 8), resulted in a 3.3:1 ratio between aerial and shore observations. Therefore, shore-based observers were seeing only 30% of the calves within their visual range of 2.6 km. Including calves missed beyond 2.6 km results in a 22% sighting rate.

Although the spatial distribution of cows with calves observed by shore-based observers was significantly different from that of other pods, with increased sightings occurring shoreward of the main migration corridor (Table 7), this distribution was biased because calf detections diminished rapidly with increasing distance, more so than the sightings of adults. Aerial survey data do not show as strong a nearshore preference.

Trends in calf counts

Although detecting calves was difficult, significant increases in average annual calf counts occurred near San Diego in the mid- to late-1970s compared to the 1950s and 1960s, and near Carmel in the mid-1980s through 2002 compared to late-1960s through 1980 (Fig. 4). The difference between averages of these annual calf counts was significant at both San Diego (t

Note: Calf counts were made during standard watches.

$= 3.566$, $P = 0.035$) and Carmel ($t = 3.157$, $P = 0.003$). This increasing trend in calf counts over time can be modeled as a linear increase in the log-transformed counts near San Diego in the mid-1970s ($R^2 = 0.61$, slope $= 0.03$, $P = 0.004$), then near Carmel in the mid-1980s ($R^2 = 0.73$, slope $= 0.05$, $P << 0.001$). However, key years were not surveyed (i.e., 1969/1970 to 1974/1975 at San Diego and 1980/1981 to 1983/1984 at Carmel), so whether there was a gradual increase or a step-wise ''shift'' is unknown. This increasing trend leveled off after 1984 at Carmel ($R^2 = 0.02$) and is not apparent in the data from the Los Angeles station ($R^2 = 0.04$).

Climate correlates

We explored possible correlations between calf presence and changes in oceanic phenomena (sea surface temperature [SST]). West Coast SST anomaly data were obtained from the National Oceanic and Atmospheric Administration (NOAA), National Weather Service, National Centers for Environmental Prediction, and Climate Prediction Center affiliated web sites.[4,5] A positive correlation between warmer water temperature anomalies and increased numbers of calves was evident at Carmel ($r = 0.48$, $P = 0.008$) and Los Angeles ($r = 0.47$, $P = 0.022$), but not at San Diego ($r = -0.14$, $P = 0.676$).

DISCUSSION

The idea that gray whales birth calves in the ''calving lagoons'' of Baja California pervades the literature. However, the evidence presented in this report shows that many, if not most, of the calves are born during the southbound migration well north of Mexico. The disparity between earlier literature and current records may in part be due to a change in where calving occurs. Calf sightings have increased over a 50-year period of shore-based surveys of gray whales migrating south along the coast of California. Because calf sightings increased first at the southernmost site (San Diego in 1976) and then farther north (at Carmel in 1985), this trend was probably more than an increased emphasis on reporting calf sightings and changes in protocol over the years. There were no reports of calves during many of the earlier censuses and, when observed, most appeared near the end of each migration. The sightings then spread through the respective seasons, first at the southern stations and later farther north.

Adult gray whales are sometimes missed by shore-based observers even during good sighting conditions (19% are missed within the viewing area during standard watches near Carmel; Rugh et al. 1993). The small size of calves makes them even more difficult to see than adults. Although not as pronounced as the pattern observed for the northbound migration (Perryman et al. 2002), southbound cows with calves appear to segregate shoreward of the main migration corridor. However, adults, as well as cows with calves, traveling very close to shore were missed (Rugh et al. 1993). Reduced visibility, especially during fog and elevated sea states, probably affects sightings of calves more than of adults. Overall, calves were greatly under-represented in the shore-based records.

The upward trend in calf sightings may be related to the increased abundance of this stock of whales (rising 2.5% per annum from 1967/1968 to 1995/1996; Buckland and Breiwick 2002) and the concomitant rise in total calf production. However, unless calving rates changed, we would expect the proportion of calves in the population to remain more or less constant given a gray whale population with a stable age structure (Rice and Wolman 1971). Instead, the increase in calf sightings may be more directly related to changes in the location of migrating whales when they give birth, assuming that the timing of parturition is less a function of location (such as in the lagoons) than of date.

Parturition begins in late December and continues through mid-February (Rice and Wolman 1971). Based on observations in the Mexico lagoons, most births occur between 26 December and the beginning of March (Swartz and Jones 1983, Sanchez-Pacheco 1998), with a peak calving date around 27 January (Rice et al. 1981). Perryman and Lynn (2002) found that the median birth date for gray whales passing through the Channel Islands was 13 January (95% confidence interval 12–15 January, based on the proportion of parturient females to those with calves). Rice and Wolman (1971) estimated a mean birth date of 10 January based on the scientific catch of parturient gray whales off San Francisco (Table 4). It seems unlikely that median calving dates have changed given that

Note: Numbers in parentheses indicate sample size.

''length of gestation varies greatly among species but is confined within narrow limits in each species'' (Fuchs and Fields 1999). The dramatic increase in calf sightings after 1980 appears to be tied to a one-week delay from 8 January (1968–1980) to 16 January (1985–2002) in the median passage date of the southbound migration (Rugh et al. 2001). Although the median timing of the southbound migration has been consistent prior to and after this shift, any delays in the first part of the migration, when most of the pregnant females pass, may affect where calving occurs.

Over at least a 38-day period, pregnant females (near full-term) passed San Francisco during the southbound migration in the 1960s, with a mean passage date of 31 December (Rice and Wolman 1971). If we allow for a one-week shift in timing, then the mean date could now be close to 7 January. Because Carmel is ~170 km south of San Francisco and the whale route roughly parallels the coast, the mean passage date for pregnant females near Carmel could now be near 8 or 9 January. This is very close to earlier estimates of calving date (10 January, Rice and Wolman 1971; 13 January, Perryman and Lynn 2002), assuming, again, that it has not changed. Theoretically, then, since 1980, nearly half of the calving occurs north of Carmel.

In order to estimate how many gray whale calves were born near or north of Carmel during the southbound migration, we used a ratio of uncorrected counts to total abundance for this whale stock, 0.145:1 (data from Laake et al. 1994, Hobbs and Rugh 1999, Rugh et al. 2002). Calf counts since 1993 (average = 29/yr) corrected by this ratio suggest that on an average year, there are 197 calves born north of Carmel. The northbound migration of adults with calves is monitored from Piedras Blancas, and calf production is estimated from these surveys (Perryman et al. 2002). Based on estimated numbers of calves from three years (1993/1994, 1995/1996, and 1997/1998), when data were available from both Granite Canyon (Carmel) for the southbound count and from Piedras Blancas during northbound counts (Perryman et al. 2002), 23% of the calving occurs north of the Carmel area. Including a factor for the low sightability of calves relative to adults would raise this estimate, while including a factor for mortality would lower it.

The delay in the migration of pregnant females may be due to increased competition for food resources in the northern feeding areas (Stoker 1990, Highsmith and Coyle 1992, Coyle and Highsmith 1994, LeBoeuf et al. 2000) as the population reaches carrying capacity (Moore et al. 2001, Wade 2002). The climatic regime shift that occurred in the North Pacific during the winter of 1976–1977 resulted in unusually warm water temperatures along the North American coast (e.g., Miller et al. 1994, Hare and Mantua 2000). A reduction in percent ice cover anomalies for the Bering and Chukchi

TABLE 6. Number of calves and total number of gray whales observed during concurrent aerial and shore-based surveys of the southbound migration in January off Granite Canyon, California.

Year	Aerial surveys†			Shore-based standard watch		
	No. calves	No. gray whales	Proportion of calves	No. calves	No. gray whales	Proportion of calves
1988	2	822	0.0024	1	2776	0.0004
1993	6	252	0.0238	5	1377	0.0036
1994	20	455	0.0440	14	1980	0.0071
1996	12	325	0.0369	5	1154	0.0043
Total	40	1854	0.0216	25	7287	0.0034

† Aerial surveys include on- and off-effort sightings.

TABLE 7. Chi-square contingency analysis of pooled data from the 1993/1994 and 1995/1996 gray whale censuses at Granite Canyon, California.

	Aerial survey†		Shore-based standard watch‡	
Distance	Cows with calves	Others	Cows with calves	Others
Nearshore	10 (4)	57 (64)	45 (11)	933 (967)
Main	7 (14)	256 (248)	12 (38)	3317 (3291)
Offshore	7 (6)	98 (99)	0 (8)	672 (664)

Notes: Distance offshore is represented by three migratory corridors: nearshore, 0.0–1.4 km; main, 1.4–2.8 km; offshore, >2.8 km. ''Others'' refers to pods without calves. Shore-based data include all sightings collected from December–February. Expected counts for within-survey type analysis are shown in parentheses.

† $X^2 = 15.76$, df = 2, $P < 0.001$.

‡ $X^2 = 129.12$, df = 2, $P < 0.001$.

Seas, formerly primary feeding areas for these whales, also occurred after 1977 (Niebauer 1998). It is important to note that El Niño events have increased in frequency since the regime shift and that there have been very few La Niña events since 1976 (Niebauer 1998, 1999), which may explain the correlations found between calf counts and positive SST anomalies. Because the North Pacific has warmed, calves likely experience reduced thermo-stress when born along the migration route. Gray whales appear to have responded to warmer waters, reduced ice cover, and changes in productivity in primary feeding areas such as the Chirikov Basin by expanding their foraging range (Rugh and Fraker 1981, Miller et al. 1985, Moore et al. 2003). Therefore, as pregnant females disperse farther to find adequate food, their migration south can take longer (assuming that the timing of the onset of the migration does not change; Rugh et al. 2001), and they might be migrating with reduced fat reserves. This may also explain the appearance of calf carcasses along the migration corridor after 1977.

Prior to the late 1990s, strandings of gray whale calves were rare north of Mexico. Stranding reports compiled from 1952 to 1981 document 50 calf strandings in Mexican lagoons and 17 along the migration route (Sumich and Harvey 1986). All of the strandings north of Mexico have been since 1977. Heyning and Dahlheim (1990) report 204 calf strandings between 1975 and 1989, mostly in Mexico, but some as far north as northwestern Alaska. However, there is no evidence that any of these calf strandings occurred during the southbound migration. Monthly surveys of a 14.5 km section of the central California coastline from 1980 to 1986 to determine deposition patterns of seabird and marine mammal carcasses yielded few cetaceans and no gray whales (Bodkin and Jameson 1991). The first record of a calf stranding during the southbound migration was a live stranding in 1980 in British Columbia, Canada (Baird et al. 2002; Table 8). This is also the northernmost stranding of a southbound calf. The majority of calf strandings occurred in early 1998 (Table 8), which coincides with the highest calf counts on record at the census stations.

The appearance of northbound calves near Carmel is of interest because northbound migrants usually do not appear in California waters until after mid-March (Perryman et al. 2002). Sightings of northbound calves during the census of the southbound migration may be a function of longer survey seasons in recent years. Prior to 1994, the census was usually terminated by the end of the first week of February, but since then the census has been extended to cover an increasingly prolonged southbound migration (Rugh et al. 2001). It is possible that these northbound calves did not migrate as far south as Mexico as may be the case for many of the southbound calves observed near Carmel and Los Angeles. A one-week (6.8-day) delay in the migration timing (Rugh et al. 2002) without a change in birthing dates would mean that calving would occur 1000 km further north, assuming a constant travel rate of 147 km/day (Swartz et al. 1987). Therefore, a whale that might have calved just as it arrived at the northernmost lagoon in Mexico prior to 1980 would now calve near Point Conception, which is roughly halfway between Carmel and Los Angeles. If, in the past, whales migrated directly to a location somewhere south of the northernmost lagoon to calve, sufficient deviation or delay in the migration would mean that calving would occur farther north of Point Conception. This, indeed, is evident after 1980. Similarly, assuming that the one-week shift in migration timing has been the only significant change in the gray whale migration over the past five decades, recent observations of newborn calves near Carmel imply that prior to 1980 some or many calves were born north of the lagoons, given the rate of travel of migrating gray whales and the distance between Carmel and the lagoons. Furthermore, given the documented difficulty in seeing calves from shore, it is possible that calves were near Carmel during the 1970s, but went unobserved until their numbers were high enough to raise the probability of some being noticed.

TABLE 8. Gray whale newborn strandings reported during the southbound migration from 1980 to 2002.

			Distance from Mexico lagoons		
Date	Location	Disposition	km	d	Source
1980					
29 Dec	Bonilla Island, BC, Canada	found alive, died (4.42 m)	3385	23	1

TABLE 8. Continued.

Date	Location	Disposition	Distance from Mexico lagoons		Source
			km	d	
2001					
9 Jan	Montana de Oro State Park, CA	alive swimming ~5 km offshore when it was struck and severely injured by a cable-laying vessel, carcass never recovered (estimated 4.5 m)	1120	8	3
10 Feb	Morro Bay, CA	alive swimming in bay, last seen alive 13 Feb, stranded dead 25 Feb, moderate decomposition (4.9-m male)	1120	8	3, 6

Notes: A gray whale was considered to be a southbound calf if it was ≤5 m in length (Rice and Wolman 1971, Perryman and Lynn 2002) and stranded between late November and early March (i.e., northbound migrants usually do not appear in California waters until after mid-March; Perryman et al. 2002). Distance (km) from Mexico was approximated following the coastal migration route, and travel time (d = days) was derived using an average travel speed of 147 km/d (Rugh et al. 2001). Abbreviations are: BC, British Columbia; CA, California; OR, Oregon. Sources are: 1, Baird et al. 2002; 2, Heyning and Lewis 1990; 3, J. Cordaro, *unpublished database*; 4, J. Hodder, *unpublished manuscript*; 5, Norman et al. 2000; 6, K. Zagzebski, *unpublished data*.

It is possible that female gray whales that reach parturition en route do not complete the migration to Mexico with their calves; instead, they might congregate in the Southern California Bight, near the Channel Islands, until their calves are large enough to return north. Lagoon use and calf production has changed significantly since the 1980s at Ojo de Leibre (one of the northernmost lagoons) and Lopez Mateos (one of the southernmost) (Fleischer and Schweder 2002). At the northern lagoon, a significant decline in peak abundance of calves as well as adults occurred in 1990, while at the southern lagoon a more gradual but highly significant decline occurred from 1981 to 1990. Overall, calf production has not recovered to levels observed in the early 1980s (Fleischer and Schweder 2002). In part, this may be due to high water temperatures during El Niño events (and possibly overall warmer temperatures since the regime shift), which seem to discourage gray whales from migrating to the southernmost lagoons (Gardner and Chávez-Rosales 2000, Urbán et al. 2003*b*). Urbán et al. (2003*a*) noted a 59% decrease in the number of cows with calves at Laguna San Ignacio during the 1982/1983 El Niño and a northward shift to waters off southern California during the 1998 event. What are the implications for survival outside the relatively protected waters of the lagoons? Besides exposure to winter storms, we also found a strong correlation between killer whale presence and calf numbers near Carmel ($R^2 = 0.72$, $P << 0.001$).

If the occurrence of calving north of the lagoons is related to the size of the gray whale population, then it also should have occurred when the population was near carrying capacity prior to commercial whaling. This idea is supported by the Makah Indians' names for the months of the year. The Makah, who live in northwest Washington ~2,500 km north of the lagoons in Mexico, call December *se-hwow-as-put'hl,* or the moon in which the gray whale makes its appearance, and they call January *a-a-kwis-put'hl,* or the moon in which the whale has its young (Swan 1870). This timing and location fits well with what we are now seeing during the southbound migration. Is it coincidental that the earliest and northernmost sighting of an adult with newborn occurred on 18 November 1998 in Discovery Bay, Washington (Shelden et al. 2000)?

In conclusion, it is evident that greater numbers of gray whale calves are born north of Mexico during the southbound migration. Calf sightings have increased across the past five decades, in part due to the increased size of the gray whale population, but the increase may also be related to environmental changes affecting a delay in the migration. Range expansion in northern feeding areas, perhaps because the population is approaching the carrying capacity of its environment, has meant that pregnant females have farther to travel at the start of the southbound migration. Warmer sea surface temperature anomalies were also correlated with increased calf counts at the northern stations as well as declines in counts at the Mexico lagoons. Assuming that parturition timing has not changed, the one-week delay has meant that calving has been occurring farther north. It appears that one-quarter to half of the calving now occurs north of Carmel.

ACKNOWLEDGMENTS

Our sincere thanks go to Alan Baldridge (Hopkins Marine Station, Stanford University, Pacific Grove, CA), who inspired this study. Sally Boeve (NMML) helped in the review of observers' records and helped make data summaries. Statistical support was provided by Jeff Laake and Nancy Friday (NMML). Dale Rice (NMML) reviewed the manuscript and provided additional background material on the San Diego studies conducted from 1952 to 1957. Phillip Colla and Harrison Stubbs (Hawaii Whale Research Foundation) generously provided underwater video and photographic documentation of a gray whale cow with newborn calf near Carmel, CA. Wayne Perryman (Southwest Fisheries Science Center) provided images of calves observed during aerial surveys. This document was greatly improved by the comments of Brian Fadely and Nancy Friday (NMML), Jim Lee and Gary Duker (Alaska Fisheries Science Center Publications Unit), Steven Swartz (NOAA Fisheries), and an anonymous reviewer.

Soviet Studies on the Distribution and Numbers of the Gray Whale in the Bering and Chukchi Seas from 1968 to 1982

Alfred Antonovich Berzin

Introduction

The main task of Soviet research of the Chukotka–California population of gray whales was to estimate their present abundance. A review and analysis of the literature and material from Soviet scientific research cruises to study the distribution and numbers of gray whales during the period of 1958 to 1964 is presented in the work of Berzin and Rovnin (1966). The present chapter does not intend to present and analyze population estimates for the Chukotka–California gray whale population produced by U.S. researchers during the past few years as this information is presented in numerous publications. At the same time, it is perfectly obvious that an exact determination of gray whale abundance must include a census of all regions the whales inhabit, particularly the summer range. The study of the whale's abundance, especially on the summer grounds, is inseparably linked to the study of their distribution. The scientific colleagues of TINRO (Pacific Research Institute of Fisheries and Oceanography) conducted systematic surveys of gray whale abundance and distribution from aircraft and vessels in the Bering and Chukchi Seas from 1968 to 1982.

Methods

The first aerial surveys of the gray whale's abundance and distribution in the coastal regions of the Bering and Chukchi Seas were conducted in 1968 and 1973 as part of the research program of TINRO. Subsequent surveys were conducted in 1974 and 1975 as part of the Soviet national research program within the framework of the "U.S.S.R.–U.S.A. Agreement for Collaboration in the Field of Environmental Conservation."

In accordance with the joint program, a research plan was formulated in 1975 for a simultaneous aerial census of Soviet and American portions of the Bering and Chukchi Seas for the purpose of surveying the entire summer range of the gray whale population (Table I). Unfortunately, the Americans were unable to conduct their surveys, which significantly decreased the effectiveness of the surveys conducted by Soviet scientists in the Soviet sector. Vessel surveys to estimate gray whale abundance and distribution were conducted jointly by Soviet and American scientists in 1979 to 1982 as part of this same program (Project 02.05-61, "Marine Mammals"). Participants from TINRO who participated in this research included V. V. Zimushko, A. P. Shustov, N. V. Doroshenko, V. N. Kolesnikov, and the author.

Aerial surveys were conducted in a twin-engine aircraft, the IL-14. Survey altitude was dependent upon weather conditions, but the optimum altitude selected was 300 m. Surveys followed parallel tracks separated by 15 km and extended a maximum distance of 250 km from shore. Survey strip width was determined by measuring the time from when a whale was spotted until the aircraft was over the animal and correlating this with the aircraft's ground speed. Maximum strip width was 5 km, but it was frequently less during surveys because of the weather conditions. In 1975 surveys were conducted in a flying "photosurveyor" which had "bubble" windows on both sides. This allowed simultaneous observation from both sides of the aircraft and doubled the effective survey zone. During each meeting with whales, V. V. Zimushko noted visibility, altitude, aircraft speed, etc. From these factors the survey strip width was determined; however, strip width changed relatively rapidly (within 15–20 min) from 270 m to 2 km.

The number of whales observed at any one moment does not reflect their true numbers as individuals may be below the surface; therefore, counts must be corrected for animals missed below the water's surface. In 1973 several systematic surveys were undertaken to determine a correction factor. Control counts were conducted from a vessel while an aircraft circled above the same group of whales. In our experience, this was the first comparison of its kind done for these whales. The counts from these surveys are a bit contradictory and insufficient, but they have the advantage of being actual counts and not estimations. The comparison of counts of the gray whales conducted simultaneously from Soviet vessels and aircraft in the coastal waters of Chukotka suggested that aerial observers detect approximately two-thirds of the whales. A correction factor is dependent upon the behavior of the whales: the group structures, their dive times, and their surface intervals. Weather conditions are not predictable and may affect the visibility of whales profoundly; in our opinion they cannot be introduced into a correction factor as this would produce uncertainties. The following relationship, recommended by Arsen'yev *et al.* (1973), was used to determine the abundance of whales in the survey area:

$$N = kn(1 + t_1/t_2)$$

where N is the general quantity of whales, n is the number of detected whales, t_1 is the time the whale is submerged underwater, t_2 is the time the whale remains at the surface, and k is a function of the aircraft's speed, visibility, and the distance of detection. V. V. Zimushko utilized this relationship in his analysis of the 1973 aerial census and estimated the population at three times the base (raw) count.

The summer distribution of gray whales is very irregular; thus, the survey area was divided into several regions each with different concentrations of whales to increase accuracy. The flight tracks were plotted on charts and the area that had been surveyed was determined, as was the number of whales encountered along a track line. From these data, whale densities in each region were calculated, and the total population was extrapolated region by region. I participated in the aerial observations of gray whales in the Bering and Chukchi Seas in 1973; based on my experience, I consider an aircraft flying at 250–300 km/hr to be a poor platform for observations of this kind. The aircraft passes over areas too rapidly to detect many great whales whose dive times are long, and because of the aircraft's large turning radius, it is difficult to return to whales once they have been detected. One must, however, utilize fixed-wing aircraft in certain conditions, like the Chukchi Sea, when a helicopter cannot be utilized.

When whales were spotted from survey vessels, the vessel followed the whales to obtain a precise count. Sighting information from years of vessel surveys in various regions of the northwest Pacific indicated that while vessels are underway the effective observation zone is up to 10 miles wide (5 miles on each side).

Results

Aerial surveys of the Bering and Chukchi Seas conducted in 1968 included the coast and up to 50 km from shore and the ice-edge zone by Herald Island (Fig. 1). In all, 124 whales were counted. The largest group seen at one time included 17 animals observed in the region of Cape Inchoun (in the Chukchi Sea). The majority of the whales were seen along the coast no more than 35 km offshore. During the 1968 survey, the distribution of gray whales in the open sea was documented: two groups of 3 animals each were counted on a transect off Cape Serdtse Kamen at a distance of 90 km from shore.

Gray whales were observed in the Chukchi Sea only in the area of Cape Dezhnev (the Bering Strait) to the settlement of Neshkan. No additional whales were counted in the remaining area north from the settlement of Neshkan along the ice edge to the pack ice near Herald Island. Only a few lone whales were observed in the area of Cape Navarin and in the area to the south at Cape Khatyrka (Zimushko, 1970).

In 1973, aerial surveys were conducted of the northwest Bering Sea and the portion of the Chukchi Sea from Cape Dezhnev to Wrangel and Herald Islands (Fig. 1). A total of 290 whales was counted. The greatest density of whales was noted in the Chukchi Sea from Cape Dezhnev to Kolyuchinsky; the density was 0.11 whales/km^2. As in 1968, no whales were observed in the northern area from Cape Kolyuchin along the ice edge to Wrangel and Herald Islands. Five individual whales were counted by Cape Olyutorsky, although no whales were seen in Olyutorsky Bay itself. Whales were seen at Cape Pouten in the Bering Sea. In the Chukchi Sea (68°N, 169°05′W) 44 whales were counted during a 12-km long, 3-min flight. Later, during a 30-min flight along the same track, 132 whales were counted. During that same year whales gathered in significant numbers further offshore, which was explained by a corresponding change in their foraging areas. Sixty-eight percent of the sightings were of whales in groups of 2 to 3 animals. The largest group included 24 animals.

In 1974, the main region of Soviet studies was the Okhotsk Sea; therefore, studies in the Bering and Chukchi Seas were limited to short cruises in a limited area by the R/V *Tamango*. The count of whales along the Koryaksk coast and the Chukotka peninsula was 198 animals. This was extrapolated to a population size of 1800 to 2000 whales as a guide to the whale density in this area (Kuz'min and Berzin, 1975). The general movements of the gray whales confirmed that a massive departure of animals from the Chukchi Sea occurs in mid-October.

In 1975 aerial surveys included the coastal regions of the northwest Bering Sea; in the Chukchi Sea an investigation was conducted from Cape Dezhnev to Cape Vankarem and along the ice edge to 68°40′N (Fig. 1). Some 873 gray whales were counted. As in previous years in the Chukchi Sea, the following traditional regions contained aggregations of gray whales:

1. From 67°30′ to 68°15′N and 171°30′ to 172°00′W.
2. From 68°10′ to 68°30′N and 171°30′ to 172°00′W.
3. From 66°30′N and 169°55′ to 170°10′W.

A dense aggregation of whales usually occurred in the Bering Strait near Cape Pouten, where 50 whales were counted in 1975 during a 3-min flight along a 12-km transect line. One of the main groups of gray whales was located, as in previous years, in the Bering Strait at 64°50′ to 65°00′N and 170°00′ to 170°20′W. Anadyrsky Bay continues to be a region with the lowest density of whales. Solitary whales were observed near Cape Olyutorsky. This same year, no whales were observed beyond the 25-km wide coastal zone.

According to the aerial observations of V. V. Zimushko, gray whales on their feeding grounds are usually observed as single animals or small groups. Out of our 232 sightings of whales, single animals were observed 102 times (44%), groups of 2 to 5 animals were seen 113 times, and groups greater than 5 animals were observed on 17 occasions (7.8%). A group size of 2 to 3 animals was most frequently seen (67.6%). As previously stated, the largest group included 24 whales.

During a Soviet–American cooperative expedition on board the R/V *Avangard* to study the abundance and distribution of gray whales in 1979, large quantities of grays were confirmed up to 100 miles from shore over depths of 50 m (Fig. 2). On October 19 at 67°47′N and 172°72′W, 260 whales were counted. All of these animals were large, and they swam as singles or in groups of 2 to 3 animals as they do in other portions of their summer range. Occasionally (eight observations), compact groups of 5 to 6 animals were observed. The largest group contained 13 whales. Large concentrations of whales (70 animals) were encountered in the region of King Island, and on October 25, 50 whales were counted north of Saint Lawrence Island. A total of 411 whales was counted during this cruise.

The results of the second Soviet–American expedition on the R/V *Razyashchy* contributed substantially to our present-day understanding of the distribution of whales in these regions (Fig. 2). Whales were first encountered in the coastal regions of Long Strait and in the eastern part of the East Siberian Sea. Large groups were encountered in the region of Cape Dvukh Pilotov (Cape of Two Pilots), and a smaller quantity was near Cape Shmidta. At the end of September, gray whales were encountered near the coastal shelf of the East Siberian Sea from Cape Yakan to Cape Billings and further west. The westernmost sighting of gray whales was at 178°30′E. The results of this cruise defined the boundaries of the gray whale distribution and identified locations of aggregations of whales in the Chukchi Sea 100 miles from shore at approximately 67°40′ to 68°15′N and 169°40′ to 172°00′W. The approximate number of whales in this region was ~2000 animals, although undoubtedly these data are only approximate and demand more precise determination. Because 588 gray whales were counted over a 4-day period, it is apparent that gray whales are abundant in this area. During the 1980 cruise 1021 gray whales were counted in this same area.

Information gathered during the 1979 and 1980 cruises confirmed that the gray whale fall migration out of the summer grounds begins in the middle of October and ends with the formation of the ice sheet. Newly pregnant females are the first to enter the summer grounds and the last whales to leave the Chukchi Sea, departing with the polar whales or bowheads (*Balaena mysticetus*).

The program of cruises on board the Soviet vessel R/V *Enthusiast* in 1982, which included American scientists, differed from the 1979 and 1980 cruises in that it started earlier (July 15) and covered a wider area in the Chukchi Sea (to 158°W) (Fig. 3).

The 1982 research may be divided into three stages. During the first stage of the work (from July 23 to August 8), gray whales were encountered in groups of 4 animals on July 25 north of Saint Lawrence Island. Upon entering the Chukchi Sea on July 27 between the settlements of Uelen and Inchoun, groups of 2 to 20 gray whales were encountered. That same day 300 gray whales were counted in an area of approximately 120 square miles north of Cape Serdtse Kamen. The center of this aggregation contained a dense group of 70 to 80 whales, all of which were feeding intensively. The following day, three groups of 40, 20, and 60 animals, respectively, were discovered

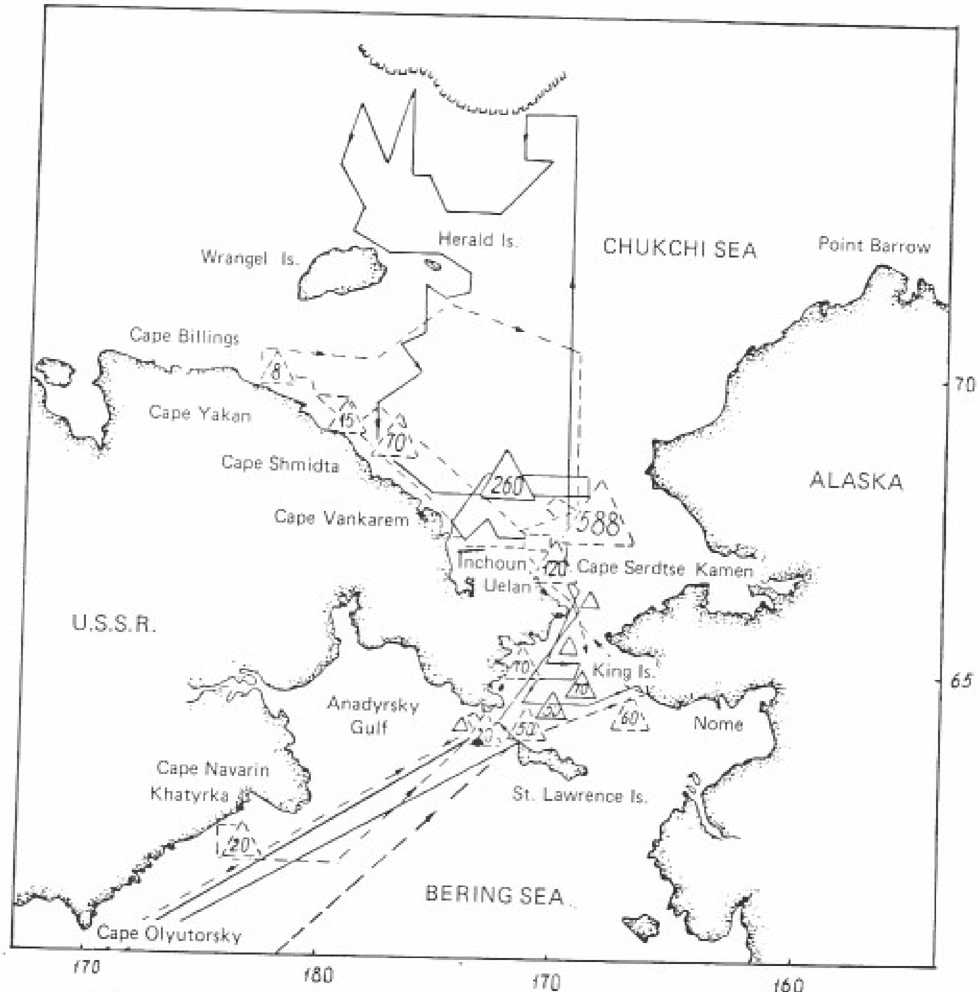

Fig. 2. *The distribution of gray whales and the routes of the R/V Avangard and R/V Razyashchy in 1979 and 1980. Symbols: solid arrow, route of R/V Avangard, 1979; broken arrow, route of R/V Razyashchy, 1980; zigzag area at top, ice edge in October, 1979. Numbers in triangles are counts of whales.*

between Cape Serdtse Kamen and Cape Vankarem. No gray whales were encountered at the ice edge to the west–northwest at Herald Island in the Chukchi Sea. On August 4 near Point Barrow (71°08′N 158°19′W), a group of 40 gray whales was encountered, our easternmost sighting of gray whales. Dense ice forced the ship to turn to the west–southwest where a group of 200 gray whales was encountered.

During the second stage (August 6–25), the ship traveled to the southwest and encountered a group of 60 gray whales in the same region. No large groups of whales were seen while traveling in a southerly direction along the coast of Alaska. Significant numbers of gray whales were again encountered in the same regions of the Chukchi coast visited during the first stage of this cruise: two groups of whales numbering

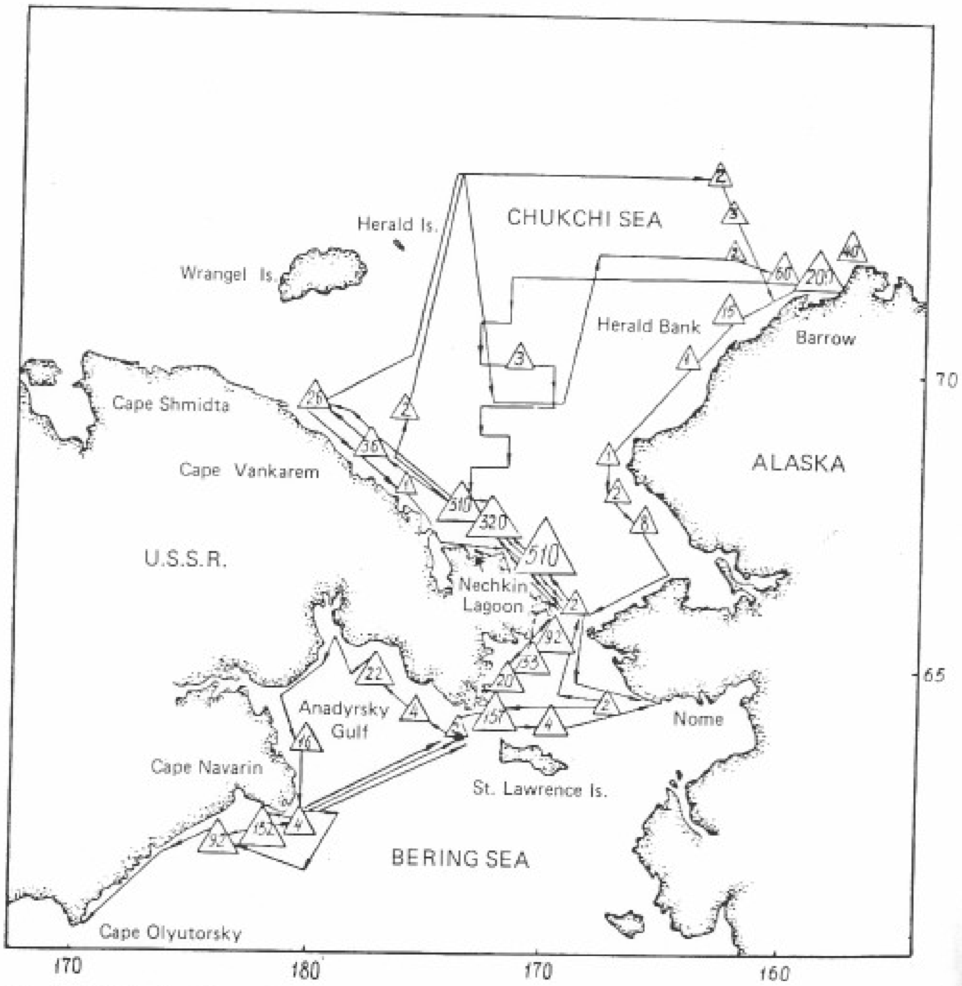

Fig. 3. *Distribution of gray whales and the route of R/V* Enthusiast *in 1982. Numbers in triangles are counts of whales.*

approximately 90 animals each were encountered in the region of Cape Serdtse Kamen. No whales were encountered during a return visit to the ice edge north of the Chukchi Sea. Five animals, a pair and a group of 3, were encountered near the ice edge at 71°56′N and 161°47′W (Fig. 3). Only 3 whales were seen during the vessel's westward track in the central Chukchi Sea; these animals were encountered southeast of Herald Banks on August 20. On August 22–23, 190 whales were counted in an area of 1000–1100 square miles located at 68°24′ to 68°00′N and 172°174′W.

In the third stage (September 2 to October 13), a 12- to 15-mile coastal zone of the Chukchi Sea from the Bering Strait to Long Strait was investigated. Near Cape Shmidta, two groups of 13 and 10 gray whales were sighted. Single whales and groups of 8 to 30 animals were observed in all the traditional areas near Cape Shmidta and Cape Dvukh Pilotov. From Nechkin Lagoon to Cape Shmidta, 259 whales were encountered during a 2-day period. Three whales were encountered at the westernmost point of the survey at the edge of the ice near Long Strait (69°27′N and 179°19′E).

Groups of 2 to 20 gray whales were encountered throughout the northern part of the Bering Sea from Cape Dezhnev to Arakemchechen Island. Near Cape Chaplino, 127 whales were counted in a 120- to 140-square mile area, and approximately 60 whales were encountered in the coastal waters of Anadyrsky Bay. At the end of September near Cape Navarin (in the region of Maino-Pilgyn), a gathering of 130 whales was observed, and in the region of Khatyrka ~90 whales were seen. This cruise confirmed the continuous distribution of gray whales in these areas. In all, 2142 whales were counted during the 1982 cruise.

Discussion and Conclusions

Studies of the Chukotka–California population of gray whales in their summer grounds have been limited basically to the collection and analysis of material generated by the whaling industry and to nearshore observations where these whales were collected. As the result of the systematic study conducted according to the Soviet national plan, as well as the joint Soviet–American program, the morphobiological aspects of the gray whale were significantly investigated and new information was obtained on the summer habits and distribution of these whales.

Analysis of the information collected over the last few years on the abundance and distribution of the Chukotka–California population of gray whales indicates that their summer grounds contain regular aggregations of animals in specific areas determined by their forage (prey) distribution. It has been established that in the Chukchi Sea, a significant part of which is relatively shallow, gray whales form aggregations a great distance from shore (in part up to 180 km) to the north of Cape Serdtse Kamen. Thus, gray whales are not a coastal species of whales in the full sense of the word, but only inasmuch as shallow depths as a rule occur nearshore.

According to Tomilin (1957), gray whales do not go farther west than Cape Serdtse Kamen. According to the latest data, gray whales do form some of their largest aggregations in this area. Our observations indicated that the gray whales westernmost distribution is off the lagoons of Tenkergyn–Pilgyn (177°30′W) and that this defines the western boundary of their range (Berzin and Rovnin, 1966). Recent studies suggest that gray whales begin to be encountered in the Long Strait and the Eastern Siberian Sea along the edge of the pack ice. Our westernmost sighting of a gray whale was 178°30′E. This suggests that the western distribution of the gray whales is limited by the pack ice, and because of the increase in the population the whales have recently expanded westward (Doroshenko, 1981). Studies of the eastern distribution of gray whales in the Chukchi Sea clearly suggest that their eastern distribution is also limited by pack ice. Our easternmost sighting of gray whales was at 158°19′W.

largest
aggregations
in Cape Serdtse

The indications in the literature of periodic penetrations of gray whales into the high latitudes near Herald and Wrangell Islands is not supported by contemporary information. Additionally, replicate surveys of the central and northern regions of the Chukchi Sea have demonstrated an absence of whales in a large area of this basin; the only exception was the sighting of a small group of whales in the shoal water to the southeast of Herald Bank in the central Chukchi Sea (Fig. 3). The extreme northernmost sighting of gray whales was in the western area at 69°27′N and on the east at 72°N.

Information on the abundance of gray whales (in groups of 100 or more) in the coastal regions to the south of Cape Navarin (Tomilin, 1957; Berzin and Rovnin, 1966) relate to the period of commercial whaling. Up until the 1970s only a few gray whales were ever encountered in these areas during the summer. Only during the migration were sightings of gray whales indicative of an increase. Gray whales have not been seen south of Glubokaya Bay for the past 20 years, and this latitude (61°12′N) is considered the southern limit of gray whale distribution along the northwest coast of the Bering Sea. Frequent recent observations of large aggregations of gray whales south of Cape Navarin, near the Maino–Pilgyn lagoon, the settlement of Khatyrka, and others, along with the discovery of gray whales near Cape Olyutorsky, is indicative of the increase of the population of whales and the southward expansion of their range to 60°N. The distribution and southern limit of the gray whale's summer grounds on the eastern shelf of the Bering Sea are not known.

The extrapolation of the census counts of gray whales in the areas investigated in 1982 allowed the calculation of the first numbers of whales arriving on the feeding grounds, although these first estimates are undoubtedly imprecise and should be improved. Approximately 10,000 gray whales inhabit an area of 45,000 square miles of the Chukchi Sea during the summer, according to V. N. Kolesnikov, and within a 14,000 square mile area of the northwest and northern part of the Bering Sea there are approximately 3,300 to 3,500 whales. As previously mentioned, we have no data on the numbers of gray whales in the eastern part of the Bering Sea. Previous information suggests the benthic communities in these areas are relatively poor, and it is unlikely that any large quantities of whales live in these areas. If one postulates a minimum number of 1,000 whales, then we may assume that approximately 14,500 to 15,000 gray whales inhabit the northern waters of the Bering and Chukchi Seas to feed during the summer. If this is compared with current American estimates of 17,000 whales in the population (Chapter 10, this volume), then we may assume that approximately 2,000 whales linger in the winter range and along the migratory route.

K statement

The Chukotka–California population of gray whales inhabits a limited and relatively easily studied area and has reestablished its abundance, following its catastrophic decline, to a current population size nearing the present carrying capacity of the ecosystem of the North Pacific. Because most of the biological parameters of the gray whale have been studied more intensively than for any other species of great whale, the gray whale may be considered a model population. Research on the Chukotka–California population of gray whales that inhabit the territorial waters of several nations need to be coordinated by all nations in all portions of its range, from the winter calving grounds, along the migratory route, and in the summer grounds. This is within our present technical capabilities and is in the best interest of the species.

Summary

This chapter presents the results of Soviet studies on the distribution and abundance of the Chukotka–California population of gray whales on their summer grounds between 1968 and 1982. Aerial and vessel observations established that gray whales regularly concentrate in the same general areas of the Bering and Chukchi Seas. The formation of permanent groups was observed at distances up to 100 nautical miles or more from the shallow coastal regions of the Chukchi Sea. Large aggregations of whales were encountered on the area's eastern boundary near the ice at Point Barrow. The area occupied by gray whales has expanded in a westerly direction and they have appeared in the Eastern Siberian Sea. An increase in abundance of a permanent population of gray whales was noted in the coastal zone to the south of Cape Navarin. Gray whales have appeared for the first time in several years near Cape Olyutorsky. These studies have defined more exactly the boundaries of the gray whale's summer habitat. Population estimates of the number of gray whales summering in the Bering and Chukchi Seas are between 14,000 and 15,000 animals, of which 10,000 inhabit the Chukchi Sea. The detailed information available for the Chukotka–California population of gray whales is the result of many years of multidisciplined investigations by Soviet and American specialists and allows us to consider a model for this population of great whales.

A Review of Russian Research on the Biology and Commercial Whaling of the Gray Whale

Alexey V. Yablokov and Luydmila S. Bogoslovskaya

Introduction

Scientific study of the gray whale (*Eschrichtius robustus*) in the Asiatic waters of the north Pacific was begun in the eighteenth century by S. P. Krasheninnikov (1755) and was renewed episodically in subsequent years by Ditmar (1890–1900), Vasil'yev (1891), Grebnitskii (1902), and Suvorov (1914). Gray whale research became specialized between 1933 and 1936 during the period of active pelagic whaling in the Bering Sea by the Soviet fleet *Aleut* (Zenkovich, 1934a,b,c, 1935a–d, 1937a,b,c, 1938a,b; Tomilin, 1937a, 1946). The results of research of the whaling industry by Soviet scientists were summa-

ISBN 0-12-389180-9

rized in the work of Sleptsov (1952), Zenkovich (1952), Tomilin (1957, 1962), and Klumov (1963).

Following World War II, gray whale research was principally conducted in association with aboriginal whaling in the waters of Chukotka Peninsula, mostly the opportunistic research of Zimushko (1969a,b, 1970a–d, 1972a,b; Zimushko and Lenskaya, 1970; Zimushko and Ivashin, 1980). In recent years, various aspects of gray whale research have been explored by the scientists of TINRO (Pacific Ocean Institute of Fisheries and Oceanography): Berzin (1974, 1978), Berzin and Kuz'min (1975), Berzin and Rovnin (1966), Berzin and Vladimirov (1981), Blokhin (1979, 1981), Blokhin and Pavlyuchkov (1981), and Doroshenko (1981). Additional research has been conducted by members of the Academy of Sciences of the U.S.S.R. and Magadanrybprom: Votrogov and Bogoslovskaya (1980), Bogoslovskaya and Votrogov (1981), Bogoslovskaya *et al.* (1981a,b, 1982), and Bogoslovskaya and Lemberg (1979), Bogoslovskaya et al. (1981b).

The limited volume of this contribution does not allow us to describe in detail the results of Soviet studies on the gray whale, which have been presented in more than 80 scientific publications, or even to mention all of them. Our main goal was to summarize data that is not well known or is mostly lacking in the English scientific literature.

Okhotsk–Korean Population

According to data compiled by earlier researchers, the whales of this population and the humpback whales (*Megaptera novaeangliae*) were very common and even abundant in the coastal waters of the northern part of the Okhotsk Sea and off the western shores of the Kamchatka Peninsula (von Ditmar, 1890–1900; Krasheninnikov, 1755; Vasil'yev (1891) indicated that the main mass of these whales migrated twice each year along the shores of the Far East Seas. Gray whales penetrated into the Okhotsk Sea from the Japanese Sea through the Tartar Strait and probably through Laperuz Strait (Sleptsov, 1961b); relatively recently they have been observed occasionally in Akademiya and Sakhalin Bays (Sleptsov, 1952).

Berzin (1978) summarized all the scattered data on the Okhotsk–Korean population of the gray whale, their wintering grounds with indications of their southern borders, their feeding grounds, and migration. He also commented on the incidental sightings of this animal in the Okhotsk Sea and ascertained the catastrophic condition of the entire population (Berzin, 1974). Solitary gray whales were encountered in 1967 and 1974 in the coastal waters of the Okhotsk Sea (Berzin and Kuz'min, 1975). The gray whales were observed in Peter the Great Bay: in July 1978 near Vladimir's Bay (one whale) and at the end of April, 1979 near Furugelm Island (two whales) (L. M. Votrogov, personal communication). Aerial surveys of the northwest coastal part of the Okhotsk Sea in the summer of 1979 demonstrated an absence of gray whales in the Sakhalin–Shantar region (Berzin and Vladimirov, 1981). Zoologist M. K. Maminov encountered one gray whale near the southeastern tip of the Kamchatka Peninsula at the beginning of October, 1979. Berzin and Vladimirov speculated that this individual was from the Japanese portion of the

Okhotsk–Korean population and possibly part of an independent population that breeds in the inner Sea of Japan. They believed that this population migrates along the eastern shores of the Japanese Islands where sightings of gray whales were previously recorded (see Chapter 3, this volume). The number of whales in the Okhotsk–Korean population prior to the beginning of the whaling industry for this species was estimated to be 1,500–10,000 animals. Contemporary censuses indicate there are no more than 100–200 animals remaining (Berzin and Vladimirov, 1981). According to Berzin (1978), the size of the Okhotsk–Korean population has diminished to its minimum; they are not recovering and their numbers continue to decline. Therefore, any whaling of this population would be catastrophic to their survival and should be banned.

Chukotka–California Population

MIGRATIONS

The spring migration of the gray whale is extended in time (Sleptsov, 1952, 1961a; Berzin and Rovnin, 1966) and is closely related to the ice condition and direction of the ocean currents (Fedoseev, 1981; Votrogov and Bogoslovskaya, 1980; Bogoslovskaya and Votrogov, 1981). These authors believe that there are several independent migratory routes of the gray whales; in the beginning of May the gray whales appear simultaneously and independently in two different regions divided by the vast area covered with ice, one near the coast of Koryak from Cape Khatyrka to Cape Navarin and the other at the southeast tip of Chukotka Peninsula in the waters between the settlement Sireniki, Cape Chaplino, and Saint Lawrence Island. Apparently animals utilize the powerful streams of the Poperechny current for their migratory movements. These streams deviate on the northwest from the Aleutian Islands and flow toward the permanent coastal polynya (an unfrozen patch of water in the midst of ice) which form in these areas (Votrogov and Bogoslovskaya, 1980). Votrogov and Bogoslovskaya (1980) proposed one more, the southernmost migratory route towards the Asian coast, along the Aleutian range and the Commander Islands. This author's opinion on the existence of possible migratory routes is based on the findings by Grebnitskii (1902) and Barabash-Nikiforov (1938) as well as some other results of recent findings (Votrogov and Bogoslovskaya, 1980).

However, the main core of the gray whale population stock moves north along the shores of North America and usually arrives in the Bering Strait by the end of May. Whales are distributed along the cracks of ice throughout the large water areas free of ice packs; one part of the herd begins its movements southward along the Asiatic coast and another part penetrates into the Chukchi Sea where the whales split off into two opposite directions, west and east, towards the Chukotka Peninsula and Alaska (Tomilin, 1937a,b; Berzin and Rovnin, 1966; Fedoseev, 1981; Votrogov and Bogoslovskaya, 1980).

The massive departure of whales from the northern seas during the fall migration begins in the middle of October (Kuz'min and Berzin, 1975; Doroshenko, 1981) to November of some years (Sleptsov, 1961a), when they share these waters with the bowhead whale (*Balaena mysticetus*). In the region of Sireniki polynya, near leads in the ice, and at the entrance to the shore of Providenya Bay, some gray whales hold out until mid-November and sometimes until mid-December. Local natives indicate the gray whale leaves the Koryak Coast by September (Bogoslovskaya *et al.*, 1982). Most of the migratory routes of the gray whales are through coastal waters, and it remains unclear whether the same animals utilize the same routes during the spring and fall migrations.

DISTRIBUTION ON THE FEEDING GROUNDS

Practically all researchers involved in the study of summer distribution of the gray whales were involved in this problem, including Zenkovich (1934a, 1937a) and Tomilin (1937a, 1957). In Soviet waters, the main concentration of the gray whale can be observed in two different regions: the southern area, from Cape Olyutora to Cape Barykov and the Lagoons of Tymne in the Bering Sea, and a northern area, from the Kresta Bay in the Bering Sea to Cape Sertse-Kamen' and the lagoon of Neshkan in the Chukchi Sea (Arsen'yev, 1961; Sleptsov, 1961a; Berzin and Rovnin, 1966; Zimushko, 1970a; Votrogov and Bogoslovskaya, 1980). Based on the data of Berzin and Rovnin, the gray whales in the Chukchi Sea do not go further west than the lagoon of Nutang'ye and Mayino-Pylgyn or further north than 69° latitude, although Sleptsov (1952) indicated that in some years the gray whales may move along the ice leads and drifting ice as far as Wrangel Island (Ostrova Vrangelya).

Recently, Doroshenko (1981) encountered gray whales for the first time in the coastal waters of the Long Strait and the eastern portion of the Eastern Siberian Sea, from Point Yakan to Point Billings. In addition, he discovered in the Chukchi Sea a large concentration (approximately 2000 whales) of animals about 160 km offshore. This concentration was located between 67°40′ and 68°15′N and 169°40′ and 172°W. The author believes that gray whales have expanded their distribution to the west as a result of the continued increase of the Chukotka–California population.

As a rule, gray whales distribute themselves in shallow waters near the shore and rarely go beyond 35 to 50 km offshore (Zimushko, 1970a; Votrogov and Bogoslovskaya, 1980). They choose to frequent areas where the salinity of the water is somewhat lower than 30%, where the wind turbulence reaches to the bottom, and the oxygen content is near 150% (Kuz'min and Berzin, 1975). They congregate and remain in areas where the concentration of benthic organisms is not less 100 g/m^2 (Berzin and Povnin, 1966). In the summer feeding grounds, the whales are unevenly distributed along the Asian coast (Fig. 1). The whales are constantly moving; their distribution in areas 3-21 varies not only from year to year, but even from month to month within the same season, as a result of constant local migrations of the gray whales between the feeding grounds (Votrogov and Bogoslovskaya, 1980; Bogoslovskaya *et al.*, 1981a, 1982).

One can assume that at the present time the populations of California and Korean gray whales do not overlap (Zenkovich, 1937a; Zimushko, 1972b; Zimushko and Ivashin, 1980); however, the question remains open whether or not these two populations were

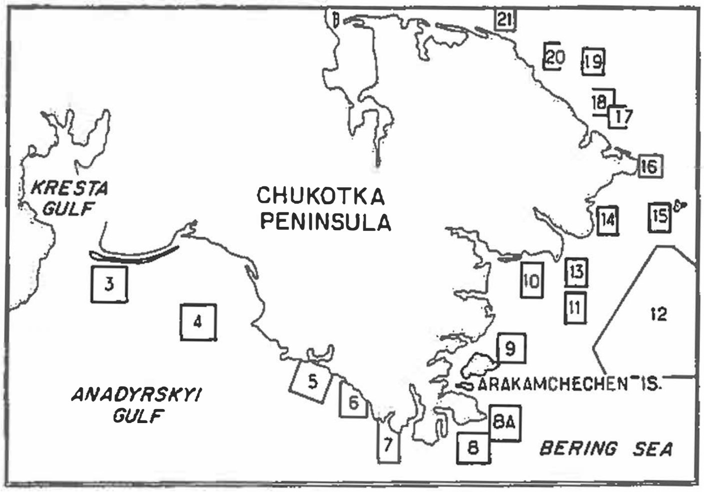

Fig. 1. *Feeding grounds of the Chukotka–California gray whales in Soviet waters, summer to early autumn. From whaling cruises 1964–1980, concentrations of whales have been discovered in areas 3–21 while other regions remain "empty."*

mixed in the past; the data of earlier studies indicated that the gray whales were usually common in the waters around Kamchatka Peninsula and the Commander Islands (Krasheninnikov, 1755; von Ditmar, 1890–1900; Grebnitskii, 1902).

There is a great deal of opinion in the literature that the gray whales of all ages, including both males and females, spend their summer in the Bering Sea. At the same time a great age differentiation of the stocks is also observed: young animals, as a rule, congregate around the Koryak coastline, from the Glubokiy Bay to Cape Navarin, but the adult groupings are in more northern waters, around Chukotka Peninsula (Zenkovich, 1934a, 1937a; Tomilin, 1937a; Sleptsov, 1952). However, working with the results obtained from the whaling industry from 1969 to 1981, as well as from direct observations, predominantly females and young whales distribute themselves mainly in the shallow coastal waters, but the large whales are found further offshore in waters up to 50–60 m deep (Votrogov and Bogoslovskaya, 1980). Moreover, there are four regions where the small animals are predominant in numbers: near Achechen lagoon, and at the mouth of Kurupka River (regions 5 and 6 on Fig. 1), near Cape Kygynin of the Arakamchechen Island (region 9 on Fig. 1), and the west portion of the Mechigmen Bay, including region 10 and the adjacent portion of the Mechigmen Inlet as well as the northern area from Cape Nunyamo, near Cape Chaplino (Bogoslovskaya *et al.*, 1981; Bogoslovskaya *et al.*, 1982). Out of 514 adult gray whales taken from the needs of the aboriginal population of Chukotka Peninsula, 69.8% were females and 30.2% were males (Rezvanov, 1981).

It is important to mention that Zenkovich (1954, 1969) reported two sightings of gray whales around the Chilean–Peruvian coastal waters of South America. This observation may support the hypothesis that some part of the gray whale population may cross the equator in the search for suitable feeding grounds.

ABUNDANCE

In 1942 the Soviet whaling vessels sighted 1197 gray whales within 46 days in the area of Anadyr Gulf and the Bering Strait (Vadivasov, 1947). In August and September of the same year, P. G. Nikulin counted 1154 whales from shore stations in the same regions, although it was known that only in August 1012 animals were observed. According to Vadivasov's data (1947) during the period between 1932 and 1941, whalers would sight every year on the average about 466 gray whales in 46 to 53 days of observations. Apparently, all animals observed belonged to the Chukotka–California population. We want to call attention to observations conducted by Zenkovich (1937a, 1954); on September 3, 1936 he encountered in the Chukchi Sea a herd of 200 gray whales, which formed five or seven different groups. Later, in one of the fijords of the Koryak coastline he counted more than 60 gray whales cleaning themselves of their ectoparasites in the brackish water.

Sleptsov (1961a) believed that by 1946 there were not less than 1500 gray whales in the Chukchi Sea and in the northwestern part of the Bering Sea. In this very same region, the author observed about 1200 gray whales from August 21 until September 11 of 1948 while aboard the whaling vessel *Purga*. He believes that the population of gray whales doubled by the beginning of 1960 and that their numbers reached 2500–3000 individuals. In 1962, 1033 gray whales were sighted in the coastal waters of the Chukotka Peninsula (Berzin and Rovnin, 1966).

V. V. Zimushko conducted three aerial surveys of the Chukotka–California population of gray whales. From July 10 to July 30, 1968, he observed 124 whales in 107,900 km^2 with an average distance from the Koryak shore and Chukotka Peninsula of 35 km; from these counts the population was estimated to be 4800–5000 whales (Zimushko, 1970a). During 159 hours of aerial surveys between August 3 and 23 and October 17 to 27 they surveyed an area of 215,932 km^2 within 240 km offshore and calculated a population estimate of 7700–7800 whales. From September 24 to 25 and October 1–9, 1975, V. V. Zimushko counted only 2000 gray whales during 89 hours of aerial surveys over 162,000 km^2 as much as 250 km from shore. The author correlated these counts with the migration of the whales during this period (Zimushko and Ivashin, 1980).

Zimushko's last population estimates agreed with the recent counts conducted during scientific expeditions in September and October, 1974, when the total number of gray whales estimated in Soviet waters was 1800–2000 (Kuz'min and Berzin, 1975). In the spring of 1978, Fedoseev (1981) conducted aerial surveys from an elevation of 100 m at different locations along the Koryak coast. He counted 30 gray whales, which, when extrapolated from these aerial surveys, suggested that not less than 1200 gray whales occupied the areas in the Bering Sea clear of ice at the end of May.

Surveying from the vessel *Zvezdnyi*, I. M. Votrogov counted 2200 gray whales between the end of June and the beginning of November, 1980 and 1438 whales from the second half of August until November 9, 1981 (Bogoslovskaya *et al.*, 1982).

Comparison of all these data obtained during aerial and vessel surveys allowed us to assume that from the time of the complete abolishing of commercial boat whaling, that is, by 1946, the numbers of the Chukotka–California population were not so low as was suggested by the majority of researchers, and accordingly, the increase of numbers of animals within the period of 1940 to 1960 was not as significant as believed. For example, Blokhin (1979) estimated a rate of increase of 18% per year.

MORPHOLOGY

The average measurements of the gray whale body are summarized in Table I. In spite of some scatter in the data, we may assume that on the average an adult female whale is approximately 0.3 m longer than a male.

Zimushko (1972b) compared pecularities of the external morphology of Chukotka–California and Okhotsk–Korean (data by Andrews, 1914) populations of gray whales. This comparison raises some doubts in the previous conclusion that the whales of the Okhotsk–Korean population are generally larger than individuals of the Chukotka–California population. On the other hand, the distance from the tip of the rostrum to the base of the pectoral fins, from the tip of the rostrum to the eye, the maximum width of the pectoral fin, and the length of the baleen plates were statistically greater in the Okhotsk–Korea whales than similar measurements in Chukotka–California whales. Also, the whales from the waters of Chukotka Peninsula have smaller numbers of baleen plates and on the average fewer throat grooves. The authors at present believe that these differences may indicate the existence of two distinctive groups of gray whales in the northern Pacific, which may allow them to be designated as subspecies.

Zimushko (1972b) revealed that male gray whales differed from females in the relative size of the body and head. In addition, females have significantly longer tail sections in relation to the smaller width of the flukes. The average number of baleen plates in both sexes was practically the same: 323 ± SE 4.9 in females ($n = 111$) and 322 ± SE 3.4 in males ($n = 70$).

The vibrissae of the gray whale embryos are distributed almost equally on upper

Table I
Average Length of Gray Whales Taken in the North Pacific[a]

Males (m)	Females (m)	Comments
11.3 (8.5–14.3) $n = 88$	11.9 (8.6–15.0) $n = 104$	Pelagic whaling in the Bering Sea, 1933–1936
11.5 (8.2–13.0) $n = 39$	12.2 (7.7–14.2) $n = 55$	Coastal (in-shore) whaling off the Chukotka Peninsula, 1965
12.2 (9.3–14.1) $n = 26$	12.2 (8.8–13.8) $n = 15$	Same as above, 1966
12.6 ± SE 0.09 $n = 70$	12.9 ± SE 0.07 $n = 111$	Same as above, 1965–1971

Table II
Average Number of Vibrissae on the Head of the Fetus of the Gray Whale[a]

	Upper jaw	Lower jaw
Males	131	141 (117–165)
Females	155	131 (100–172)

[a] From Zimushko (1972b) and Zimushko and Ivashin (1980).

and lower jaws (Table II). It was learned that the total number of vibrissae is slightly less in near-term fetuses, and their number is significantly less on the upper jaw of the adult whales. Thus, Tomilin (1937c) counted just 60 vibrissae on the upper jaw and 120 vibrissae on the lower jaw of an adult female.

Bogoslovskaya and Lemberg (1979) showed that the structure of the gray whale brain is typical of that of other baleen whales; except for the more simplified picture of the arched convolutions, the brain of the gray whale resembles the brain of the sei whale (*Balaenoptera borealis*).

Zimushko (1970d) examined the reproductive system of the gray whale, including 70 ovaries collected during 1965–1968 in the waters of Chukotka Peninsula. He describes in detail the morphology of the ovaries (ovaries of sexually mature females weighed from 318 to 1830 g, but together with the corpora lutea were up to 4820 g) and also the stages of development of follicles and the corpora lutea. Zimushko concluded

Table III
Dimensions of Some Internal Organs of the Gray Whale[a]

Organ	Size	Comments
Heart	131 ± 16 SE (90–166) kg	Sexually mature males and females
	172 kg	Pregnant female 13.4 m
Liver	519 (455–580) kg	Sexually mature males and females
Spleen	3.2 (2.5–4.3) kg	Same
Lungs	333 kg	Same
Testes	23 (14–27) kg	Sexually mature
	50–74 cm length	
	43 kg	Both testes, 12.1 m
	54 kg	Both testes, 13.6 m
Brain	4376 kg	Pregnant female, 13.4 m
	4200 kg	Unknown sex, 11.0 m
	4300 kg	Unknown sex, 12.0 m
Intestine (total length)	177.3 m	Pregnant female, 13.4 m
Urinary bladder (maximum volume)	12.0 liters	Adult male and female

[a] From Bogoslovskaya and Lemberg (1979), Zenkovich (1937b), Zimushko (1972b), and Zimushko and Ivashin (1980).

that the atrophied follicles remain in the ovary for a relatively short time compared to the traces of the corpora lutea and scars from ovulation; between these, there is a distinct histological difference.

There is only one known instance of the complete weighing of a gray whale by Soviet researchers (Zenkovich, 1937b). This pregnant female, carrying a fetus 207 cm long and weighing 126 kg, was caught on August 19, 1936 in the Bering Sea. The female's length was 13.35 m and she weighed 31,460 kg not including the weight of the blood; the blubber weighed 9,100 kg; the muscles, 6,729 kg; the head, 1,692 kg; the lower jaw, 1,265 kg; the tongue, 1,278 kg; the vertebral column plus the ribs and scapulae (with remnants of the muscles), 6,163 kg; the pectoral flippers, 612 kg; and the internal organs, 4,493 kg. Zenkovich concluded that the approximate weight of a gray whale may be determined by $V = (L D^2)/3$ where L = the body length and D = its maximum height. Some measurements of the internal organs of the gray whale are presented in Table III.

In conclusion, on the morphological peculiarities of the gray whale we wish to note that according to Tomilin's data (1937a, 1957) the depigmented white spots, some of which develop from the attachment of parasitic barnacles (*Cryptolepas rhachianecti*) can be repigmented following the removal of the barnacles. As this process continues on different parts of the body at different times, the general color of the whale's skin is mottled with some dark and some light areas. In 1957 Tomilin reported sighting a partially albino gray whale in the Bering Sea. The anterior part of the body of this whale was completely white.

GROWTH AND AGE

Among the gray whales studied by the Soviet researchers in the waters of the North Pacific, they came across whales ranging from 7.7 to 14.3 m long. After comparing whale

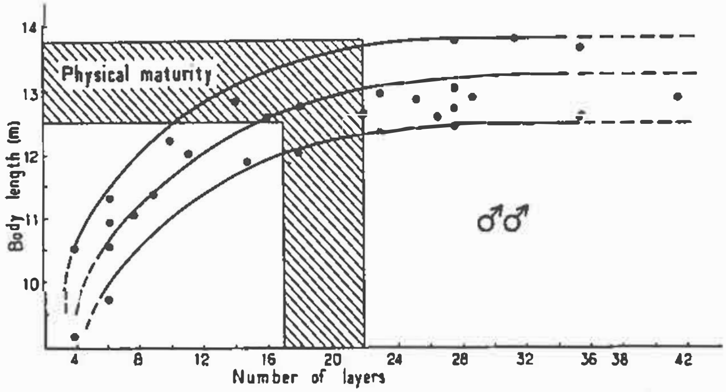

Fig. 2. *Correlation between the body length and the number of ear plug layers (1 layer = 1 year) of male gray whales (n = 29), which allows the determination of the age of physical maturity. (Data by Zimushko (1970b) and Zimushko and Ivashin (1980).) Lines are theoretical curves fit to the mean values (middle line), largest values (upper line), and smallest values (lower line). Hatched area indicates the range of absolute values for body length and number of ear plug layers for the onset of physical maturity.*

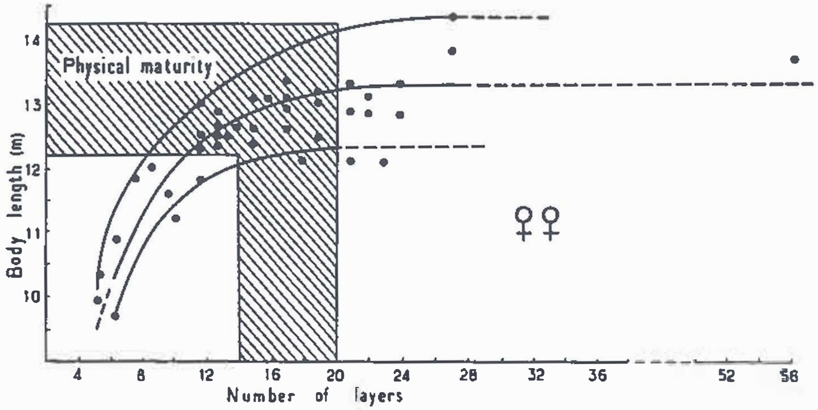

Fig. 3. *Correlation between the body length and the number of ear plug layers (1 layer = 1 year) of female gray whales (n = 41), which allows the determination of the age of physical maturity [Data by Zimushko (1970b) and Zimushko and Ivashin (1980).] See Fig. 2 for symbol designation.*

body size to the number of layers in the wax ear plugs of whales (one layer comprises one light and one dark lamina), Zimushko (1970b) concluded there is no significant difference in the rate of growth between male and female whales under 12.2 m; the average body length of males and females at the age of 1 year is 8.9 meters (range 8–9.5 m), and at 2 years it is 10.4 m (range 9.5–10.7 m). Further growth of both males and females is slower (Fig. 2), without considering the slightly larger dimensions of the females (sexually mature females on the average are larger than males by 0.3–0.4 m). The 3-year-old whales average about 11 m (range 10.7–11.6 m).

The analysis of relatively large amounts of data, obtained by Zimushko in the Chukotka Peninsula coastal waters in 1965–1976 and summarized in Figs. 2 and 3, allow us to estimate the age of physical maturity of the gray whale. It is determined by the cessation of the growth rate of the body and occurs in males when they reach an average length of 13.2 m; in the case of some smaller animals, it occurs when they reach a length of 12.5 m. This occurs when the animals reach an average age of 19 years (range, 17–22 years), when one considers that each layer of the ear plug is equivalent to 1 year of a whale's life. In females, physical maturity on the average occurs at a body size of 13.2 m, but apparently with a greater range among individuals (the smallest mature female was 12.2 m in length). The data indicated that the age of attaining physical maturity for females encompasses a range of 14 to 20 years, averaging 17 years. We want to add that the maximum number of layers in the ear plug of the gray whale was shown by Zimushko (1970b) to be 56 layers for a female 13.8 m long and 42 layers for a male of 12.9 m.

The data on the length of gray whale embryos and young whales, when presented as a circular graph, demonstrate the range of the size during embryonic growth and during the first year of life (Fig. 4).

Measurements conducted by Zimushko (1972b) on 12 skulls of the gray whale showed that with age the length of the rostrum increased relative to the length of the lower jaw.

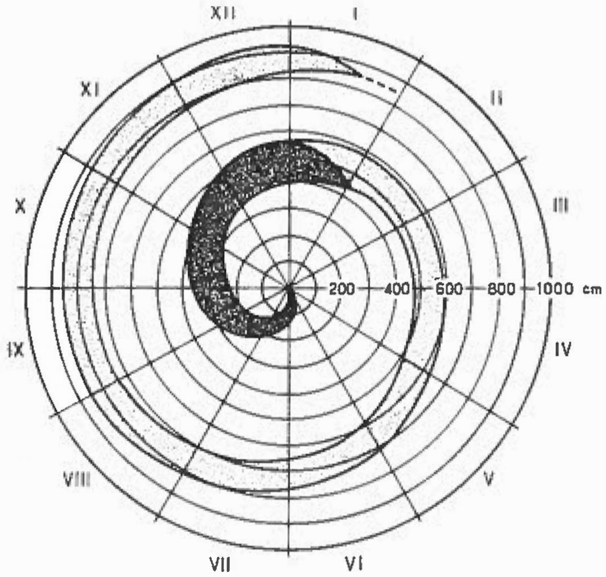

Fig. 4. *Growth of gray whale embryos and neonates according to combined data by Tomilin, 1937c; Zenkovich, 1937a; Rice and Wolman, 1971; and Zimushko and Ivashin, 1980. HEAVY STIPPLING indicates embryo length during pregnancy; embryos 25–140 mm long (not shown) can be found in whales taken in the second half of February (Rice and Wolman, 1971). LIGHT STIPPLING shows observed dimensions of body length during the first year of life. Roman numerals are months from Jan.–Dec.; Arabic numerals are body length in centimeters.*

REPRODUCTION

Attainment of sexual maturity occurs at different ages in female and male gray whales. Sexual maturity in females was determined by the presence of an embryo, corpus luteum, corpus albicans, or evidence of ovulation. Age of sexual maturity of females varied from 8 to 12 years (8–11 layers in the earplugs) when they reached a length of approximately 12 m (Zimushko, 1969b; Zimushko and Ivashin, 1980). The smallest female with a corpus of pregnancy was 11.3 m long although one 12.5 m female had no corpora. The largest number of corpora (11) was found in a 13.2 m female, and the average number of corpora for mature females was 5.1 (Blokhin, 1982). Males aged 6 to 7 years were found to be either immature or mature whereas those males aged 8 years (not less than 8 layers in the earplugs) with lengths of 11.5 m were usually mature (Zimushko, 1969b; Zimushko and Ivashin, 1980). There was a considerable increase in size and weight of the testes when the body length reached almost 11 m (Zimushko, 1969a). The investigation of mature male whales collected from July to October revealed that males had no spermatozoids in their epididymides, indicating a marked seasonality of the mating condition in male gray whales (Zimushko, 1969a).

The sexual cycle in female gray whales is believed to last 2 years and includes copulation, pregnancy, lactation, and a resting period after reproduction. The duration of pregnancy is nearly a year (Tomilin, 1957). Bogoslovskaya *et al.* (1981) found that pregnant females are the first to arrive off Chukotka and they are the first to leave, which corresponds with the findings of Rice and Wolman (1971) that pregnant females were the first to begin the northerly spring migration to the summer range, and they were the first to arrive at the breeding grounds after the fall southerly migration. This migratory timetable is supported by the findings of Blokhin (1982) who reported that the percentage of pregnant females in the 1980 catches was highest in the summer (July) and steadily declined during the 4-month fishing season and was lowest in autumn (October).

Analysis of the correlation between the number of corpora lutea and ovulation in females of reproductive age showed that the average biennial rate of ovulation in physically mature females was 1.4 (Blokhin, 1981). It also was shown that the first ovulation in the young females results in pregnancy, since there were some females whose ovaries showed some signs of pregnancies but no signs of ovulation. On the other hand, there were ovaries that indicated multiple ovulations, but no signs of pregnancy. The overall ratio of pregnant to nonpregnant female whales was 1:1 and supports the 2-year reproductive cycle proposed by Rice and Wolman (1971). On the average, according to Zimushko (1972a) and Zimushko and Ivashin (1980), in females 12.0–12.5 m long the ratio between signs of ovulation and signs of pregnancy was 1:1; in females 13.0–13.5 m long the ratio was 2.5:1. If this finding can be confirmed in the future it may indicate that with maturity (age) the intervals between pregnancies increase.

It is very important to note that some lactating females could also be pregnant at the same time. Zimushko (1969b) encountered seven such females. The occurrence of females simultaneously pregnant and lactating may serve as an indirect confirmation that some females give birth yearly. Determining the exact number of these females is difficult because of the ban on whaling females with calves; collection of this material can only be accidental. However, during observations in the waters of Chukotka Peninsula from 1965 to 1968 about 20% of such females were encountered; this may indicate a relatively widely distributed phenomenon of simultaneous lactation and pregnancy among female gray whales.

In his work, Zenkovich (1938a) described the composition of the milk in lactating gray whale females taken in September (the time when lactation has usually ceased). The milk had a fat content of 53%, a water content of 40.6%, and a dry content of 6.4%. Based on Tomilin's (1946) calculation, during the period of nursing the calf consumes 36.6 kg of milk per day on the average; for the total lactation period this would be approximately 5000 kg of milk. In July to September 1965 to 1970 some nonpregnant females were found to be lactating and others had recently finished lactating (Zimushko and Ivashin, 1980). Blokhin (1982) reports that many of the nonpregnant females taken in October 1980 had large corpora and well developed mammaries, indicating that they had recently weaned their calves. From these data it appears that lactation lasts approximately 7 months and that gray whale calves are weaned when their body length is about 7 m (Zimushko and Ivashin, 1980). Examination of the stomachs of whales from 7.7 to 9.0 m long showed that they were feeding on amphipods. Ascidians, polychaetes, algae, and mud were also found in their stomachs (Zimushko and Ivashin, 1980).

FEEDING

Zenkovich (1934c, 1937a,b) and Tomilin (1937a) were the first researchers who determined that along the Asian coast the main food source of the California gray whales is benthic amphipods; while in the Bering Strait and the Chukchi Sea, they feed predominantly on *Ampelisca macrocephala* but near the Koryak shore they feed on *Pontoporeia* sp. Further study of gray whale feeding by Sleptsov (1952) determined the maximum volume of the stomach of the gray whale was 350 liters; Klumov (1963) compiled the first list of the food species of the gray whale which consisted of 17 different species of invertebrates.

Furthermore, a detailed study of the differences in the aspects of feeding by gray whales off the coast of Chukotka Peninsula was done by Zimushko and Lenskaya (1970) from the analysis of 70 stomach-content samples of gray whales between 1965 and 1969. Blokhin (1981) and Blokhin and Pavlynchkov (1981, 1983) collected stomach samples from 38 whales and Bogoslovskaya and Votrogov (1981, 1982) also sampled 230 stomach contents from whales taken between 1979 and 1980 by the whaling vessel *Zvezdnyi*.

The list of the prey species of the gray whale, based on the data from all authors, consists of 60 species of amphipods and 80–90 other species of invertebrates, as well as algae and significant amounts of sand or pebbles which are present in the stomachs of these whales at all times. According to data by Bogoslovskaya *et al.* (1981a, 1982) the primary prey species of gray whales are 18 species of amphipods from the 12 families of the suborder Gammaridae. No age or sex difference of these prey species has been determined (Zimushko and Lenskaya, 1970; Blokhin and Pavlynchkov, 1981, 1983), but there is a clear difference between the southern (from the Island of Kosa Meechken up to the Providenya Bay in the Bering Sea) and the northern (from the Cape Nunyamo in the Bering Sea up to the Cape Serdtse-Kamen' in the Chukchi Sea) regions of feeding according to the dominant species of amphipods (Fig. 1) (Bogoslovskaya *et al.*, 1981a, 1982). The same authors showed that the aquatic region between Providenya Bay and Cape Nunyamo is characterized mostly by the variety of composition of invertebrates; *Pontoporeia femorata* as a dominating species in the southern regions is gradually replaced by *Ampelisca macrocephala* in the northern regions.

Gray whales congregate in "feeding spots," regions where amphipods accumulate. These areas probably provide a main food resource for other marine mammals and other species as well. For instance, in the aquatic region near the walrus (*Odobenus rosmarus*) hauling-out ground on the Arakamchechen Island gray whales and walruses graze in close association (Bogoslovskaya *et al.*, 1981b, 1982).

Tomilin (1946) calculated that a single fully grown gray whale would consume between 379 and 2496 kg of benthic organisms within a 24-hr period. Recently Zimushko and Lenskaya (1970) determined a 24-hr feeding bout would result in the ingestion of 1200 kg of the food species, 300 kg of which would be freshly ingested. These same authors came to the conclusion that the Chukotka–California population would consume 850,000 tons of food species on their feeding grounds during one season. According to the type of feeding, Tomilin (1954) separated gray whales into absolutely specific groups of benthic foragers and provided a description of morphological characteristics indicative of their benthic feeding habits (head, oral cavity, filtering apparatus, etc.).

GROUPING AND SOCIAL BEHAVIOR

Many aspects of the behavior of whales are touched upon in the works of Zenkovich (1934a, 1937a, 1954), Tomilin (1937a,b,c, 1954, 1957), Sleptsov (1952, 1961a), Zimushko and Ivashin (1980), Bogoslovskaya *et al.* (1981a, 1982), and Bogoslovskaya and Votrogov (1981). These investigators reported that gray whales feed in small groups of 2–4 whales, or more often as single whales (commonly pregnant females). It is not unusual for a herd to consist of 30–40 animals and sometimes 100–400. During the times of such large congregations, lasting from 1–4 days, strange and unexplained behavior is observed which is presumed to be connected with courting and mating behavior, as has been suggested by Tomilin (1937a) and the whalers of the Chukchi Sea.

Zimushko stated (Zimushko and Ivashin, 1980) that in 1973, of 232 whales encountered 44% were single, 24% were in pairs and 13% were in threes; 13 groups of 4 and 12 groups of 5 were also sighted. Groups of 7 and 8 animals were encountered three times each; the largest congregation included 24 whales. In 1980 Bogoslovskaya and Votrogov (1982) encountered 2447 whales of which singles were 47%; pairs, 31%; threes, 13%; and other groupings 9%; correspondingly in 1981 from 1595 whales, singles included 65%, pairs, 25%, threes, 6%; and others, 4%. These observations were conducted from whaling vessels, small motor boats, and Eskimo kayaks.

Among the groupings, the pairs are the most frequent associations. Adult animals are very often strongly attracted to each other during grazing and migrating when they are constantly together and very close; they observe the same breathing regime, surfacing synchronously or with a slight difference in breathing rhythm. The adult animals help each other, often reaching self-sacrificing measures; also there is a mutual attachment between paired females as strong as between male and female (Bogoslovskaya *et al.*, 1982). Groups of larger than three animals are usually unstable. Sex composition of the groups varies: there are different types of pairs, female and male, two females, and two males. Trios include two females and one male (or vice versa), and in the groups of five animals there were two males (Zimushko and Ivashin, 1980; Bogoslovskaya *et al.*, 1982).

It is important to describe the relationship between the mother and the calf. Nursing apparently ceases when the calf reaches a length of 8.5 m, but 9.6-m juveniles were observed swimming with their presumed mothers although they (the juveniles) had been feeding on benthic organisms (Tomilin, 1937a). Bogoslovskaya et al. (1982) assumed that the majority of the young whales separated from their mothers in July to August and congregated in certain areas, usually shallow waters and lagoons. Zenkovich (1937a) pointed out an example when the mother whale attacked the whale boat of the *Uelen* whalers after they wounded her calf. The same authors indicated that when the mother whale is killed, the juvenile whale usually leaves; therefore, in the gray whales at this stage in the calf's life, there is a one-sided attachment of the mother to the calf.

Tomilin (1937a,b) and Zenkovich (1937a,b, 1954) described in detail [after von

Ditmar (1890–1900) and apparently Krasheninnikov (1755)} a specific migration of whales with heavy infestations of skin parasites into the freshwater lagoons and shallow waters off the Koryak coast. The whales entered the lagoons, and dozens of them filled the shallow lakes connected with the sea. Some whales were just lying on the sand bars; with the tide they would move out to sea, and begin to feed as if nothing had happened. Some whales would lie immobile at the surface not paying attention to the approaching boats or even prods of the oars, as if they were sleeping (Zenkovich, 1954).

According to the observations of the Eskimos of Naukan the gray whale is capable of getting off the sand bars if next to a deep channel. He then arches, pushing with the rostrum and tail into the ground, which is possible because of the free neck vertebrae (Sleptsov, 1952).

Many whalers consider the gray whale the most intelligent of all large whales. He knows how to leave when pursued, changing his course drastically or surfacing at the same place where he dove, zig-zagging, entering shallow waters to escape, or surfacing without blowing although revealing only their blowholes (Zenkovich, 1934a, 1954). While being pursued, the gray whales increase their usual speed from 3–4 knots to 7–8 knots (Tomilin, 1937c). They can hold on in the unfrozen patches of water among the pack ice and shallow ice fields and at the very edge of the Arctic ice (Sleptsov, 1961b; L. S. Bogoslovskaya and T. N. Votrogov, unpublished notes). Gray whales coexist peacefully with the other mammals inhabiting the Chukchi Sea. On the feeding grounds they are found with the humpback whales and walruses. For example, in region 9 near the largest hauling ground of the walrus on Arakamchechen Island, whales and walrus graze in very close proximity to each other. Observers never recorded any aggressive behavior between these two species (Bogoslovskaya *et al.*, 1981b). Some authors indicated that the gray whales feeding near the entrance to Providenya Bay do not react to or feel threatened by the passing of nearby boats. They ceased to feed and demonstrated evasive behavior after persistent pursuit by vessels, however.

The behavior of gray whales suggests a plasticity or flexibility which allows them to utilize successfully the entire variety of coastal resources, from subtropical to polar regions.

POSITION OF THE SPECIES IN THE ECOSYSTEM

The position of the gray whale in the North Pacific ecosystem is determined by its interrelationships with food organisms (see above), parasites, enemies, and commensals. Some of these relationships were studied by Soviet researchers for the Chukotka–California population.

Practically all whales observed in the wild or killed by commercial whaling are covered with parasites such as *Cryptolepas rhachianecti* and whale lice (*Cyamus scammoni, C. ceti, and C. kessleri*) (Tomilin, 1937b; Zenkovich, 1935a; Zimushko and Ivashin, 1980). All authors noticed that the majority of the parasites accumulated on the head, around the blowhole, on the jaws, in the regions of the anal and genital orifices, and on the fins. Gray whales enter (brackish) water in coastal lagoons and the mouths of rivers to get rid of these parasites. Apparently this cleaning procedure is very successful. In

1978, a great number of of large black whales (body length between 12.5 and 13.5 m) approached the Chukotka Peninsula coast; all of them were free of parasites (Votrogov and Bogoslovskaya, 1980).

Soviet helminthologists found new species of endoparasites of the gray whale, which included helminths, acanthocephalans, and trematodes (Treshchev *et al.*, 1969; Zimushko and Ivashin, 1980). Most of these helminths were found only in the intestines of the gray whale. Of all the whales studied by Zimushko, 68.3% were infested by the cestode *Priapocephalus eschrichtii*, 58.7% by the trematode *Ogmogaster pentalineatus* (up to 1000 organisms in one whale), and by the acanthocephalans *Corynosoma semerne* and *C. septentrionalis* (29.9%), *C. validum* (24.4%), and *C. strumosum* (9.7%); the trematodes *Orthosplanchus pigmaeus* and *O. plicatus* were found only once. There is a similarity between the helminth fauna of the gray whales and pinnipeds, especially between the walrus and the bearded seal (*Erignathus barbatus*) who also feed on benthic organisms.

Apparently the gray whale has no other enemies than the killer whale (*Orcinus orca*), which pursue the gray whale and attack by grasping them by the pectoral flippers and the flukes and trying to open the whales' mouths to bite into the tongue (Zenkovich, 1934a, 1954). Gray whales escape from killer whales by swimming into shallow water, often inside the surf zone (Zenkovich, 1934a, 1954).

Many researchers commented on the strong correlation between feeding gray whales and large congregations of sea birds, including *Fulmarus glacialis*, *Larus hyperboreus*, *Rissa tridactyla*, *Aethia pusilla*, *Fratercula corniculata*, and *Puffinus tenuirostris*, which often landed on the whales' backs before they dove (Tomilin, 1937b; Zenkovich, 1954; Bogoslovskaya *et al.*, 1981a). Apparently whale feeding is responsible for bringing to the surface benthic invertebrates which then are easy prey for these birds.

WHALING

From ancient times, the gray whale was the object of aboriginal hunting by the native inhabitants of Kamchatka, the Koryak region, and the Chukotka Peninsula (von Ditmar, 1890–1900; Krasheninnikov, 1755). The most intensive whaling of young gray whales was common on the coast of Mechigmensky Bay, as indicated by many hundreds of the skulls of these animals that were discovered in the ruins of the ancient settlements (Bogoslovskaya *et al.*, 1981b; Bogoslovskaya and Votrogov, 1982a; Chapter 5, this volume). Species identification of the skulls was conducted by L. S. Bogoslovskaya with the assistance of A. G. Tomilin. The history and specific characteristics of the different aboriginal whaling tribes was described by I. I. Krupnik (Chapter 5, this volume).

From 1932 until the complete ban on whaling for gray whales in 1946, the Soviet whalers conducted the hunt on the Chukotka–California population in the Bering and Chukchi Seas (Zenkovich, 1947; Vadivasov, 1947). Whales from the Okhotsk–Korean population were hunted very sporadically during World War II in the region of Peter the Great Bay (Sleptsov, 1961b). In 1969, the aboriginal hunt of the gray whale ceased as a result of a large number of "struck-and-lost" whales. Aboriginal whaling in the Chukotka Peninsula was replaced by the modern whaling vessel *Zvezdnyi*. Statistics of aboriginal and vessel catches of gray whales from 1932 to 1980 are shown in Table IV.

Table IV
Whaling Statistics for the Gray Whale
from the Chukotka–California Population[a]

PROTECTION

All Soviet researchers recognize the critical condition of the Okhotsk–Korean population of the gray whale, which they feel is on the brink of extinction. The status of the Chukotka–California population is satisfactory; however, its existence is threatened by disturbance in the breeding grounds, by pollution along the migration route, and by extensive fisheries along the migratory route and the summer and fall feeding grounds (Bogoslovskaya *et al.*, 1982). Thus, beginning in 1974 the whaling vessel *Zvezdnyi* took one or two whales each year that bore marks of civilization on their bodies; remnants of synthetic ropes, fishing nets, etc. (L. M. Votrogov and L. S. Bogoslovskaya, unpublished notes). Fishing nets that became attached to the peduncles of the whales were probably acquired during the migration along the North American coast, and from their condition these wounds appeared to be 3–5 months old. We wish to emphasize that all the whales seen with fishing gear remnants on their bodies were adult, large animals, which were able to free themselves from the gear. Young animals and yearling calves are probably not as successful.

In conclusion, we wish to call attention to the intensive utilization by man of the natural resources in Alaska and Far Northeastern Asia. The utilization of natural resources along the coastal shelf and coastline jeopardizes the benthic communities and marine fauna in which the gray whale is playing a very visible role. In this regard, it has been proposed that a portion of the Bering Strait, which is important to gray whales as a feeding area, should be set aside as a protected area (Bogoslovskaya *et al.*, 1982).

Conclusions

The present short survey could not include many current observations of the biology of the gray whale contained in numerous Russian research publications. We have not included here any statistical data of the whaling industry, most of which has been made available due to the International Whaling Commission. The authors tried to illuminate those areas of research on gray whales that are known to a lesser degree in the English-speaking scientific community.

Summary

This article provides information on observations of the Okhotsk–Korean population of gray whales. Also, fundamental results of studies of the migration, summer–fall distribution, abundance, morphology, growth, reproduction, feeding, parasites, and behavior of the Chukotka–California population of the gray whale are summarized. Position of the gray whale in the ecosystem of the North Pacific is considered, as are problems associated with commercial whaling and protective measures of these two populations of this species.

Acknowledgments

The authors gratefully acknowledge the help given to us during the compiling of this review. We wish to thank A. A. Berzin for helping to prepare the bibliography of the majority of Russian research on the gray whale, as well as L. M. Votrogov who provided his field notes.

The editors wish to express their thanks to Elena Baskin and Vladimir Gurevich for their assistance in translating this chapter.

ABSTRACT

A total of 176 sightings of 488 gray whales (*Eschrichtius robustus*) were made during 85.6 hours of aerial surveys in the southern Chukchi Sea and northern Bering Sea, east of the International Date Line, from August to early November 1980-1989. Surveys were flown infrequently and effort varied considerably between years and geographic areas. Gray whales were sighted in all areas where surveys were flown, with the exceptions of Kotzebue Sound and Norton Sound. Abundance indices of whales per unit effort (WPUE) in the northern Bering Sea were higher than those in the southern Chukchi Sea during every month except September, when survey coverage was inadequate for abundance calculations, indicating comparatively higher overall use of that area or suggesting the onset of the southbound migration. Most gray whales were feeding (57%, $n = 276$). Incidental sightings of gray whales observed in and near the study area by other researchers were reviewed to better assess gray whale activity and migration patterns.

KEYWORDS: GRAY WHALES; SURVEYS-AERIAL; BERING SEA; NORTH PACIFIC; DISTRIBUTION; MIGRATION

INTRODUCTION

The distribution and migration of the California-Chukotka stock of gray whales is well-documented for most of its range (Swartz, 1986). However, information is still limited for some regions, including the northernmost summering areas in Alaskan waters. Distribution, migration timing and observed behaviours have been described for gray whales in the northern Bering and eastern Chukchi Seas in the summer (Moore and Ljungblad, 1984; Moore *et al*., 1986b; Würsig *et al*., 1986), the northeastern Chukchi Sea in the autumn (Moore *et al*., 1986a; Clarke *et al*., 1989) and the eastern Alaskan Beaufort Sea in the autumn (Rugh and Fraker, 1981; Würsig *et al*., 1983). These reports are augmented by reviews of opportunistic sightings in Alaskan waters (Maher, 1980; Marquette and Braham, 1982; Braham, 1984). However, specific information on gray whales in the southern Chukchi Sea and northern Bering Sea east of the International Date Line (IDL) between late summer and autumn is particularly scarce. Aerial surveys have occasionally been conducted in this area since 1980 as one component of a larger survey effort for endangered whales in the Beaufort, Chukchi and Bering Seas. This paper summarises the sightings of gray whales reported during these surveys and reviews other relevant information from the literature.

METHODS

The study area included coastal and offshore regions of the southern Chukchi Sea and the northern Bering Sea (63° to 69°N) east of the IDL (Fig. 1) which was divided into survey blocks. The area approximates the boundaries of the Hope and Norton Basin Outer Continental Shelf (OCS) Planning Areas, as designated by the US Department of the Interior, Minerals Management Service (MMS) for decision-making regarding offshore oil and gas activities. Two types of aerial surveys were flown: transect surveys along randomly selected east-west transect lines in survey blocks; and search surveys while transiting to offshore survey blocks (Moore *et al*., 1986b). Surveys were flown in a *Grumman Turbo Goose* model G21G at 152-458m altitude and speeds of 222-296km per hour.

Data routinely collected at each sighting included aircraft altitude, time, latitude, longitude, ice conditions, sea state, visibility, species, number of animals at the surface, number of visible calves, orientation of individual(s) at first sighting, behaviour and inclinometer angle. Whale behaviour classifications included swimming, diving, resting, milling, feeding, mating, cow-calf interaction and displaying. Survey effort and gray whale distribution were analysed for each month. Temporal (by month) and spatial (by survey block) abundance were derived as number of whales per survey hour (WPUE, whales per unit effort).

RESULTS

A total of 85.6 survey hours was flown, with 47.3 hours in the southern Chukchi Sea and 38.3 hours in the northern Bering Sea between August and November 1980-1989[1] (Fig. 2; Table 1). Survey effort was not consistent between years (Fig. 3): there were no surveys in the study area in 1982, 1984, 1985 or 1988. Flight effort in September was limited to the northernmost section of the study area near Point Hope, while survey coverage was most widespread in October. Total flight effort per month varied from 6.4hrs in September to 34.9hrs in October, with 70% (50.9hrs) of total survey effort in October and November.

There were 176 sightings of 488 gray whales in the study area (Fig. 4; Table 2). Gray whales were sighted in all areas where surveys were flown with the exception of Kotzebue Sound (blocks 30 and 31) and Norton Sound (block 29). In August, whales were seen just south of St Lawrence Island and in offshore waters between the Bering Strait and St Lawrence Island, with a single sighting of three animals north of Bering Strait in the southern Chukchi Sea. In September, gray whales were nearshore south of Point Hope

---

[1] Limited aerial survey effort continued in the study area in November 1990 and 1991 (Clarke and Moore, 1993); no gray whales were seen and the survey effort is not incorporated here.

peninsula. The October sightings were offshore in the south-central Chukchi Sea and north-central Bering Sea, with scattered sightings along the coast. In November, gray whales were seen west of St Lawrence Island and in offshore areas south of Bering Strait, with one whale north of Bering Strait.

Monthly abundance indices (WPUE) for the southern Chukchi Sea (Table 1) were highest in October (5.3) and September (5.0) and negligible in August and November (< 0.5). WPUE in the southern Chukchi Sea was highest in block 23 (12.3) in October and block 22 (6.4) in September. In the northern Bering Sea, WPUE values were highest in October (11.3) and November (10.8) and considerably lower in August (3.0). The highest WPUE value was in block 26 in November (32.1). Comparing the two regions, WPUE was higher in the northern Bering Sea during every month except September, when survey coverage (0.8 hours) was inadequate. The indices were probably influenced by the sporadic survey effort, but may indicate comparatively greater use of the northern Bering Sea region or be an indicator of the onset of the autumn southbound migration from the Chukchi Sea.

The majority of whales seen were feeding (57%, $n = 276$), as evidenced by mud streaming from the whale's mouth or by the presence of conspicuous mud plumes, which are large billows of sediment brought to the surface by bottom feeding whales. For a significant proportion (25%, $n = 124$) of whales, no behaviour was recorded. Other behaviour observed included swimming (16%, $n = 78$), diving (1%, $n = 7$) and displaying (1%, $n = 3$). Feeding whales often changed swim direction while at the surface and generally

Table 1

Relative abundance of gray whales by survey block, August-November 1980-89 (does not include 12 whales seen in unblocked areas in August 1981 and November 1980). WPUE = whales per unit of effort (i.e. per hour).

did not show any concerted movement in any one direction. Therefore, whales seen feeding were not considered to be actively migrating and swim direction analyses excluded feeding whales. Consequently, there were insufficient data on swim direction collected to warrant analysis. One calf was seen in the study area, south of Point Hope in September 1987 (Clarke *et al.*, 1989).

DISCUSSION

Gray whales in the southern Chukchi Sea and northern Bering Sea of Alaska in late summer and early autumn have not been extensively studied for several reasons. The southern Chukchi and northern Bering seas are not important areas of offshore oil exploration and development, a factor greatly influencing the degree of interest and funding available for biological studies in the region. Additionally, unlike bowhead whales (*Balaena mysticetus*) which are actively hunted by Alaskan Eskimos, gray whales make only a minor contribution to native subsistence in a few US communities (Marquette and Braham, 1982; Krupnik, 1987). Thus, the incentive in the USA to support research on sustainable yields for gray whales is not as great as for bowhead whales. Finally, the California-Chukotka gray whale stock was removed from the Endangered Species List in June 1995 after having recovered to, or bypassed, pre-exploitation size (Breiwick *et al.*, 1988). Gray whales therefore do not receive the same scientific and financial consideration shown to other, more critically endangered, whale populations such as the bowhead whale or the North Atlantic right whale (*Eubalaena glacialis*).

Consequently, most information available concerning gray whales in and adjacent to the study area comes from incidental sightings made during research targeting other species. The data suggest that the southern Chukchi Sea supports relatively high gray whale densities throughout the late summer and autumn. Large gray whale aggregations were described from aerial and shipboard surveys both along the northern coast and offshore of the Chukotka Peninsula (Fig. 5). Soviet researchers conducting aerial surveys in August and October 1973 reported the highest densities of gray whales nearshore north of the Chukotka Peninsula between Cape Dezhneva (East Cape) and *ca* 175°W. Large aggregations were also located offshore at 68°N, 169°05’W (Zimushko and Ivashin, 1980; Berzin, 1984). Likewise, in late September and early October 1975, aggregations were located offshore north of Cape Serdtse-Kamen and north of Cape Dezhneva. During joint Soviet-American research cruises, large groups of gray whales were seen in October 1979 (>250) and October 1980 (>580) north of Cape Serdtse-Kamen (Berzin, 1984) as well as nearshore along the northern Chukotka coast (Miller *et al.*, 1985). Large aggregations were again reported along the coast and north of the Chukotka Peninsula in August and September 1982, with scattered sightings near Point Hope (Berzin, 1984; Miller *et al.*, 1985). Similarly, Blokhin (2003) counted 1,450 gray whales in a broad area north of the Chukotka Peninsula in August 1986. Joint Japanese-Russian-American oceanographic cruises in September-early October 1992-1994 documented gray whale aggregations north of the Strait and nearshore along the northern Chukotka coast (George, 1992; Moore, 1993). These data, combined with the gray whale sightings reported here in the southern Chukchi Sea in October 1989, indicate that the southern Chukchi Sea is an important gray whale habitat throughout late summer and autumn.

Incidental sightings data for the northern Bering Sea lead to more ambiguous conclusions. Gray whale aggregations are routinely reported along the southern Chukotka coast between Cape Dezhneva and Provideniya in association with Soviet whaling (Fig. 5; Zimushko and Ivashin, 1980; Berzin, 1984; Miller *et al.*, 1986; Blokhin, 2003). Whales were seen there as late as November in 1984 and 1987 (Blokhin, 1990). In addition, Blokhin (1990) noted that large numbers of gray whales occupy Mechigmen Bay (Mechigmenskiy Zaliv) from August to October in some years. Aggregations of gray whales were also reported offshore between St Lawrence Island and Bering Strait in September-October 1975 (Zimushko and Ivashin, 1980) and in November 1980 (Fig. 4), but these waters have rarely been surveyed in the autumn. Additional incidental data include five sightings of an unspecified number of whales near St Lawrence Island in September-October 1958-1981 (Braham, 1984), two gray whales in northwest Norton Sound in September 1982 (Leatherwood *et al.*, 1983) and scattered sightings of a few gray whales north of St Lawrence Island in December 1984 (Kibal’chich *et al.*, 1986). Gray whales were observed

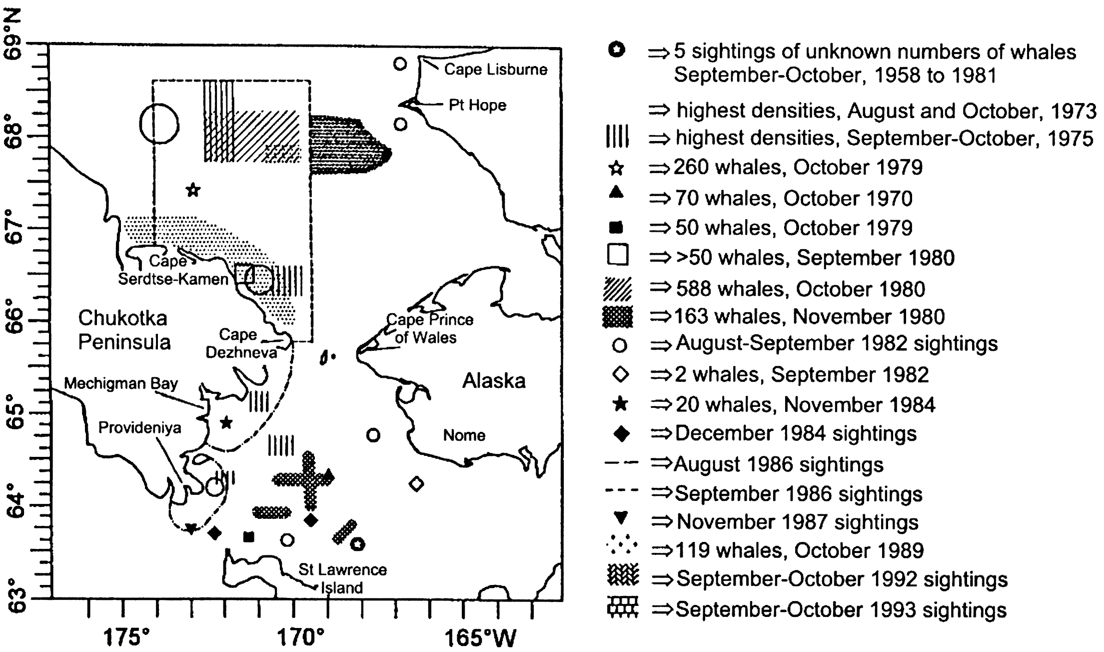

Fig. 5. Gray whale sightings and high density areas in or adjacent to the study area, 1958-93.

during the joint Japanese-Russian-American oceanographic cruises in late September and early October 1992 and early October 1993 south of the Strait (George, 1992; Moore, 1993).

Describing patterns of gray whale abundance and migration based on the available data is difficult owing to the lack of consistent and comparable survey effort, but some trends are worth noting. Gray whales have been seen in the northern Bering Sea as late as November and December (see Figs 4 and 5), by which time others will have reached the coasts of Oregon and California on their southbound migration (Herzing and Mate, 1984; Graham, 1990). The onset of the southbound migration from the southern Chukchi and northern Bering Seas is probably influenced by ice conditions. Rugh (1984) noted that the 1977 southbound migration past Unimak Pass was 10-11 days earlier than that in 1978, when ice conditions were far lighter and the ice front was much further north. Overall, ice front advances could be correlated with differences in median whale migration dates during 1977-9, although year-to-year variations in ice conditions were far greater than in whale migration dates (Rugh, 1984). Likewise, Graham (1990) estimated the peak migration date past San Clemente Island during the 1988/1989 southbound migration (14 January) to be six days earlier than that of the 1986/1987 migration (20 January) and five days later than that of the 1987/1988 migration (9 January); 1986 and 1987 were both considered light ice years, while 1988 was a heavy ice year in the Alaskan Arctic (Moore and Clarke, 1990). Blokhin (1990) also suggested that gray whales are probably present along the coastline of the Russian Far East, including the Chukotka Peninsula, into December, depending on the prevailing ice conditions. Therefore, while ice cover probably influences gray whale distribution and migration timing in the southern Chukchi and northern Bering Seas, the extent of the influence is unknown.

Gray whales return annually to particular regions in the southern Chukchi and northern Bering Seas which are apparently rich feeding grounds for adult whales (Clarke *et al.*, 1989; Blokhin, 2003) and/or weaning areas (Yablokov and Bogoslovskaya, 1984; Moore *et al.*, 1986b). The size segregation observed off Chukotka may be related to differential prey availability. Stoker (1990) suggests that smaller whales feed on smaller amphipods commonly found inshore, while larger whales feed further offshore on larger amphipods. Estimates of standing benthic stocks in various regions of the northern Bering and Chukchi Seas indicate that gray whales take advantage of those areas where the benthic community biomass is most dense, such as the Chirikov basin south of St Lawrence Island. Areas where gray whales are usually not seen feeding, such as north of St Lawrence Island, are often characterised by benthic communities dominated by species not preferred by gray whales (Stoker, 1990). Blokhin (2003) reported that preliminary hydrobiological results indicated that the area between Cape Serdtse-Kamen and Cape Dezhneva had the highest measured biomass of prey preferred by gray whales (62% of the total measured benthic biomass). This area was where the greatest proportion of whales (57%) was seen. However, it was pointed out that the occurrence of whales did not always coincide with areas of high benthic concentration and it was consequently suggested that gray whales probably graze from area to area. The lack of gray whale sightings in Kotzebue and Norton sounds may be due to the lack of preferred prey in those areas. Such sounds typically contain brackish water, which support prey species ingested by anadromous fishes rather than mysticete whales (Cooney, 1981). Additionally, Frost and Lowry (1988) report that crangonid shrimp, a preferred food for spotted seals and white whales but not gray whales (Nerini, 1984), are abundant in Kotzebue Sound.

The information presented here is of limited significance due to the circumstances under which it was collected, as it does not lend itself to the testing of hypotheses on gray whale abundance, migration patterns and behaviour. There has been no additional dedicated research on gray whales in the northern Bering and southern Chukchi Seas since 1989. Aerial surveys dedicated to determining gray whale distribution and relative abundance in this area were flown for one week in summer 2002 (Moore *et al.*, 2002). Results from that limited effort suggest that the northern Bering Sea may no longer be a primary feeding ground. Information on gray whales in this area will probably continue to result from incidental sightings by researchers on projects targeting other species or with other primary interests. Despite this, the material presented here provides some additional insights into gray whale natural history in a geographic area that is not well known.

ACKNOWLEDGEMENTS

This work was completed through funding from the US Minerals Management Service, Alaska OCS Region, Anchorage, Alaska. Several individuals have participated in data acquisition and analysis throughout the years and we especially thank D. Ljungblad, R. O'Hara, R. Van Schoik, J. Bennett, M. Platter-Reiger and F. Shipp, as well as pilots D. Moore, G. Candee and J. Warren of the Office of Aircraft Services, for dedicated and safe service. The draft manuscript was reviewed and greatly improved by comments from: C. Hui (USFWS, Pacific Wildlife Research Center, UC Davis, California, 95616, USA); D. Rugh (NMFS, National Marine Mammal Laboratory, Seattle, Washington, 98115, USA); and R. Reeves (27 Chandler Lane, Hudson, QC, J0P 1H0, Canada). We thank them all.

ABSTRACT

A retrospective summary of gray whale and benthic fauna distribution and abundance in the 1980s was undertaken to provide a baseline for comparison to present conditions. As reported in previous studies, the central Chirikov Basin was the area of highest relative abundance of both whales and benthic fauna. Ampelicid amphipods were the dominant benthos (70%) in the area where gray whale distribution was clustered and relative abundance was highest. The Eastern North Pacific (ENP) gray whale population grew at an estimated 3.29% between 1967/68 and 1987/88, with population size in 1987/88 estimated at 21,296 (CV=6.05%) whales. A 30% decline in benthic biomass was reported for the Chirikov Basin from 1986 to 1988, but estimates of gray whale numbers continued to climb to an estimate of 26,635 (CV = 10.06%) in 1997/98. While the reason for the recent very high mortalities of ENP gray whales is unknown, a reduction in available prey leading to starvation has been suggested as a possibility. Available measurements of benthic community biomass and faunal structure in the northern Bering and southern Chukchi seas indicates a downturn in productivity and shift in prey species in the 1990s. While studying the situation at one feeding location is inadequate for an assessment of prey availability, the Chirikov Basin may provide a key index to the response by the ENP gray whale population to changing conditions on their sub-Arctic and Arctic feeding grounds.

INTRODUCTION

Gray whales (*Eschrichtius robustus*) are opportunistic foragers. While all other mysticetes filter or scoop prey from the water column, gray whales suction mud, epi- and infauna from the seafloor (Nerini, 1984) and, when prey densities are high enough, zooplankton from the sea surface (Darling *et al.*, 1998). Suction feeding is highly disruptive to the benthos (Oliver and Slattery, 1985), directly effects the local distribution of seabirds by bringing benthic prey to the surface (Grebmeier and Harrison, 1992), and may be considered a specialized type of niche construction (Odling-Smee *et al.*, 1996). Gray whales feed extensively in the northern Bering Sea, especially in the Chirikov Basin between St. Lawrence Island and Bering Strait (Moore *et al.*, 1986; Moore and DeMaster, 1997). Whales feed there on comparatively dense populations of ampeliscid amphipods, which dominated benthic samples obtained in the late 1970s through the mid-1980s (Stoker, 1981; Grebmeier *et al.*, 1989). In the mid-1980s, the

Chirikov Basin was reported to have the highest secondary production rates for any extensive benthic community (Highsmith and Coyle, 1990), although the abundance and biomass of the amphipod community appeared to be in decline by the end of that decade (Highsmith and Coyle, 1992).

The recent increase in documented mortalities of gray whales from the Eastern North Pacific (ENP) stock (Norman *et al.*, 2000), and the emaciated condition of several of those whales, generated speculation that starvation was the primary cause of death. Unfortunately, there is no simple way to test this hypothesis, due to the extensive range and prey plasticity of the species. Gray whales are foraging opportunists; that is, they seem to eat whenever they can. Although benthic amphipods dominated in stomach samples from gray whales taken by Soviet whalers in the Chirikov Basin, Nerini (1984) listed prey items from 19 genera, including sponges, polychaete worms, a wide variety of crustacea, and molluscs. Whales feed from the lagoons of Baja California, Mexico, all along their migration route to Alaska, even when localized sampling indicates low (potential) prey densities (Oliver *et al.*, 1983; Nerini, 1984). Furthermore, it is clear that some whales feed extensively in the summer offshore Vancouver Island (Darling *et al.*, 1998; Kvitek and Oliver, 1986), as well as other areas far south of Chirikov Basin. Most recently, feeding gray whales were reported in Ugak Bay, off the eastern coast of Kodiak Island, Alaska, from mid-August 1999 through March 2000 (K. Wynne, pers. comm., University of Alaska-Fairbanks, 118 Trident Way, Kodiak, AK 99615 USA).

Although prey availability can not be assessed over the full range of the gray whale, a review of habitat features associated with gray whale feeding aggregations reported for the 1980s may be an important first step towards understanding the conditions conducive to robust foraging. Here, we summarize gray whale distribution and relative abundance in Chirikov Basin from aerial surveys conducted from 1980 through 1984. Benthic biomass and abundance data, previously reported in Grebmeier *et al.* (1989), is incorporated via Geographic Information System (GIS) mapping to provide a direct comparison of relative abundance measures for predator and prey in this prime gray whale feeding area.

METHODS

Gray whale distribution and relative abundance were derived from aerial surveys conducted in autumn 1980 and during summer 1981-84. Both search and line transect surveys were flown in a fixed-wing aircraft. Details of survey protocol were previously described in Moore *et al.* (1986). The aerial survey study area was post-stratified to three regions (Fig. 1), focused on the Chirikov Basin south of Bering Strait (regions 1 and 2) and waters around St. Lawrence Island (region 3) in the northern Bering Sea. Relative abundance was calculated as the number of whales seen per survey kilometer, using all survey effort; and as number of whales per transect-kilometer (t-km), which excludes counts of whales made while circling overhead and searching along coastal areas. The calculation using only t-km is considered a less-biased index of abundance, but it excludes most of the survey effort in region 3. Density estimates for sub-blocks of the three regions, calculated for July 1980-83 using strip transect techniques, can be found in Moore *et al.* (1986).

Water column and benthic sampling stations were occupied, both north and south of Bering Strait, from July to September 1984-86. Details of sampling protocol are given in Grebmeier *et al.* (1989). In brief, benthic samples (0.1m^2 van Veen grabs) were washed on 1mm sieve screens and animals were identified to family level and then counted and weighed to determine wet weight biomass and abundance. Highly mobile epifauna, such as crabs and sea stars, were excluded from the analysis, while relatively sessile epifauna and infauna were included. Abundance data were then used in a numerical clustering program, which grouped sampling stations according to faunal similarities, as developed by Stoker (1981) and Feder *et al.* (1985). Surface sediments (to 1cm) were sectioned, dried, homogenized and sampled for grain size, then correlations between animal abundance and sediment parameters were investigated using various correlation tests.

Results of aerial survey sampling of whale distribution and relative abundance, relative to benthic sampling for faunal composition abundance and biomass, were subsequently compared via Geographic Information System (GIS) mapping. This provided a unique integrative approach for a retrospective comparison of predator and prey domains in the Chirikov Basin, a prime gray whale feeding area.

RESULTS

A total of 37,519km of aerial survey was flown in spring, summer and autumn 1980-84 (Table 1). Gray whales were never seen during April surveys and never in region 1 in May (Table 2). Comparatively high counts of gray whales were made in region 2 in May and most regions during the other months. Relative abundance indices suggest substantial intra- and inter-annual variability in gray whale occurrence. For example, in October 1980 relative abundance indices were similar in regions 1 and 2, but by November abundance in region 1 was nearly twice that of region 2, suggesting whales aggregated in the more northern region late in the feeding season that year. Perhaps more suggestive of intra-annual shifts among regions is the 1981 data where highest abundance indices moved from region 2 in May, northward to region 1 in June, back to region 2 in July and south to region 3 in August. Among years, 1983 stood out as a year of peak gray whale abundance in the Chirikov Basin; perhaps this coincided with or was related to a strong El Niño condition.

A total of 10,658km of line transect survey was conducted, with comparatively uniform effort in 1981-84 (Table 3). Relative abundance for each month in which whales were seen again suggest clear inter- and intra-annual variability in gray whale habitat use (Table 4). For example, relative abundance in region 1 was particularly high in November 1980 and again in June 1981 and July 1983. Indeed, with few exceptions, the pattern reflected by relative abundance indices derived from transect-only effort (Table 4) is not demonstrably different from that calculated from cumulative survey data (Table 2). Both are shown in this report to reinforce the sense of whale movements and aggregation indicated by the variability in indices over time.

July was the only month in which surveys were flown over four consecutive years and corresponds best with the period when benthic data were sampled. Combined July survey effort consisted of 12,281km overall (Fig. 2A), including 5,489km of line transect survey (Fig. 2B). Gray whale distribution was clustered in mid-regions 1 and 2 (Fig. 3). This distribution corresponds fairly well with measures of benthic biomass (Fig. 4A) and abundance (Fig. 4B). Biomass was especially high in mid-region 1, where stations showing 23-32gC/m^2 were common. Biomass at stations in regions 2 and 3 ranged from 14-32gC/m^2.

Abundance indices were high in mid-regions 1 and 2, with multiple stations where individuals numbered >10,000/m^2. In region 3, abundance was particularly high at a station southeast of the island; unfortunately, there were no stations near the northwest and southeast coast of the islands where most of the whales were seen.

Abundance data from each station (Fig. 4B) were clustered on the basis of similarities in relative percent of faunal composition, resulting in the description of seven faunal communities in the study area (Fig 5). These communities were identified as faunal group I, II, III, IV, VIII, X and XI in Grebmeier *et al.* (1989). Four of the seven communities were associated with the comparatively cold, saline, nutrient-rich Bering Shelf-Anadyr Water (BSAW), but not with warm, fresh and nutrient-poor Alaska Coastal Water (ACW). A summary of abundance, biomass and sediment composition at these stations shows that faunal groups 1 and 3 represent communities where abundance and biomass were exceptionally high (Table 5). Not surprisingly, these faunal groups correspond with areas where gray whale sightings show the densest clusters (ref. Fig. 3). Indeed, gray whale relative abundance, derived from aerial survey data pooled from July 1981-84, was from two to nearly six times higher in regions 1 and 2 than in region 3 (Fig. 6). Regions 1 and 2 clearly correspond with faunal communities I and III, where abundance and biomass was at least twice as high as at other stations in the study area. While ampeliscid amphipods comprised 70% of the faunal abundance in group I communities, they were only 21% of the abundance in group III communities. Notably, faunal community III was also identified in the area southeast of St. Lawrence Island, near where gray whales sightings were clustered (ref. Fig. 3).

Finally, although it is outside the bounds of our designated study area, benthic sampling southwest of St. Lawrence Island (*i.e.* region 3) suggests that a decline in productivity and a change in dominant benthic fauna occurred in the 1990s. Biomass from samples collected southwest of St. Lawrence Island in June 1990, June/July 1993 and May/June 1994 indicate a drop in benthic biomass from over 45gC/m^2 in 1990 to about 20gC/m^2 in 1993-94 (Fig. 7). Although there is considerable inter-annual variability in benthic biomass measures, recent studies indicate this drop continued through 1998 and 1999 (summarized in Grebmeier and Dunton, 2000).

DISCUSSION

This retrospective analysis of gray whale and benthic fauna distribution and abundance in the Chirikov Basin is meant to provide a baseline for comparison between a period when gray whales fed in what was considered a prime foraging habitat (*i.e.* the early 1980s) and a period when habitat may be less than optimal. The Eastern North Pacific (ENP) gray whale population was estimated to number 16,555 (SE = 690) in 1979/80, increasing to 20,348 (SE=726) by 1985/86 (Buckland and Breiwick, in press). In the three years following (1986-88), Highsmith and Coyle (1992) noted a 30% decline in the abundance and biomass of the amphipod community in Chirikov Basin, yet the gray whale population continued to grow. In 1987/88, gray whales were estimated to number 21,296 (CV = 6.05%), increasing to 23,109 (CV = 5.42%) individuals by 1993/94 (Buckland *et al.,* 1993; Rugh *et al.*, 1999). The most recent (1997/98) estimate of 26,635 (CV = 10.1%) whales is coincident with further declines in benthic biomass reported for sampling stations south of St. Lawrence Island (Grebmeier and Dunton, 2000). Collectively, these data suggest a decline in the gray whale prey base (*i.e.* carrying capacity), starting in the mid-1980s, that had no immediate affect on ENP gray whale recruitment.

But are we seeing the effects of a decline in prey on the ENP gray whale stock now? Because gray whales feed at so many locations along their migration route (Nerini, 1984; Darling *et al.*, 1998), offshore Alaska (Braham, 1984; Moore *et al.*, 1986) and the Chukotka Peninsula (Blohkin, 1984), it is simplistic to equate the current spate of high mortalities (Norman *et al.*, 2000) with a decline in prey biomass and abundance in the Chirikov Basin. However, this formerly-prime feeding area may be a bellwether for the state of gray whale foraging habitat, if either prey abundance or quality has changed significantly. For example, Grebmeier and Dunton (2000) note that while benthic biomass north of Bering Strait has remained high, there has been a change in dominant fauna that is likely the result of changing hydrographic conditions. This is important to note because gray whale prey quality varies with species composition. For example, large *Ampelisca macrocephala* are especially lipid rich, as compared to other common amphipod prey (e.g. *Byblis* spp.), so conditions that favor *Bybliss* spp. over *A. macrocephala* will result in a poorer diet for gray whales. Further, prey species size is influenced by organic matter flux, with the density of small amphipods (e.g. *A. birulai*) favored when organic flux is low (Coyle and Highsmith, 1994). Finally, warming seas will elevate amphipod food requirements which may lead to elevated predation rates, both factors selecting for smaller prey species (Coyle and Highsmith, 1994). Thus physical forcing, which directly effects current strength and flow, is key to any assessment of gray whale prey availability.

The Chirikov Basin and areas southwest of St. Lawrence Island and north of Bering Strait are the downstream end of the productive current that runs along the Aleutian chain, sometimes called the 'Green Belt' (Fig. 8). These productive zones are the result of carbon and nutrient transfer to the shallow shelves of the northern Bering and Chukchi seas (Grebmeier and Barry, 1991). Productivity along the 'Green Belt' is largely determined by the Pacific Decadal Oscillation (PDO), which reflects the relative position and strength of the Aleutian Low (Francis *et al.*, 1998). Overall, a decline in seabird and marine mammal populations in the North Pacific has been found to correlate with the PDO, although linking mechanisms remain very poorly understood (Springer, 1999). Recent evidence points to a weakening of current flow in the Gulf of Anadyr and through Bering Strait (Roach *et al.*, 1995), which may be a driving factor in the amount and type of food available to gray whales in a portion of their range historically considered their primary feeding habitat. Only focused research, integrating scales from atmospheric oscillations to gray whale distribution and body condition, will elucidate this possible connection.

ACKNOWLEDGEMENTS

Gray whale sighting data were obtained during aerial surveys funded by the Minerals Management Service, Alaska Region, and made available for this paper by Dr. Cleve Cowles and Steve Treacy of that office. Kate Wynne (U AK-Fairbanks) generously shared her recent observations on gray whales feeding near Kodiak Island, and Lee Cooper (UT-Knoxville) allowed us to include Figure 8 in this manuscript. Marcia Muto (NMML) provided editing assistance. We thank all these people for their help.

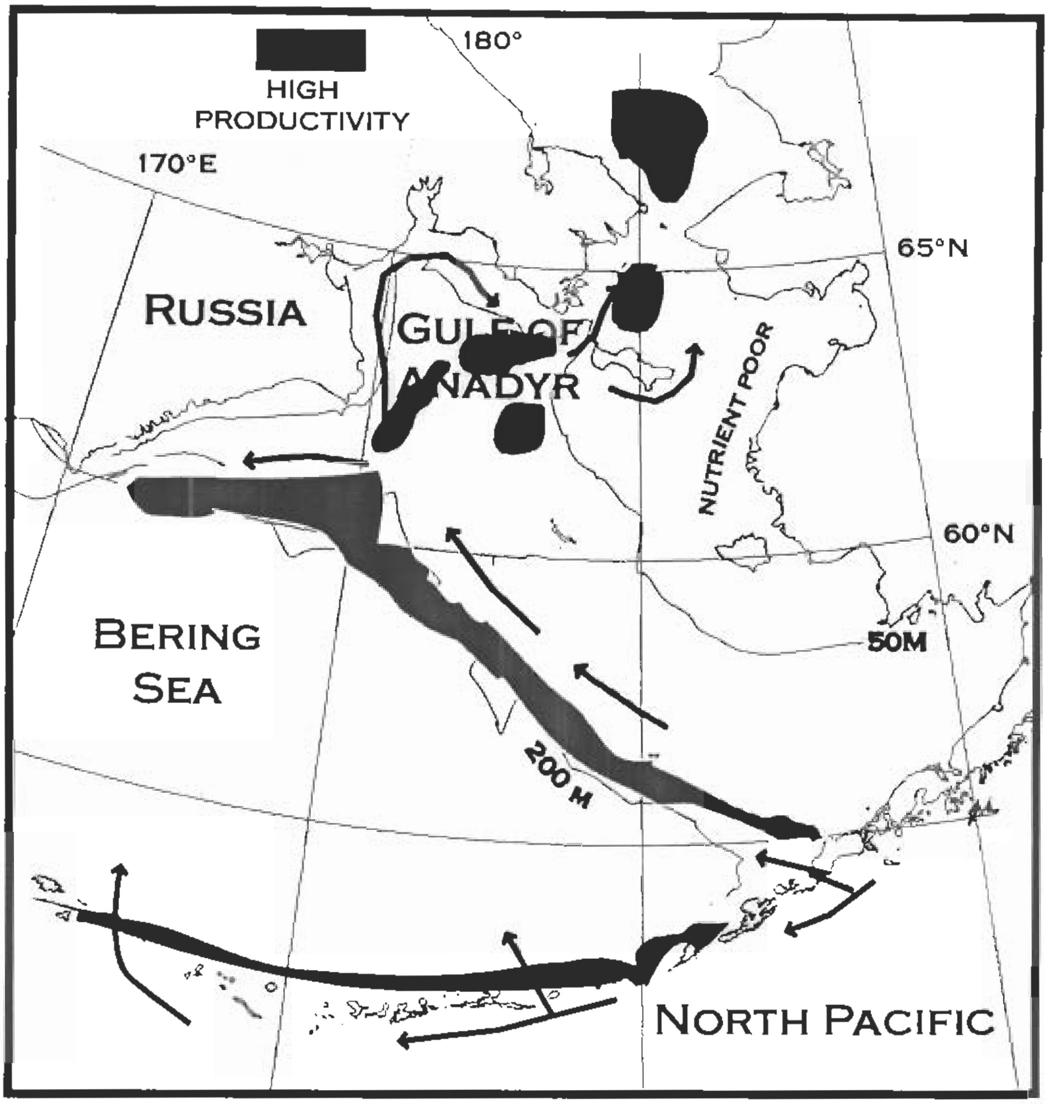

Figure 1. General surface circulation and areas with high water column primary productivity (up to 800 g C m^{-2} y^{-1}) in the Bering and southern Chukchi Seas. High production on the northern shelf is restricted to waters influenced by the Anadyr Current; Alaska Coastal Waters are typically nutrient-poor. Prevailing currents transport particulate organic carbon northward through Bering Strait onto the Chukchi Sea continental shelf. Modified from Walsh et al. (1989) and Springer et al. (1996).

Gray whale distribution relative to forage habitat in the northern Bering Sea: current conditions and retrospective summary

Sue E. Moore, Jacqueline M. Grebmeier, and Jeremy R. Davies

Abstract: Hundreds of gray whales (*Eschrichtius robustus*) stranded dead along beaches from Mexico to Alaska in 1999 and 2000. The cause of the mortalities remains unknown, but starvation resulting from a reduction in prey, especially in the Chirikov Basin, was suggested as the cause. In the 1980s, the Chirikov Basin was considered a prime gray whale feeding area, but there has been no recent comprehensive assessment of whale or prey distribution and abundance. In 2002, a 5-day survey for gray whales revealed restricted distribution in the basin and a 3- to 17-fold decline in sighting rates. To put these data in context, a retrospective summary of gray whale and benthic fauna distribution and abundance was undertaken. During the 1980s, gray whale sighting rates in the Chirikov Basin were highly variable. Ampeliscid amphipods dominated the benthos where gray whale sighting rates were highest. Available measures of biomass suggest a downturn in amphipod productivity from 1983 to 2000, when estimates of gray whale population size were increasing, suggesting that the whales simply expanded their foraging range. We encourage long-term study of the Chirikov Basin as a location where predator–prey responses to changing ocean climate can be researched, because decadal time series data are available.

Résumé : En 1999 et 2000, des centaines de baleines grises (*Eschrichtius robustus*) se sont échouées mortes sur les plages, depuis le Mexique jusqu'en Alaska. La cause de cette mortalité est inconnue, mais on a suggéré qu'elle pouvait être due à la famine, à cause d'une réduction de la densité des proies, particulièrement dans le bassin de Chirikov. Durant les années 1980, le bassin de Chirikov était considéré comme un site d'alimentation de premier choix pour les baleines grises, mais il n'y a pas eu d'évaluation détaillée récente de la répartition ou de la densité des baleines et de leurs proies. En 2002, un inventaire de 5 jours a révélé que la répartition des baleines grises était restreinte dans le bassin et que le taux de repérage avait diminué de 3 à 17 fois. Pour mettre ces données dans leur contexte, nous avons entrepris une revue des répartitions et des densités des baleines grises et de la faune benthique au cours des années. Durant les années 1980, les taux de repérage des baleines grises dans le bassin de Chirikov étaient très variables et ils atteignaient leur maximum lorsque les amphipodes ampéliscidés dominaient le benthos. Les données de biomasse disponibles montrent un déclin de la productivité des amphipodes de 1983 à 2000, au moment où la taille estimée de la population de baleines s'accroissait, ce qui laisse croire que les baleines ont simplement étendu leur aire de recherche de nourriture. Nous favorisons l'établissement d'études à long terme dans le bassin de Chirikov pour suivre les réactions des systèmes prédateurs–proies aux changements climatiques de l'océan, car il existe déjà des séries de données temporelles à l'échelle des décennies.

[Traduit par la Rédaction]

Introduction

Two populations of gray whales (*Eschrichtius robustus*) occur in the North Pacific, nominally called Eastern and Western stocks (LeDuc et al. 2002). The Eastern North Pacific (ENP) population was removed from the list of endangered and threatened species in 1994, after three decades of research supported the conclusion that it had recovered from removals during commercial whaling (Buckland and Breiwick 2002). In March 1999, a scientific panel convened to conduct a review of population status 5 years after the delisting also concluded that the population was healthy and not in need of legislative protection (Rugh et al. 1999). That same year, the counts of dead gray whales stranded on beaches along their migration route skyrocketed to 273, an order of magnitude higher than in any prior year. In 2000, 354 dead gray whales

were reported. This dramatic increase in documented mortalities and the emaciated condition of many of the whales, generated speculation that starvation linked to a downturn in benthic productivity in the Chirikov Basin was the primary cause of death (LeBoeuf et al. 2000). Unfortunately, there is no simple way to test this hypothesis, owing to the prey plasticity and extensive foraging range of gray whales (Moore et al. 2001).

Gray whales feed on a broad range of invertebrates. Nerini (1984) listed prey of 19 genera reported from gray whale stomachs, including a wide variety of amphipods (e.g., *Anonyx*, *Atylus*, *Lembos*, *Pontoporeia*), decapods (e.g., *Chionoecetes*, *Nectocrangdon*, *Nephrops*), and other invertebrates, such as molluscs, polychaete worms, and even sponges. While all other mysticetes filter or scoop prey from the water column, gray whales suction sediment and epi- and in-fauna from the sea floor (Nerini 1984) in addition to filtering zooplankton from the sea surface and water column where prey densities are high (Darling et al. 1998; Dunham and Duffus 2001, 2002). Suction feeding is highly disruptive to the benthos (Oliver and Slattery 1985) and may be considered a specialized type of niche construction (Odling-Smee et al. 1996). In the 1980s, gray whales fed extensively in the Bering Sea, especially in the Chirikov Basin between St. Lawrence Island and Bering Strait (Braham 1984; Moore et al. 1986, 2000). In the basin, the whales' primary prey were ampeliscid amphipods (Yablokov and Bogoslovskaya 1984), which dominated benthic samples obtained from the late 1970s through the mid-1980s (Stoker 1981; Grebmeier et al. 1989). In the mid-1980s, the Chirikov Basin was reported to have the highest secondary production rates of any extensive benthic community (Highsmith and Coyle 1990). However, the abundance and biomass of the amphipod community appeared to be in decline by the end of that decade (Highsmith and Coyle 1992; Sirenko and Koltun 1992).

Gray whales feed opportunistically from the lagoons of Baja California, Mexico, all along their migration route along the west coast of North America to Alaska (Nerini 1984). Furthermore, it is clear that some whales spend the summer feeding offshore Vancouver Island (Kvitek and Oliver 1986; Darling et al. 1998; Dunham and Duffus 2001, 2002), off the southeastern coast of Kodiak Island, Alaska (K. Wynne, personal communication), along the north and south coasts of the Chukotka Peninsula (Berzin 1984; Miller et al. 1985), at shoals in the northeastern Chukchi Sea (Moore et al. 2000), and in some years, as far east as the Canadian Beaufort Sea (Rugh and Fraker 1981). While this extensive foraging range begs the question of the relative importance of the Chirikov Basin as a prey source, when combined with prey plasticity it may suggest why this species has recovered from whaling in the ENP.

Our interest in gray whales focuses on their potential role as conspicuous bio-indicators of environmental variability. Because gray whales forage where prey densities are high, they can reflect local areas of very high secondary productivity (hereinafter "hotspots") and indicate when conditions that support that productivity change. The spike in gray whale mortalities, observation of emaciated whales, and reported decline in benthic biomass in the northern Bering Sea set the stage for inquiry into the current status of gray whale distribution and relative abundance in the Chirikov Basin. Thus, in 2002, we conducted an abbreviated aerial survey to determine gray whale distribution and relative abundance to compare with data from the 1980s. The dramatic changes seen led us to prepare a fine-scale retrospective analysis to compare the distribution and relative abundance of gray whales with that of the benthic-community distribution in the early to mid-1980s. This is the first direct collation of relative-abundance measures for predator and prey in this formerly prime gray whale feeding area and provides a baseline for future comparisons. This type of retrospective approach is fundamental to climate-change models that seek to include apex predators as indicators of environmental variability.

Methods

Gray whale distribution and relative abundance were derived from sightings made during aerial surveys conducted in autumn 1980 and during the summers of 1981–1985 and 2002. Survey protocols used during the 1980s were adopted for the 2002 surveys, to allow direct comparison of results. Line-transect surveys, with randomly derived start and end points, were flown in a fixed-wing aircraft at altitudes of 150–450 m. Two observers maintained a continuous watch for whales, while a third observer–recorder entered data on a portable computer that was linked to the aircraft avionics. Search surveys were conducted to and from the start and end points of transect lines and the aircraft occasionally deviated from the trackline to circle a sighting, to allow observers to make certain species identification and obtain an accurate count. Additional details of this protocol are described in Moore et al. (1986).

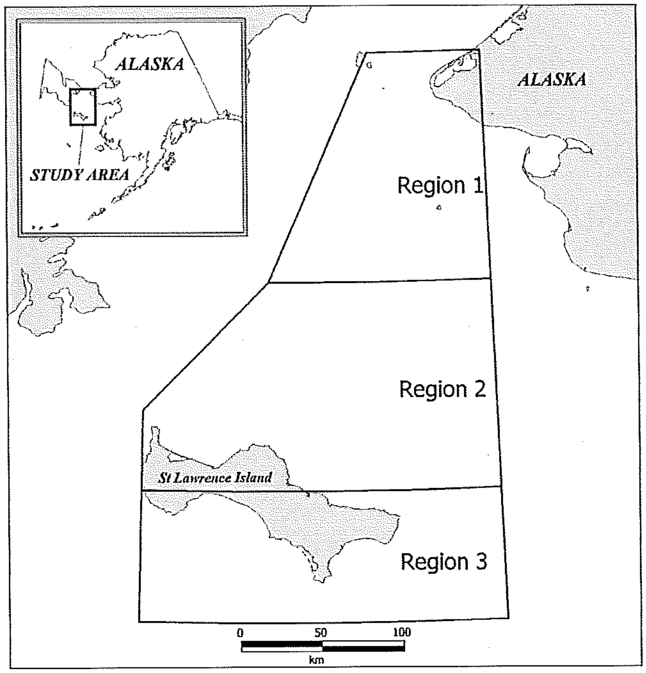
The survey area was post stratified to three regions (Fig. 1), focused on the Chirikov Basin (regions 1 and 2) and waters south and east of St. Lawrence Island (region 3). Whale distribution was plotted and an index of relative abundance calculated as the number of whales seen per survey kilometre. This index was uncorrected for whales missed owing to visibility bias (i.e., observer fatigue) or availability bias (i.e., submergence; see Marsh and Sinclair 1989).

A grid of water column and benthic sampling stations were occupied, both north and south of Bering Strait, from July to September 1984–1986, with four stations occupied opportunistically through 2000. Details of sampling protocol are given in Grebmeier et al. (1989). In brief, benthic samples (0.1 m^2 van Veen grabs) were washed on 1 mm sieve screens; then, to determine abundance and wet-mass (wet-weight as used in Grebmeier et al. (1989)) biomass, animals were identified to family level, counted, and weighed. Highly mobile epifauna, such as crabs and sea stars, were excluded from the analysis, while relatively sessile epifauna and infauna were included. Abundance data were then entered into a numerical clustering program, which grouped sampling stations according to faunal similarities, as developed by Stoker (1981) and Feder et al. (1985).

Results

Aerial surveys (a total of 39 462 km) were flown in spring, summer, and autumn from 1980 to 1985 (Table 1). Gray whales were never seen during April surveys, nor in 2

Fig. 1. Study area in the northern Bering Sea post stratified to three regions: regions 1 and 2 correspond to Chirikov Basin and region 3 to waters south and east of St. Lawrence Island.



of the 4 years when surveys were conducted in May (Table 2). Comparatively high counts of gray whales were recorded in October and November 1980 (the only year of substantive survey effort in autumn), May and June 1981, and July 1983. Differences in sighting rates indicate substantial intra- and inter-annual variability in gray whale distribution. For example, in October 1980, sighting rates were similar in regions 1 and 2 but, by November, the sighting rate in region 1 was nearly twice that in region 2. This suggests that either whales aggregated in the more northern region late in the feeding season that year or that whales migrating south from the Chukchi Sea moved into region 1, while whales in region 2 had already migrated south. Intra-annual shifts among regions are also evident in 1981, in which highest sighting rates jumped from region 2 in May, northward to region 1 in June, back to region 2 in July, and south to region 3 in August. Among years, 1983 stood out as a year of peak gray whale abundance in the Chirikov Basin, coincident with a strong El Niño condition in the ENP. Conversely, 1982 and 1984 were low-abundance years, although this may in part reflect low survey effort, especially in 1984.

July was the *only* month in which surveys were flown over 5 consecutive years and corresponds best with the timing of benthic sampling. Combined July survey effort consisted of 14 224 km (Fig. 2A). Gray whale distribution was clustered along a central axis in regions 1 and 2, off the northwest coast of St. Lawrence Island in region 2, and off the southeast coast of the island in region 3 (Fig. 2B). Fine-scale sighting rates were highest in regions 1 and 2 and southeast of St. Lawrence Island in region 3 (Fig. 3A) and provide a pattern of whale distribution for scaled comparison with benthic-community sampling stations.

Six benthic communities were identified in the study area, clustered on the basis of similarities in relative percentage of faunal composition (Fig. 3B). Four faunal groups (FGs I, III, IV, and XI) were associated with the comparatively cold, saline, nutrient-rich Bering Shelf – Anadyr Water (BSAW), with two groups (FG VIII and FG X) associated with warm, less saline, and nutrient-poor Alaska Coastal Water (ACW). Biomass of amphipods in FG I was especially high in midregion 1, with one station measuring 30–40 g C/m^2 and numerous stations showing 20–30 g C/m^2 (>10 000 individuals/m^2). Conversely, biomass at most stations in regions 2 and 3 ranged from 10 to 20 g C/m^2, with the highest measure at 20–30 g C/m^2.

Of the six benthic communities characterized, abundance and biomass were exceptionally high in FG I and FG III (Ta-

Note: Sighting rate is the no. of whales/10 km of survey effort; —, no survey effort.

ble 3). Ampeliscid amphipods dominated (70%) the FG I community, but comprised only 21% of the abundance within FG III. The correspondence of feeding whales with FG I, but not with FG III, suggests that the prey abundance threshold was somewhere between 21 and 70% Ampeliscidae. Conversely, some feeding whales occurred in the area of FG IV, where Ampeliscidae comprised only 11% of the community. Sediment composition is key to tube-building benthic organisms, such as *Ampelisca macrocephala*, and it is not surprising that substrate associated with FG I was composed primarily of fine and very fine sand, the type of material required for tube construction. Conversely, sediments associated with FG III and FG IV contained substantial proportions of silt and clay.

At fine scale, the highest gray whale relative abundance (2–5 whales/km; Fig. 3A) was associated almost exclusively with FG I (Fig. 3B). Whale abundance was especially high in the central portions of mid-regions 1 and 2, where benthic biomass was measured at 30–40 g C/m^2 or higher. Conversely, gray whale distribution did not overlap FGs III, VIII, and X, where ampeliscids comprised 21% of the abundance; nor did it overlap FG IV, which was dominated by bivalves. Combined, these results suggest that, at least in the mid-1980s, gray whales were selectively foraging on high-density patches of ampeliscid amphipods, nearly to the exclusion of other possible prey.

After 1986, benthic station 1 (BS1; Fig. 3B) in region 1 was occupied four times, BS2 and BS4 were sampled on three occasions, and BS5 was occupied in 1999 and 2000 (Fig. 4). Dramatic declines in Ampeliscidae biomass (9–15 g C/m^2) were measured at three stations, with some suggestion of recovery at BS1 since 1993 and at BS2 since 1999. Results of the 2002 aerial surveys depict a corresponding decline in gray whale distribution and relative abundance. Although the study area was nearly completely surveyed during the 5-day effort (Fig. 5A), gray whale distribution was restricted to the northern portion of the Chirikov Basin and waters offshore northeast and southwest St. Lawrence Island (Fig. 5B). Sighting rates in the three regions dropped 3- to 17-fold, with the greatest difference between survey periods evident in region 2 (Table 4). While this 1-week survey can be considered only a “snapshot” of gray whale occurrence, it does suggest a marked downturn in whale foraging since the 1980s.

Discussion

This retrospective analysis of gray whale and benthic fauna distribution and relative abundance in the northern Bering Sea provides a baseline for comparing a period when gray whales fed in what was considered a prime foraging

Fig. 2. Combined aerial survey effort (A) and gray whale (*Eschrichtius robustus*) distribution (B) in the study area for July 1981–1985.

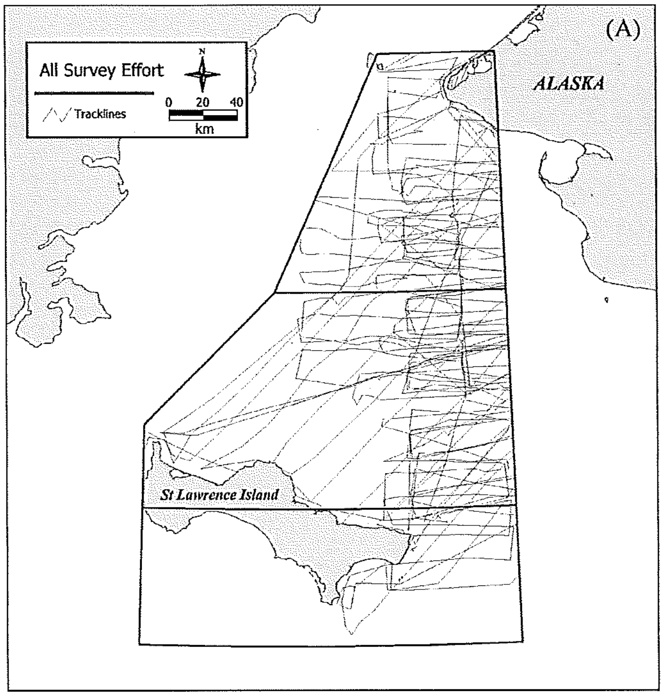

Fig. 3. Sighting rates (no. of whales/km) for gray whales, in 5-km blocks, for July 1981–1985 (A) and the distribution of benthic faunal communities in 1984–1986 (B); modified from Grebmeier et al. (1989). In B, note locations of the benthic stations (BS1, BS2, BS4, BS5), for which time series are shown in Fig. 4.

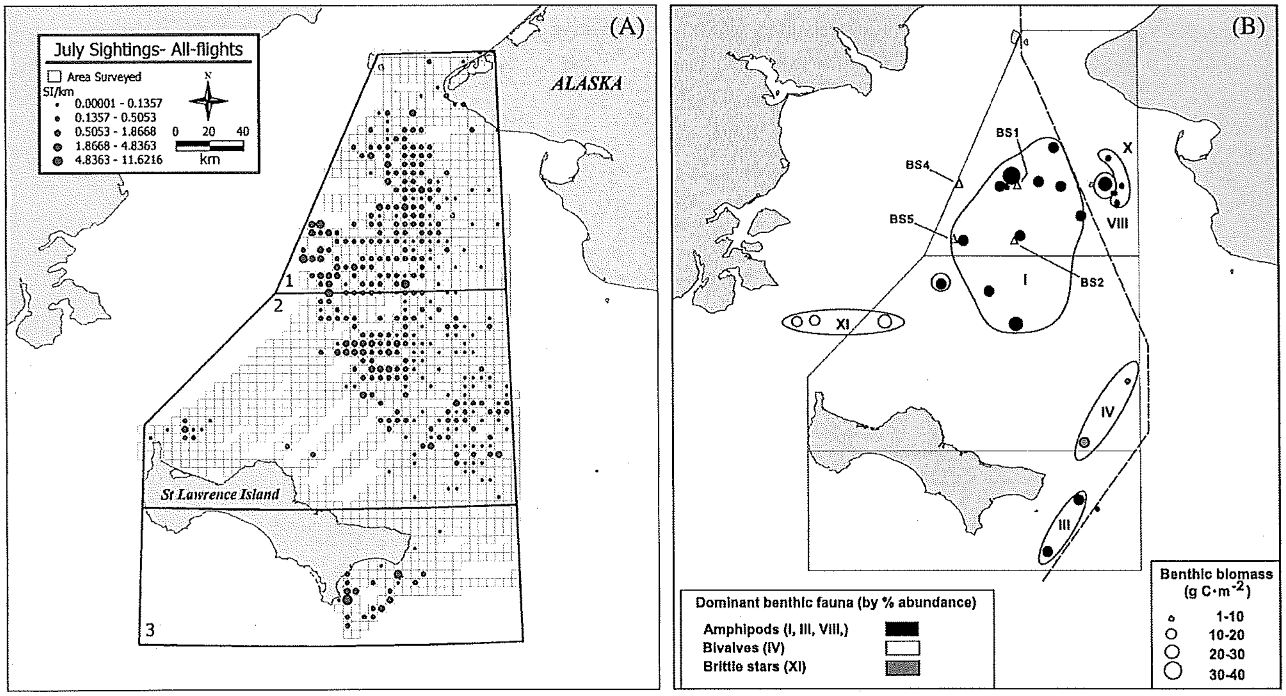

habitat (i.e., the 1980s) with a time when this habitat may be less than optimal. Regional indices of relative abundance show that gray whales were dynamic in their movements through the Chirikov Basin from May through November. In some years, the highest regional indices occurred in autumn, suggesting that whales may have aggregated to feed in the basin prior to initiation of the southbound migration. In July, fine-scale indices of whale abundance were associated with the highest biomass of one particular amphipod-dominated faunal group, suggesting strong prey selection, as shown for

gray whales feeding offshore Vancouver Island (Dunham and Duffus 2001, 2002).

Coyle and Highsmith (1994) predicted that the gray whale foraging rate on the ampeliscid amphipod communities in the Chirikov Basin, as seen in the 1980s, could not be sustained. Yet collective data suggest that the 30% decline in the gray whale prey base reported for 1986–1988 (Highsmith and Coyle 1992) had no immediate measurable effect on whale recruitment. The ENP gray whale population was estimated to number 16 555 (SE = 690) whales in 1979–1980, increasing to 20 348 (SE = 726) whales by 1985–1986 (Buckland and Breiwick 2002). In 1987–1988, when amphipod biomass was dropping, the population was estimated to number 21 113 (SE = 688) whales (Buckland et al. 1993), with the estimate increasing slightly to 23 109 (SE = 1262) individuals by 1993–1994 (Buckland and Breiwick 2002). The highest estimate, 26 635 (SE = 2681) gray whales in 1997–1998 (Rugh et al. 1999), overlapped further declines in the benthic biomass measured at sampling stations in the north-central Chirikov Basin (Fig. 4) and south of St. Lawrence Island (Grebmeier and Dunton 2000). This apparent delay in the response of gray whales to their diminished food resources seems to conflict with the Perryman et al. (2002) model that shows a fairly sensitive positive correlation between gray whale foraging time in the Chirikov Basin (as inferred by ice cover) and calf recruitment.

Because gray whales feed on such a wide variety of prey and at so many locations along their range, it seems an oversimplification to equate the high mortalities in 1999 and 2000 solely to (or to focus recruitment models on) whale foraging opportunities in the Chirikov Basin. However, this formerly prime feeding area may be a bellwether for the state of gray whale foraging habitat, if either prey abundance or quality has changed significantly. Grebmeier and Dunton (2000) note that, while benthic biomass north of Bering Strait has remained high, there has been a change in dominant fauna that is likely the result of changing hydrographic conditions. This is important, because gray whale forage quality varies with species composition. For example, large *A. macrocephala* are especially lipid rich compared with other common amphipod prey (e.g., *Byblis* spp.), so conditions that favor *Byblis* spp. over *A. macrocephala* will result in a poorer diet for gray whales even when biomass remains high. Of note, *Byblis* spp. are the dominant amphipod found in samples from the central southern Chukchi Sea (J.M. Grebmeier, unpublished data). Further, prey species size is

2002	0.070	0.008	0.014

influenced by organic-matter flux, with the density of small amphipods (e.g., *Ampelisca birulai*) favored when organic flux is low (Coyle and Highsmith 1994). Finally, warming seas will elevate amphipod food requirements, which may lead to elevated predation rates, both selecting for smaller prey species (Coyle and Highsmith 1994). Thus physical forcing, which directly affects pelagic–benthic coupling of biological processes in the northern Bering and Chukchi Seas (Grebmeier 1993; Grebmeier and Cooper 1995), is key to any assessment of gray whale prey availability.

The Chirikov Basin and areas southwest of St. Lawrence Island and north of Bering Strait are at the downstream end of the productive current that follows the edge of the continental shelf in the Bering Sea called the "Green Belt" (Springer et al. 1996). These productive benthic zones are the result of carbon and nutrient transfer to the shallow shelves of the northern Bering and Chukchi seas (Grebmeier and Barry 1991). Productivity along the "Green Belt" is strongly influenced by the Pacific Decadal Oscillation (PDO), which reflects the relative position and strength of the Aleutian Low (Francis et al. 1998). Overall, a decline in seabird and marine mammal populations in the North Pacific correlates with the PDO, although linking mechanisms remain poorly understood (Springer 1999). Recent reports of an overall decline in carrying capacity in the Bering Sea during the past two decades (e.g., Schell 2000) are countered by observations of increases in concentrations of various species of zooplankton there (e.g., Napp et al. 2002). So, as yet there is no clear picture of marine ecosystem response to atmospheric oscillations, and its affect on benthic environments such as the Chirikov Basin.

Perhaps most important to benthic infauna, sediment grain size is directly related to current strength. Recent evidence points to a weakening in current flow in the Gulf of Anadyr and through Bering Strait (Roach et al. 1995). Changes in current strength and flow directly impact carbon deposition, sediment composition, and benthic-community structure (Grebmeier 1993). Individual species of benthic infauna require specific sediment regimes within which to feed and grow. Over the last decade, the sediment structure in the northern Bering Sea has changed and sediments in the Chirikov Basin have become coarser, suggesting a changing hydrographic regime. Since the dominant ampeliscid amphipod in the FG I group (Fig. 3B) is a tube builder that agglutinates fine sediment into its tubes, coarser sediments could lead to a reduction in amphipod numbers. In addition, a 30% decline in sediment oxygen uptake in the productive areas to the southwest of St. Lawrence Island was observed during the 1990s (Grebmeier and Cooper 1995). This decline in sediment oxygen uptake is another indication of a reduction of carbon supply to the benthos.

As the ENP gray whale population has increased, top-down (predation) and bottom-up (production) effects have acted negatively and synergistically to reduce available prey in the Chirikov Basin. Seemingly, gray whales have responded to this by expanding their foraging range. Still, we encourage long-term study of the Chirikov Basin as the best location to investigate predator–prey responses to changing ocean climate, because decadal time series data are available.

Acknowledgements

Gray whale sighting data from the 1980s were obtained during aerial surveys funded by the U.S. Minerals Management Service (MMS), Alaska Region, and made available for this paper by Dr. Cleve Cowles and Steve Treacy of that office. We thank the pilots at Office of Aircraft Services (OAS), Anchorage Region, for safe and professional flying, as well as the dedicated observers who assisted with the MMS surveys. Janet Clarke was key to "resurrecting" the transect lines from the 1980s for application to the 2002 survey. She also participated in many of the surveys (1980s and 2002) and provided data summaries for all flights. Dave Weintraub and the team at Commander Northwest Ltd. provided professional and safe flying during the 2002 surveys. Kate Wynne (University of Alaska, Sea Grant Program, Kodiak, Alaska) generously shared her recent observations on gray whales feeding near Kodiak Island. Dave Rugh (National Marine Mammal Laboratory (NMML)) provided constructive comments on an early version of the manuscript and Marcia Muto (NMML) provided comprehensive editing assistance. We thank all these people for their help.

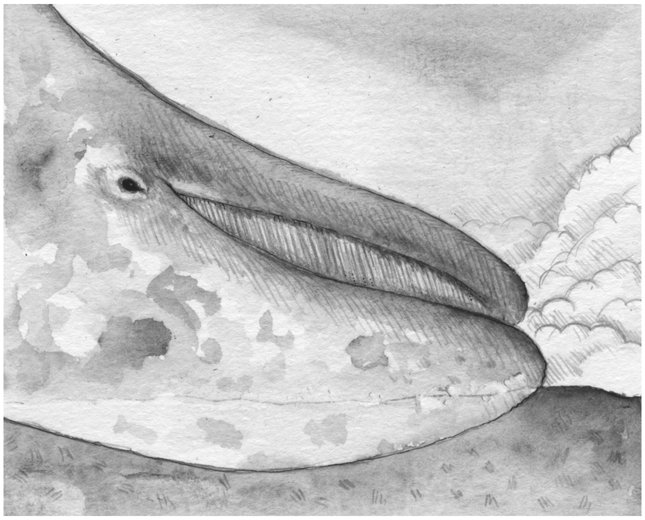
SPECIES CASE STUDIES

TWENTY-THREE

Gray Whales in the Bering and Chukchi Seas

RAYMOND C. HIGHSMITH, KENNETH O. COYLE,
BODIL A. BLUHM, AND BRENDA KONAR



Among the large cetaceans, gray whales *(Eschrichtius robustus)* are unique in three important ways: They are benthic feeders; they undertake one of the longest migrations of any mammal; and they may be fully recovered (at least the eastern Pacific stock) from overharvesting by commercial whaling. The eastern (Chukotka-California) gray whales migrate annually between the mating regions and calving lagoons on the west coast of Baja California to summer feeding grounds in the northern Bering Sea and the Chukchi Sea (Rice and Wolman 1971; Marquette and Braham 1982; Findley and Vidal 2002). The purpose of this chapter is to explore the arctic ecosystem dynamics that justify such a migration and the impacts of the whales upon the system. We will conclude the chapter with an oceanographic production model that both explains the current location of major gray whale feeding sites and can be used for predictive purposes.

Commercial whaling is thought to have reduced the eastern North Pacific gray whale population from 15,000–20,000 to 4,000–5,000 or fewer animals by the late nineteenth or early twentieth century (Rice and Wolman 1971; Reilly 1984; Henderson 1984). Recovery to prewhaling levels had occurred by about 1980 (Reilly 1984), although numbers continued to increase through the 1990s and reached an estimated maximum of 28,000 by 1998 (Rugh et al. 2003). Based on studies of the gray whale prey community, composed of benthic ampeliscid amphipods, in a major feeding site (the Chirikov Basin, B5 in Figure 23.1), it was predicted that the growing gray whale population would not be supportable at the site (Highsmith and Coyle 1992; Coyle and Highsmith 1994), and indeed the eastern population appears to have declined by as many as 11,000 animals by 2000 (LeBoeuf et al. 2000; Moore et al. 2001; Perryman et al. 2002; Rugh et al. 2003).

Northern Feeding Sites

The distribution and relative abundance of gray whales in the Bering and Chukchi seas can be inferred from the results of various aerial and shipboard surveys conducted by Russian and U.S. scientists over the past several decades. The whales are widely dispersed and are usually observed singly or in small groups (Zimushko 1970; Berzin 1984; Table 23.1), not a surprising distribution given the large benthic area needed to support the energy requirements of each whale (Highsmith and Coyle 1992). In the west, consistently large numbers have been seen between Cape Dezhnev (northeastern tip of Chukotka) in Bering Strait to about Cape Schmidt (Table 23.1; C1–C3 in Figure 23.1), with the greatest concentrations off Cape Serdtse Kamen (C1 in Figure 23.1; Berzin 1984). Relatively few whales were observed in or south of the

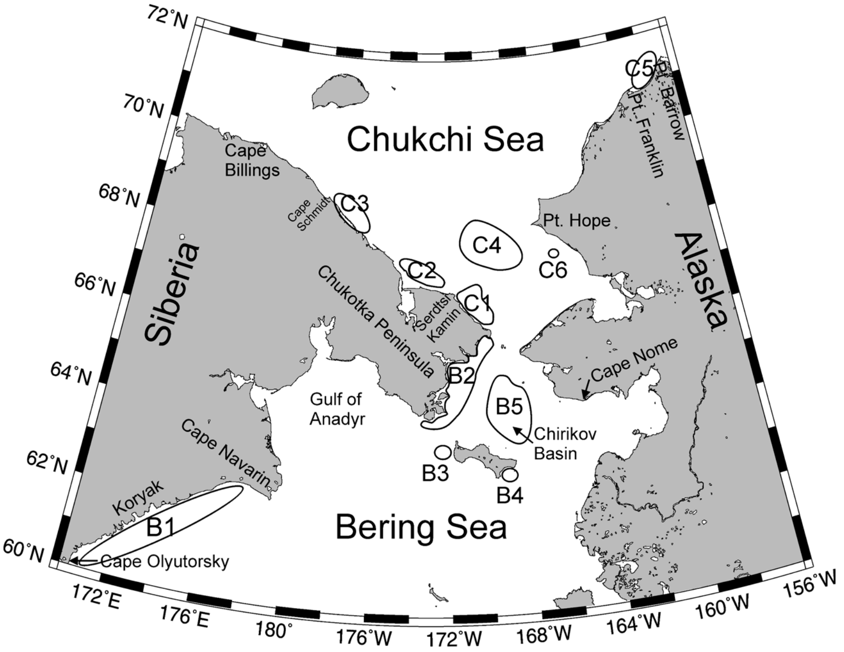


FIGURE 23.1. Map of the northern Bering and Chukchi Seas showing locations of significant gray whale feeding sites. See Table 23.1 for references.

Gulf of Anadyr. The westernmost sighting of gray whales in the Chukchi is 178°30′E (between Cape Schmidt and Cape Billings; Figure 23.1; Berzin and Rovnin 1966; Doroshenko 1981; Berzin 1984). There have been reports of some whales in the C4 area on both sides of the Convention Line (Maher 1960; Wilke and Fiscus 1961; Johnson et al. 1981; Marquette et al. 1982; Braham 1984; Moore and Ljungblad 1984). In the east, gray whales occasionally venture into the western Beaufort Sea (Maher 1960; Rugh and Fraker 1981; Marquette and Braham 1982).

Berzin (1984) suggested that the western (~179°W) and eastern (~157°W) distribution limits of feeding gray whales in the Chukchi Sea are set by the point at which the whales encounter the ice pack. Specific locations vary annually, and with the retreat of the ice pack in recent decades it will be interesting to see whether the whales extend their foraging range. An alternative hypothesis (see the last section of this chapter) is that the western and eastern foraging limits are determined by high benthic production derived from the variable location of the broad (60 km) frontal zone formed off the north Chukotka coast by the intersection of the Siberian Coastal Current and Bering Sea Water (Figure 23.2; Weingartner et al. 1999). This front extends northeastward and intersects the Alaskan coast near the easternmost distribution of significant numbers of feeding gray whales near Point Barrow (C5 in Figure 23.1). The lack of concentrated food may also explain the general absence of gray whales in the north-central Chukchi Sea (Berzin 1984). The southern limit of gray whale foraging in the eastern Bering Sea is off the southeastern coast of St. Lawrence Island at approximately 63°N (B4; Figure 23.1). In the western Bering Sea, after the end of commercial whaling, the southern extent of Chukotka-California gray whale feeding aggregations was at Glubokaya Bay (61°12′N; B1 in Figure 23.1), but as the protected population grew, sightings extended to Cape Olyutorsky (60°N) by the early 1980s (Berzin 1984). These southern distribution limits are presumably determined by the location of soft-bottom depositional habitats with high prey biomass.

Most eastern North Pacific gray whales feed each summer on benthic organisms, especially infaunal amphipods, on the broad continental shelves of the northern Bering Sea and the Chukchi Sea. The majority of foraging activity occurs in water depths of approximately 50 m or less (Rice and Wolman 1971; Berzin 1984; Braham 1984; Nerini 1984; Yablokov and Bogoslovskaya 1984; Highsmith and Coyle 1990, 1992; Moore et al. 2000; Clarke and Moore 2002) and where benthic biomass is very high (Berzin and Rovnin 1966). A variety of foraging sites have been determined (Figure 23.1; Table 23.1). Because gray whales are submerged most of the time (Wursig et al. 1986), the number of whales counted (Table 23.1) is sometimes multiplied by a factor of up to three to obtain an estimate of the actual number of whales at a site (Berzin 1984).

The Chirikov Basin has been identified repeatedly as a major gray whale feeding site (B5 in Figure 23.1; Braham 1984; Moore and Ljungblad 1984). Concentrations of foraging animals occur at both ends of St. Lawrence Island (B3 and B4 in Figure 23.1). Early-arriving whales probably feed in the region until ice conditions allow dispersal farther north (Braham 1984). Thomson and Martin (1986) estimated that 15% of the total whale population remained in the Chirikov

NOTE: For areas referenced, see Figure 23.1. Total for B1 and B2 was 1,800–2,000; total for C1 and C4 was 873.

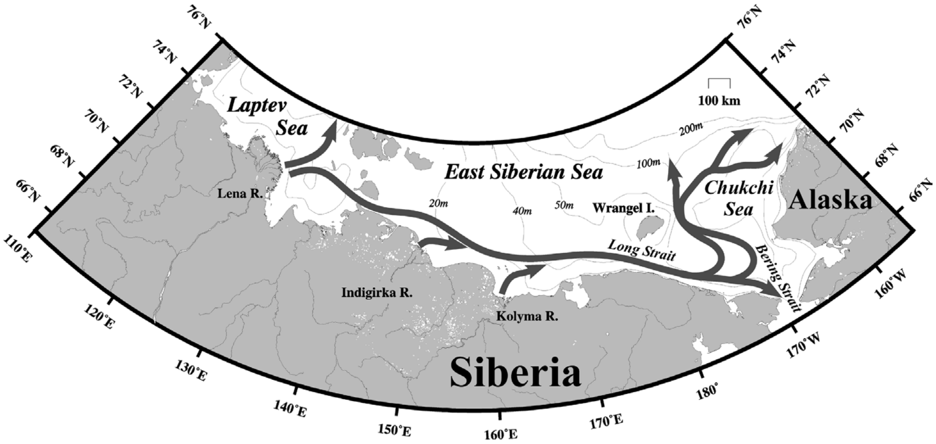

FIGURE 23.2. Map showing the East Siberian Current and region of wide frontal zones established when the northward flowing Bering Sea Water is encountered. From Weingartner et al. 1999.

area to feed during the summer. Soviet scientists estimated that 3,300–3,500 animals were Chirikov residents in the summer of 1982 (Berzin 1984), approximately 19% of the total population (Breiwick et al. 1988). An estimated 70% of the total population (Highsmith and Coyle 1992) feed in the Chirikov while transiting through the area during the spring and fall migration.

In 2003, we made two cruises (June and September) to the C4 region east of the Convention Line. Within an area bounded by 67°00′N to 68°10′N and 168°00′W to 169°00′W (eastern fourth of C4 in Figure 23.1), we counted more than 1,000 gray whales in 4–5 days. Each cruise used a point transect survey. Of those whales observed closely, about half produced mud plumes, an indication of bottom feeding. The whales were arrayed along a broad east-west oceanographic front created by the confluence of the eastward-flowing Siberian Coastal Current (cold, dilute) and northward-flowing Bering Sea Water, which is warmer and saltier (Figure 23.2; Weingartner et al. 1999). It should be noted, however, that the Bering Sea Water includes cold, dense nutrient-laden Anadyr Water, which may underlie the warmer water for tens of kilometers. The highest whale concentrations were observed along the Bering Sea Water (southern) side of the frontal area. We posit that whales observed feeding west of the Convention Line were also orienting to the same frontal system (Figure 23.2).

Animals that are as large and abundant as gray whales and that concentrate most of their feeding during approximately half of the year (Rice and Wolman 1971; Oliver et al. 1983; Perryman and Lynn 2002), need to forage where there is either sustained high primary production or a concentration of production from elsewhere (Moore and DeMaster 1997). Various studies (Walsh et al. 1989; Springer et al. 1996; Weingartner 1999; Figure 23.2) and satellite images (Figure 23.3) show that a plume of production extends from the Gulf of Anadyr through the Bering Strait to the gray whale feeding grounds in the Chukchi Sea (Figure 23.1). The Anadyr Water is upwelled and delivers nutrients as well as phytoplankton to the Chukchi sites. As has been suggested for the Anadyr-fed Chirikov Basin (B5 in Figure 23.1; Hansell 1989; Walsh et al. 1989; Springer et al. 1996), there must be poor coupling between phytoplankton production and zooplankton grazers in areas C1–C5. Thus, much of the diatom biomass settles to the shallow (<50 m) bottom (Grebmeier and McRoy 1989; Fukuchi et al. 1993; Feder et al. 1994) and is consumed by the benthos, which in turn is preyed upon by gray whales and other benthic feeders.

Although the northern feeding grounds are clearly important influences on the distribution and abundance of gray whales, it has become apparent that feeding may occur during the northern migration (Braham 1984) and that tens to a few hundred whales may remain at places, such as Vancouver Island and Kodiak Island, along the migration route during the summer (Darling 1984; Murison et al. 1984; Oliver et al. 1984; Kvitek and Oliver 1986; Calambokidis et al. 2002; Dunham and Duffus 2002; Stelle 2002; Moore et al. 2003). The feeding methods utilized during migration tend to vary, and may include skimming, filter feeding, and benthic feeding in soft-bottom locations. These observations are important for present-day understanding of gray whale ecology and also provide interesting insights into gray whale survival over the millennia. As recently as 10–12 thousand years ago, sea level was roughly 75 m lower than it is today (Hopkins 1967), one consequence being that the areas that are currently the major northern feeding sites utilized by gray whales were emergent. This raises questions about how these animals survived in the absence of required food resources and feeding sites as we presently know them. The ability to utilize alternative feeding modes and locations may have been critical to survival of the species during glacial periods when the continental shelf areas of the northern seas were above sea level.

Benthic Feeding in the North

Gray whale stomach contents collected from the Chirikov Basin and Russian coast indicate that the primary food is infaunal amphipods, primarily the large *Ampelisca macrocephala*

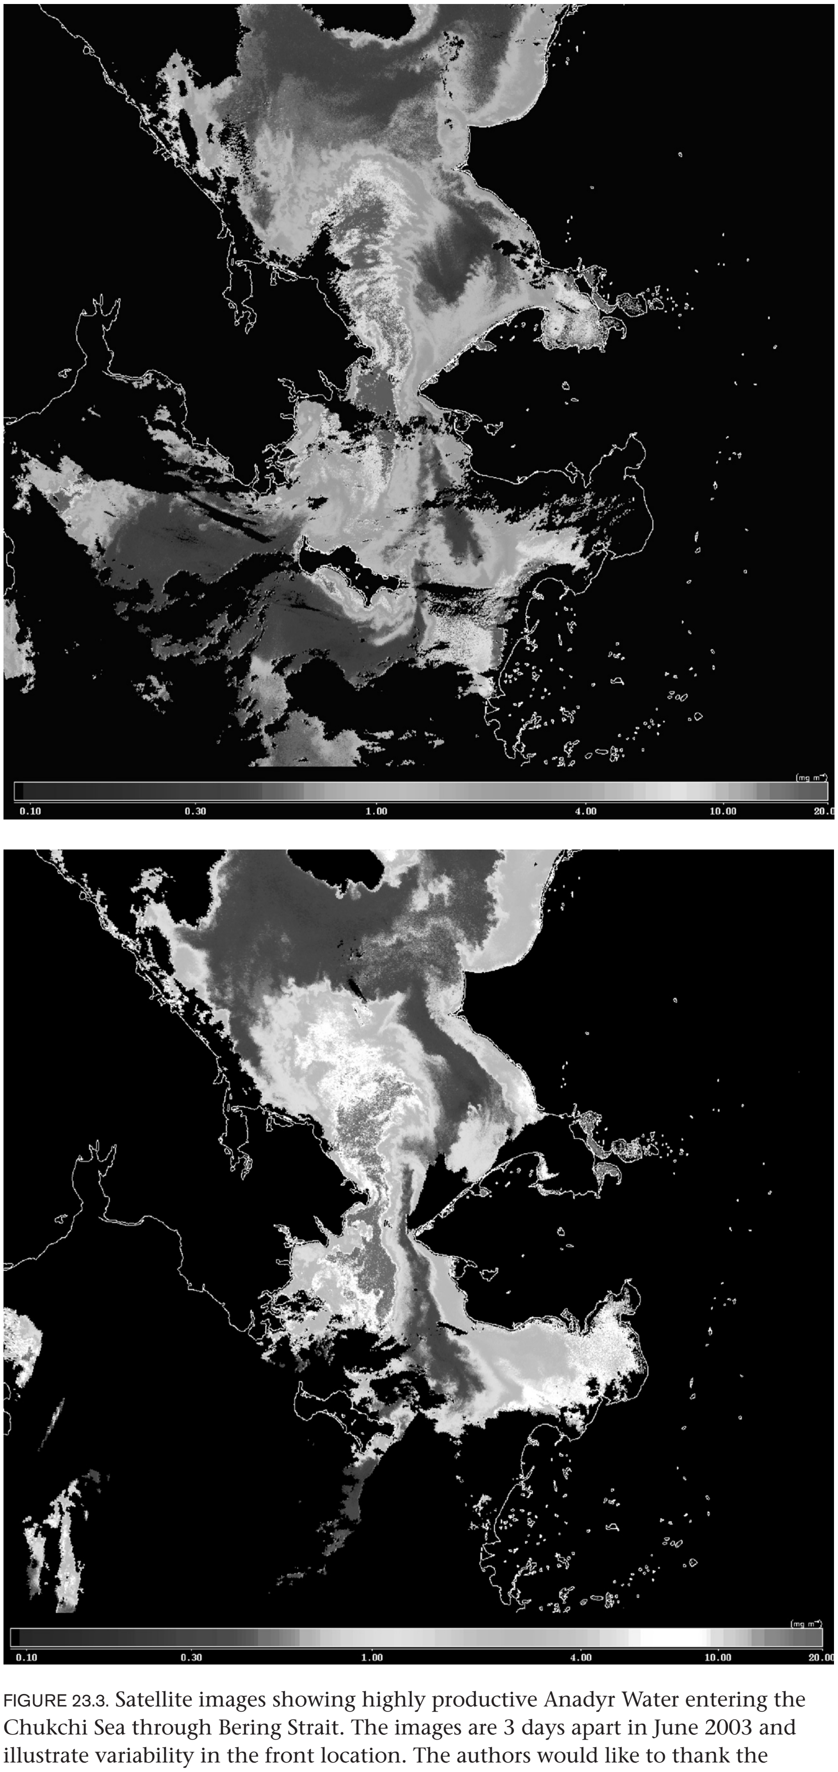

FIGURE 23.3. Satellite images showing highly productive Anadyr Water entering the Chukchi Sea through Bering Strait. The images are 3 days apart in June 2003 and illustrate variability in the front location. The authors would like to thank the SeaWifs Project (Code 970.2) and the Goddard Earth Sciences Data and Information Services Center/Distributed Active Archive Center (Code 902) at the Goddard Space Flight Center, Greenbelt MD 20771, for the production and distribution of these data, respectively. These activities are sponsored by NASA's Earth Sciences Enterprise.

(Nerini 1984; Yablokov and Bogoslovskaya 1984; Highsmith and Coyle 1990, and references therein). The whales prey on the amphipods by placing one side of their mouth on the sandy-mud bottom and sucking out large pits as they swim (Ray and Schevill 1974; Nerini and Oliver 1983; Nerini 1984; Swartz and Jones 1987). Many gray whales produce a mud plume when they surface, which is interpreted to indicate that the whale just made a feeding dive (Scammon 1874; Moore and Ljungblad 1984; Nerini 1984). The distribution of barnacles *(Cryptolepas rhachianecti)* on the whales' heads suggests that they tend to roll on their right side to feed as they work the bottom sediments (Kasuya and Rice 1970; Blohkin 1984). Also, baleen on the right side tends to show greater wear.

In contrast to the Chirikov Basin (B5 in Figure 23.1) and the northern Russian sites (B2 and C1–C3 in Figure 23.1), whales feeding along the Koryak Coast (B1 in Figure 23.1) and on the northeast shore of the Gulf of Anadyr tend to feed on amphipods in the genus *Pontoporeia* (Haustoriidae), particularly *P. femorata* (Nerini 1984; Yablokov and Bogoslovskaya 1984). Stomach contents also included the amphipods *Anonyx* (Lysianassidae) and *Atylus* (Demaxinidae) and polychaetes in the family Oweniidae (Blokhin 1984). Adults of the various amphipod species reach lengths of 13 to 27 mm (Nerini 1984).

The gray whale feeding site in which the prey community has been studied most extensively is the Chirikov Basin (B5 in Figure 23.1; Nerini and Oliver 1983; Braham 1984; Nerini 1984; Nelson and Johnson 1987; Highsmith and Coyle 1990, 1991, 1992; Moore et al. 2003). More than 90% of the stomach contents from this area were *A. macrocephala* (Bogoslovskaya et al. 1981), which requires a soft-sediment habitat. The Chirikov seafloor is covered by an approximate 2-m-thick layer of fine sand (0.125 mm), deposited at the end of the last glacial period, about 10,000 years ago (Johnson and Nelson 1984; Nelson and Johnson 1987).

Ampelisca macrocephala is the largest and most abundant of the eight ampeliscid species present in the Chirikov Basin, reaching lengths of 3 cm and mean densities of about 2,500/m^2 (Coyle and Highsmith 1989; Highsmith and Coyle 1990, 1992). This species constructs mucous tubes that extend a few centimeters into the loose sediment. *A. macrocephala* feed by positioning themselves ventral side up at the opening to their tubes and creating a mouthward feeding current with their abdominal appendages (Highsmith and Coyle 1991). Diatoms in the water column near the seafloor are the primary food source for the amphipods, but they are also capable of sweeping the sand surface around their tubes to a distance of about 1 cm with their long second antennae and wafting any food items detected into the feeding current. The latter feeding method was utilized in experiments in which settling larvae and newly metamorphosed juveniles of a potential space competitor, the sand dollar *Echinarachnius parma,* were eaten, suggesting that *A. macrocephala* is also a facultative predator (Highsmith and Coyle 1991). *A. macrocephala* is long-lived with low fecundity (~60 eggs/brood) and a high age (4–5 years) at first reproduction (Highsmith and Coyle 1991; Coyle and Highsmith 1994). *A. macrocephala* appears to dominate smaller amphipod species with higher reproductive rates and shorter life cycles by outcompeting them for space (Coyle and Highsmith 1994).

The population dynamics and life history features of gray whale prey items at other feeding sites have not been studied. Also, there appears to be little stomach content information from other northern areas. The stomach of a first-year male near Cape Lisbourne contained the benthic isopod *Tecticeps alascensis* (Kim and Oliver 1989).

Nerini (1984) proposed that when gray whales forage on the seafloor, they consume the benthic invertebrates susceptible to the sucking mode of feeding in proportion to their abundance in the community, as the whales lack the means to sort prey. Approximately 60 benthic amphipod species and 80–90 other benthic invertebrate species have been recorded in the diets of gray whales (Blokhin 1980, 1984; Zimushko and Ivashin 1980; Bogoslavskaya et al. 1982; Nerini 1984; Yabolokov and Bogoslovskaya 1984), but most of these species are a small proportion of the stomach contents, commensurate with field abundances. In contrast, the pelagic mode of feeding usually reported along the migration route (Nerini 1984; Dunham and Duffus 2002; Stelle 2002) appears to target swarms or schools of a particular species (Kim and Oliver 1989).

Our 2003 work in the Chukchi Sea (the eastern portion of C4 in Figure 23.1) indicates that gray whales feeding there utilize prey other than infaunal amphipods. We collected 105 grab samples in the area where the whales were feeding and found no *A. macrocephala* and few other infaunal amphipods. The surface sediments were light brown and very soft, but at 2–3 cm deep they turned dark and claylike in texture and appeared to be anoxic. Confirming that the surface sediments were unconsolidated, otter trawls collected large numbers of shallow burrowers such as the small sea cucumbers *Cucumaria japonica* and *Chiridota* sp.; the protobranch bivalves *Ennucula bellotii, Nuculana pernula,* and *Yoldia hyperborea*; and the moonsnail *Cryptonatica affinis*. Epifauna was quite abundant as judged by 10-minute otter trawls that typically included numerous snow crabs *(Chionoecetes opilio)*; lyre crabs *(Hyas coarctatus)*; hippolytid, pandalid, and crangonid shrimp; small seastars (*Leptasterias* sp.); brittle stars *(Ophiura sarsi)*; basket stars *(Gorgonocephalus caryi)*; and occasional sea anemones, compound ascidians, flatfish, and sculpins. Acoustic scattering layers over the bottom consisted of krill, *Thysanoessa raschii,* and arctic cod, *Boreogadus saida*. Most of the listed invertebrates previously have been found in gray whale stomachs near the Chukotka Peninsula, where they appear to have been incidentally caught while the whales were targeting the dominant (>90%) infaunal amphipods (Blokhin 1980; Bogoslovskaya et al. 1982; Nerini 1984; Yablokov and Bogoslovskaya 1984). With infaunal amphipods absent at C4, one or more of the locally abundant shallow-infaunal or epifaunal species, or the dense near-bottom crustacean and fish accumulations, or some combination of these groups, must constitute the gray whale's principal prey.

Of the approximately 70 gray whales near the ship that we observed closely, about half produced light-colored mud plumes, similar to the upper 2–3 cm of surface sediment brought up in van Veen grabs. These findings further suggest that the whales are feeding on near-bottom epifauna or skimming shallow-dwelling infauna from the bottom.

Impacts of Gray Whale Feeding

A large, abundant predator is expected to have a strong role in structuring the biological community in which it feeds (Paine, Chapter 2 of this volume; Jackson, Chapter 4 of this volume; Williams, Chapter 15 of this volume). Gray whales in the northern feeding grounds probably exert their strongest impacts through sediment disruption and removal of the spatially dominant prey species (Nerini and Oliver 1983; Oliver and Slattery 1985; Moore and DeMaster 1997).

Biological Impacts

Daily consumption of benthic organisms by large adult gray whales has been estimated at 379–2,496 kg (Tomilin 1946) and at 1,200 kg (Zimushko and Lenskaya 1970). The latter authors also estimated that the gray whale population at that time consumed 773,000 metric tons of food per year on the northern feeding grounds. This estimate is based upon estimated daily food intake, number of feeding days, and population size. For example, using 1,200 kg day^{-1} and 180 feeding days (May–October) translates into a population of about 3,600 whales needed to consume 773,000 mt yr^{-1}. This estimate is probably too low, because the 1980 population estimate of 15,500 whales (Reilly 1984; Rugh 1984) extrapolates to a 1970 population of about 11,000 individuals, based on a growth rate of 3% per year (Reilly et al. 1983). Eleven thousand gray whales would consume about 2,462,400 mt yr^{-1}. Estimates of this type are subject to substantial errors, but the inescapable conclusion must be that a huge invertebrate live-weight biomass is removed from the benthic communities of the northern Bering and Chukchi Seas each year. This underscores the requirement of gray whales for feeding sites with very high secondary production.

In the well-studied Chirikov Basin (B5 in Figure 23.1), ampeliscid production has been estimated at 170–230 kcal m^{-2} yr^{-1}, more than entire community production at other highly productive locations such as Georges Bank and Long Island Sound (Highsmith and Coyle 1990, 1992). Indeed, the amphipod community inhabiting approximately 40,000 km^2 of the Chirikov Basin in the late 1980s was one of the most productive benthic communities in the world. Based on whale energy requirements and population growth and benthic amphipod production, Highsmith and Coyle (1992) and Coyle and Highsmith (1994) predicted that gray whales were at or near the carrying capacity of the Basin and that by 2000 the amphipod community would not be able to support continued whale predation. Research cruises in late June through early July and September of 2002 and 2003, and a National Oceanic and Atmospheric Administration (NOAA) survey in 2002 (Moore et al. 2003), yielded very few sightings of gray whales in the central Chirikov region, supporting that conclusion. Preliminary results of our 2002–2003 field work indicate that amphipods are still present in the Chirikov Basin, but they have a patchier distribution and overall lower densities than in the 1980s. AUQ1

Physical Impacts

The major physical impact of gray whale feeding is the reworking of surface sediments (Johnson and Nelson 1984; Nerini 1984; Nelson and Johnson 1987; Nelson et al. 1987). A variety of information indicates that this is an important ecosystem-level process. Using side-scan sonar, Johnson and Nelson (1984) and Nerini (1984) detected numerous pits in the sandy floor of the Chirikov Basin that they attributed to the benthic feeding activities of gray whales. In shallow, nearshore areas off the Southeast Cape of St. Lawrence Island, pits were also observed by divers (Nerini 1984). Comparisons of fauna in recently made pits (same season) with adjacent areas revealed a reduction in infaunal abundance of up to 50% and a shift in species from tube-building polychaetes and amphipods to free-living amphipods, especially scavengers (Klaus et al. 1990). Feeding pits cover an estimated 1,200 km^2 or 5.6% of the Chirikov feeding area each year. Associated with this process, an estimated 172 million cubic meters of sand is resuspended, with the clay fraction (4.3×10^6 mt) advected by currents to the Chukchi Sea (Nelson and Johnson 1987; Nelson et al. 1987).

Gray Whale Distribution Model: Bering and Chukchi Seas

The data reviewed in this chapter and in recent oceanographic publications suggest a unifying model that incorporates the major ocean currents, pelagic primary production, and subsequent benthic secondary production to explain the distribution of gray whale feeding sites in the Bering and Chukchi Seas (Figure 23.4). Large marine mammals, especially those that migrate annually, are good indicators of ecosystem productivity, because they are forced to feed efficiently and therefore aggregate in areas of plentiful prey (Moore and DeMaster 1997). The most important gray whale feeding locations are B5 in the Chirikov Basin (at least until recently) and C4 in the Hope Basin (Figure 23.4). The next most important feeding locations appear to be B1, B3, B4, C2, and especially C1, where numerous whales are typically observed. The most important foraging location along the Alaskan coast is C5 between Point Franklin and Point Barrow. Areas C3 and C6 each appear to be utilized by 100–200 whales (Berzin 1984; personal observation, respectively). The Chirikov Basin (B5) was not utilized by many whales in 2002 or 2003, but we include it in our model because it has been the most commonly noted gray whale feeding site over the last century and probably has been a major feeding location since the last ice age.

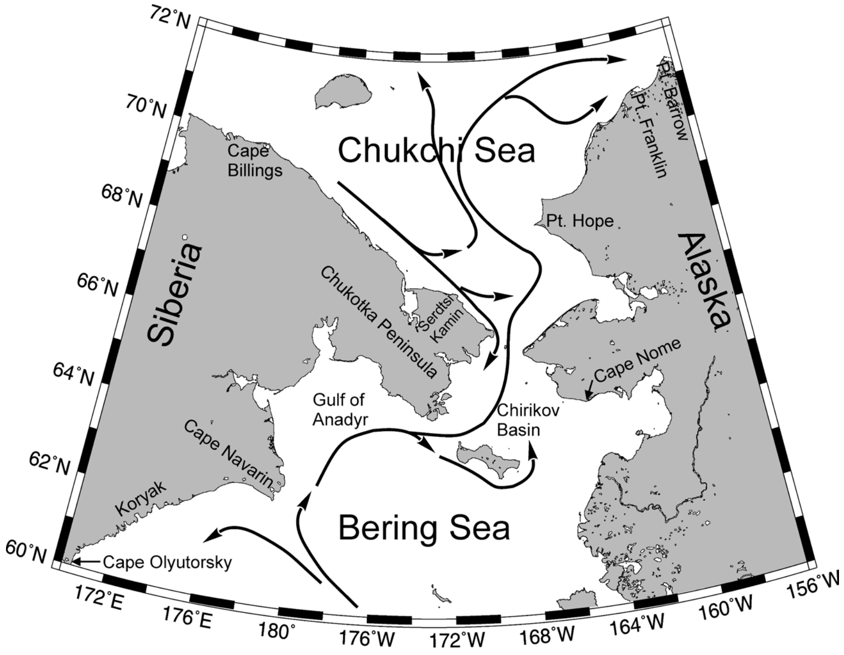

FIGURE 23.4. Model of gray whale distribution in the Bering and Chukchi Seas. Cold, nutrient-rich water upwells near Cape Navarin and the northern Gulf of Anadyr and delivers nutrients and primary production biomass at frontal zones to benthic communities with high secondary production utilized as feeding sites by gray whales.

The Green Belt in the Bering Sea consists of waters running from southeast to northwest along the Bering shelf slope (Hansell et al. 1989; Springer et al. 1996). Deep, nutrient-rich waters of the Green Belt upwell near Cape Navarin and in the Gulf of Anadyr (Figure 23.4). Some of the nutrient-laden water deflects southward along the Koryak coast and fuels high production in feeding area B1. Water deflecting north transits the Gulf of Anadyr, carrying high nutrient concentrations that generate high primary production (Sambrotto et al. 1984), especially by diatoms (Whitledge et al. 1988). The Anadyr Water passes between the Russian coast and St. Lawrence Island to Bering Strait (Walsh et al. 1989), thus enriching feeding area B2 and much of B5 (Grebmeier et al. 1988; Highsmith and Coyle 1990, 1992; Fukuchi et al. 1993). Some of the Anadyr Water also transits around the south side of St. Lawrence Island and then crosses the Chirikov Basin to Bering Strait. The Chirikov Basin appears to be a depositional area as northbound water slows because of the constriction at the Bering Strait (Coachman et al. 1975). Also, the cold, dense Anadyr Water extends along the seafloor many kilometers eastward beneath the warmer Alaska Coastal Water.

Up to one-third of local and advected production, both of which are dominated by diatoms (Whitledge et al. 1988; Highsmith and Coyle 1990, 1992; Fukuchi et al. 1993), settles to the seafloor in the Chirikov Basin and provides food for the ampeliscid amphipods in feeding area B5 (Figure 23.4). Thus, in the Bering Sea this upwelling system provides nutrients and food for benthic amphipods, such as *Pontoporeia femorata* along the Koryak coast (B1) and southern Gulf of Anadyr, and *Ampelisca macrocephala* along the Chukotka Peninsula (B2), the western and eastern ends of St. Lawrence Island (B3, B4; Grebmeier and Cooper 1995), and the Chirikov Basin (B5).

Once through the Bering Strait, the plume of productive Bering Sea Water (Figure 23.3) slows and moves north and west until it encounters the East Siberian Current and forms a front approximately 60 km wide (Figure 23.2), which may occur anywhere from Serdtse Kamen west to the Cape Schmidt area (C1–C3; Figure 23.5; Weingartner et al. 1999). The resulting meander of the front provides an abundant food supply to the benthic communities in the region, especially areas C1, C2, and C4 (Blackburn 1987; Grebmeier et al. 1988; Grebmeier 1993), and to some extent C3. The front is wide in area C4 because the dense Anadyr Water, bearing high phytoplankton concentrations from the Bering Sea, underlies warmer, less productive surface waters for tens of kilometers, and thus delivers considerable production to the benthos. The extension of the bottom front northward along the Hope Valley then swerves northeastward (Weingartner et al. 1999) to Point Franklin on the Alaska coast and provides an energy source for gray whale prey in area C5 (Feder et al. 1994). The only feeding site not presently accounted for by this model is the small feeding area C6, directly east of C4. It is possible that the front with productive Anadyr water on occasion extends that far east to deposit diatoms, but we have no data at present indicating that this occurs.

As gray whales appear to feed on shallow infauna and epifauna, soft sediments are a necessary condition for gray whale bottom feeding. However, sediment grain size may not be as restrictive (Feder et al. 1994) as sometimes has been suggested (Johnson and Nelson 1984; Nelson and Johnson 1987; Moore et al. 2003). For example, fine sand occurs in the Chirikov Basin (Johnson and Nelson 1984), but the bottom in the Hope Basin (C4; Figure 23.4) is dense black silt and clay overlain by 2–3 cm of loose, fine sediments (unpublished observation). We have also observed ampeliscid amphipods in coarser sediments than those in the central Chirikov Basin. Thus, extensive gray whale feeding areas in the Bering and Chukchi seas are soft-sediment habitats with very abundant infaunal or epifaunal prey species supported by high deposition rates of phytoplankton produced by upwelled waters of the Green Belt and Anadyr stream, termed Bering Sea Water in the Chukchi Sea.

The apparent mortality of as many as 11,000 gray whales over a recent three-year period, indicating a food shortage, and the apparent nonuse of much of the Chirikov Basin in 2002 and 2003, suggest that the cause of the population decline is associated with reduced primary or secondary production in area B5 (Figure 23.4). This decline in production could be caused by a reduced flow of nutrient-rich, productive Anadyr Water through the Chirikov Basin or by reduced production of ampeliscid amphipods as a result of overgrazing by the whales. Indeed, if the Green Belt ceases to function, resulting in reduction or loss of upwelled water moving through the northern Bering Sea and setting up a major frontal system in the Chukchi Sea, the known feeding sites would probably not be able to support current levels of gray whale predation.

AUQ2 The gray whale is one of the oldest and more generalized whale lineages (cite). Gray whales have undoubtedly had to respond to changing food supplies over evolutionary time and are known to feed on a variety of pelagic and benthic prey along the northern migration route between Baja California and Alaska (Dunham and Duffus 2002). These observations raise the intriguing question of where and how eastern gray whales fed during the Pleistocene glacial advances, the most recent of which ended just 10,000–12,000 YBP. At that time, all of the present foraging locations in the Bering and Chukchi seas were emergent, and marine access to the Arctic was blocked by the Bering land bridge. Perhaps eastern gray whales in these earlier times mingled with the western stock and fed in the Sea of Okhotsk or spread out in small numbers at various locations along the present migratory route. We may never have a complete understanding of long-past events, but the model we propose accounts for the current feeding ecology of the gray whale. Changes in the upwelled currents and formation of fronts delivering particulate organic carbon to the seafloor have the potential to expand, reduce, or eliminate feeding sites and to create new sites.

Concluding Remarks

Gray whales offer a unique opportunity to advance our knowledge of large whale ecology because they follow well-known, coastal migratory routes (making them countable), feed largely on benthic organisms at well-defined locations, and have profoundly responded to whaling and to management. Indeed, eastern North Pacific gray whales are the only whale stock/species to have recovered to estimated prewhaling numbers following the cessation of industrial whaling. The coastal migration route makes it possible to estimate changes in population size and calving rates. The shallow feeding sites make it possible to study the foraging ecology of the whales and their impacts on the prey community and habitat on a systemwide basis. Gray whale management thus can be viewed as a large experiment that produced interesting and informative results. We have made great progress in our understanding of gray whales, but the species and its associated ecosystem have much more to tell us. The challenge, in our view, is to conduct multidisciplinary research on appropriate scales of space and time.

ABSTRACT

This study documents the range, abundance and movements of a feeding aggregation of gray whales (*Eschrichtius robustus*) in the Pacific northwest. Identification photographs were collected by eight collaborating organisations between March and November 1998. Surveys extended between northern California and southeastern Alaska. Effort was variable by region and was concentrated off the northern Washington coast and Vancouver Island. Of 1,242 occasions when suitable photographs of gray whales were obtained in 1998, 155 unique whales were identified. Each individual was photographed an average of 8.0 times (SD = 8.4, range 1-42) and the average tenure of whales seen multiple times was 56 days (SD = 41, range 1-170). Whales seen longer than three months generally were seen in multiple regions. Movements among regions in 1998 were documented for 57 whales with the most frequent interchange among three adjacent areas from northern Washington to central Vancouver Island. The overall pattern of movements among regions was complex; whales were not always moving in the same direction at the same time of year. Movements within 1998 among more distant locations did occur but were less frequently observed. Total distances between resighting positions for individual whales ranged from < 1 to 526 n.miles. Most whales photographed in 1998 had been identified in previous years when compared to photographs collected by some of the collaborators. At least 86 (55%) of the whales identified had been seen previously. The rate of inter-year resightings was highest for whales identified off northern Washington and three areas off British Columbia (from southern Vancouver Island to north of Vancouver Island). In these areas, from 70-100% of the whales seen in each region had been photographed previously. Mark-recapture abundance estimates based on comparisons to samples in 1996 and 1997 were 181 and 179, respectively. The management implication for these whales has become controversial due to the resumption of whaling by the Makah tribe in northern Washington, an area used by both migrating and feeding whales. This research shows that there are a few hundred gray whales that range in summer months from at least northern California to southeastern Alaska. The mechanism by which these animals are recruited into this group and the degree to which they should be managed as a separate unit from the overall population is not resolved.

INTRODUCTION

Gray whales make one of the longest migrations of any mammal between their winter breeding grounds off Baja California, Mexico, and their feeding grounds in the Bering and Chukchi Seas. Migrations along the Pacific northwest coast occur in December and January when the animals are southbound and again in the spring when the whales are northbound. Outside these migratory time periods, summer feeding aggregations of gray whales have been reported in a number of areas along the coasts of California, Oregon, Washington and British Columbia (Howell and Huey, 1930; Gilmore, 1960; Rice, 1963; Rice and Wolman, 1971; Patten and Samaras, 1977; Flaherty, 1983; Darling, 1984; Murison *et al.*, 1984; Nerini, 1984; Sumich, 1984; Mallonée, 1991; Avery and Hawkinson, 1992; Calambokidis *et al.*, 1992; 1994; Weitkamp *et al.*, 1992). These animals have been referred to as summer or seasonal residents (Pike, 1962; Darling, 1984; Murison *et al.*, 1984; Weitkamp *et al.*, 1992) and more recently as the 'Pacific Coast Feeding Aggregation' whales (National Marine Fisheries Service [NMFS], 2001).

In the early 1970s, photographic identification research demonstrated that many of the gray whales that would remain off Vancouver Island to feed through late spring and summer were the same individuals that returned to the same area each year (Hatler and Darling, 1974; Darling, 1984). Similarly, gray whales photographically identified off Washington State and northern British Columbia from late spring to autumn were also found to return annually (Calambokidis *et al.*, 1994). These whales appear to be part of the overall eastern gray whale population and generally arrive and depart from these feeding grounds concurrently with the migration to and from the wintering grounds. Gray whales in these regions have been observed feeding on a variety of prey including herring eggs/larvae, crab larvae, amphipods, mysids and ghost shrimp (Murison *et al.*, 1984; Nerini, 1984; Oliver *et al.*, 1984; Weitkamp *et al.*, 1992; Duffus, 1996; Darling *et al.*, 1998). Movements over distances of less than 100km and changes in distribution of

animals in response to shifting prey types have been documented (Darling, 1984; Darling *et al.*, 1998). Darling (1984) suspected gray whales seen along the coast of British Columbia in summer months were part of a larger 'northwest coast' sub-population that numbered at least 100 animals.

Information on the status, range and movements, and abundance of these whales is crucial in the management of gray whales especially due to the resumption of whaling by the Makah Tribe in northwest Washington State. Although the current management plan for hunting of gray whales calls for targeting migratory animals, it may be difficult to avoid taking whales from this seasonal feeding aggregation (Quan, 2000). It is currently unclear whether the feeding aggregation of gray whales in the Pacific northwest should be treated as a separate population. Genetic differences have not been found to date between these animals and the overall population (Steeves *et al.*, 2001).

This paper examines the range of movements and tenure of individual gray whales between spring and autumn 1998 based on photo-identification research conducted collaboratively in many regions between northern California and southeastern Alaska. With data on these whales from previous years, this paper also examines site fidelity, interchange and estimate of abundance.

MATERIALS AND METHODS

Identification photographs of gray whales were collected by eight collaborating organisations between 12 March and 18 November 1998 from northern California to southeastern Alaska (Table 1). Effort by region was variable with most intensive coverage along the southern and western coast of Vancouver Island. Effort and identifications were grouped into 12 regions (Fig. 1) based on bodies of water and operating areas for surveys.

Photographic identification methods

Although a variety of vessels were used in different areas, most of the effort was conducted using small vessels (< 10m) and photo-identification methods were similar. Whales were approached slowly from the side at a distance of 50-100m. Both left and right sides of the dorsal region around the dorsal hump and the flukes of gray whales were photographed if possible. Most groups used 35mm cameras usually equipped with 300mm lenses and high-speed black and white negative film. Markings used to distinguish whales included pigmentation of the skin, mottling and scarring, which varied among individuals and have provided a reliable means of identifying gray whales over periods of

close to 20 years (Darling, 1984; Darling *et al.*, 1998). The relative spacing between the knuckles along the ridge of the back behind the dorsal hump was also used to find photographic matches.

Photographic matching

Comparison of whale photographs to determine matches was made in a series of steps. First, the negatives of gray whales were examined and the best image of the right and left side of each whale (for each sighting) was selected and printed (17.8 × 6.4cm). To determine the number of whales seen during the season, all photographs from 1998 were compared to one another to identify whales seen on multiple days. Finally, a comparison was made between the best photograph in 1998 and Cascadia's catalogue of whales seen in past years (see below). Whale photographs that were deemed of suitable quality but did not match the existing catalogue (compared by two independent matchers) were assigned a new identification number.

Information on sightings from previous years came from two sources. Cascadia's catalogue from past years consisted of 835 records of 171 unique gray whales identified between 1984 and 1997. While most of these identifications were from Washington State, including Puget Sound and inland waters, small samples were also collected off California and southern British Columbia. These photographs were collected by Cascadia Research personnel or other collaborating scientists and naturalists. Additionally, individual research groups participating in the 1998 collaboration provided information on past years' sightings of animals they saw in 1998 (they did not have access to the entire collection of 1998 photographs). Since these groups only compared photographs from their own regions to its past collections, there was not a complete comparison among these collections. The proportions of individuals identified in previous years, therefore, are reported as minimums.

RESULTS

Sighting patterns and movements within 1998

From the 1,241 occasions when suitable photographs of a gray whale were obtained in 1998, 155 were identified as unique whales (Table 1). Each individual was photographed from 1-42 times (mean 8.0, SD = 8.4). The largest number of individuals were identified off the southern coast of Vancouver Island, especially in June and July, and from central Vancouver Island around Clayoquot Sound in July and August (Table 2).

Of the 155 identified whales, 117 (75%) were photographed on more than one day. Time between multiple sightings of individual whales ranged from 1-170 days (average of 56 days, SD = 42). Whales seen with a tenure of over three months generally were seen in multiple regions. The whale (ID# 192) seen over a 170 day period was first seen on 4 May and was resighted 42 times up to 21 October: it was seen from 4 May to 6 July off the West Coast Trail of southern Vancouver Island; 9 to 31 July in the Clayoquot Sound vicinity of central Vancouver Island (with a single resighting off the West Coast Trail on 24 July); 6 to 27 August off the West Coast Trail; and then from 5 September to 21 October, it was seen repeatedly off the northern Washington coast.

Movements among regions in 1998 were documented for 57 whales (Table 3): 38 seen in two regions; 18 in three regions; and 1 in four regions. The most frequent interchange was among three adjacent sites from northern Washington to central Vancouver Island (Table 4a). The overall pattern of movements among regions was complex (Fig. 2). Whales were not always moving in the same direction at the same time of year. Despite the wide variations in movement patterns of different individuals, a few patterns could be discerned. A high concentration of whales identified off southern Vancouver Island in June (40 individuals) and July (45) then appeared to disperse somewhat with 19 transits observed from this area north to Clayoquot Sound in July and, to a lesser degree, August. Some animals also moved south from southern Vancouver Island at this same time with 10 transits to the Washington coast and several more toward Oregon and California (arriving in later months). In August, the number of whales in the Clayoquot Sound area (42 individuals) peaked and a high number of transits were observed late in the month and extending into September from this area back to southern Vancouver Island (14 transits) as well as other areas primarily to the south.

Movements within 1998 among distant locations were rare. Only one whale was found to move from northern California to another location: whale ID# 76 was seen multiple times between 12 June and 9 July off southern Vancouver Island and was not observed again until 10 October when it was seen feeding off Point St George in

northern California. Identifications were primarily made late in the season off Oregon (August) and California (October).

Distance and travel speed were also examined for the 117 whales that were seen on more than one day (Fig. 3). Total distances between resighting positions for individual whales ranged from < 1 to 526 n.miles (great-circle route). The distance a whale was documented travelling through the season averaged 110 n.miles (SD = 137) and was generally directly related to the number of times and span of time over which it was seen. The majority of travel speeds were well under 1 n.mile per hour as would be expected for feeding whales and because the data underestimate the true distance covered (and therefore the speed). Some whales remained in the same area for long periods; for example, ID# 231 was seen 30 times over a 136-day period (23 May to 6 October 1998) off southern Vancouver Island. It accumulated a total distance travelled of only 74 n.miles. The most rapid movement was for an animal (ID# 295) seen seven times from 10-25 August but which moved from central Vancouver Island to Oregon in that period (308 n.miles in less than 10 days). For the eight whales documented moving over 400 n.miles, one transited in one direction from Vancouver Island to California, while the remaining seven made multiple transits in different directions among locations.

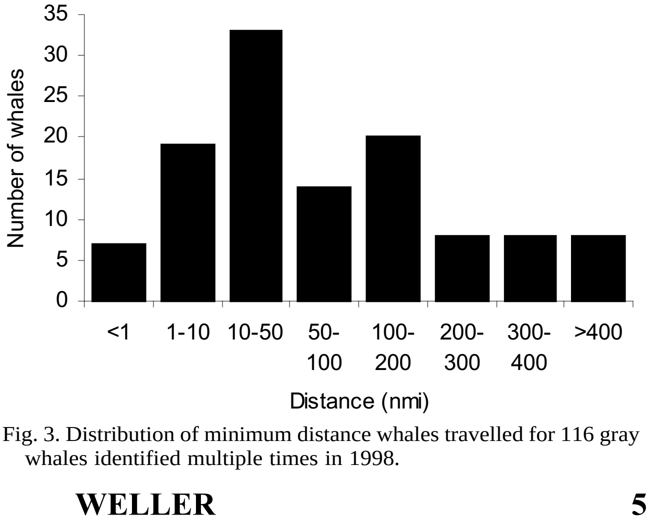

Fig. 3. Distribution of minimum distance whales travelled for 116 gray whales identified multiple times in 1998.

Inter-year resightings

Most of the whales photographed in 1998 had been identified in previous years (Tables 3 and 4b). At least 86 (55%) of the whales identified had been previously identified. This number is a minimum because the matches to past years come from comparison of all 155 of the whales identified in 1998 to the historical catalogue maintained by Cascadia Research of whales primarily seen off Washington. There were also matches to previous years identified by several of the collaborating research groups but these were confined to comparisons of whales identified in the same area (the full 155 whales were not compared to the historical catalogues of the other collaborating research groups). Such a comparison would yield additional documentation of resightings of whales in previous years.

Inter-year resightings were highest for whales identified off northern Washington and the three regions of British Columbia from southern Vancouver Island to north of Vancouver Island. In these areas, from 72-100% of the whales seen in each region had been identified in a previous year. These areas are the regions with the heaviest consistent survey effort in past years.

For some areas, such as Oregon and California, there were few identification photographs available from previous years so inter-year resightings were primarily animals that had been seen in other regions in past years. For Oregon, where no identification photographs were available previously, 8 of 18 (44%) whales identified in 1998 had been seen in six other regions from Grays Harbor to northern British Columbia in the previous years (Table 4b). Whales identified off California in 1998 had been seen previously in the Grays Harbor area, the northern Washington coast and the Strait of Juan de Fuca. Three of the whales identified off California were also seen in the only past sample available: a collection of 13 whales identified in November 1991 in the same location they were photographed in 1998 (off Point St George).

Whales identified in 1998 in southern Puget Sound and Boundary Bay had not been seen in a previous year in any region. This finding from southern Puget Sound is consistent with observations from past years; the presence of gray whales in this area is highly variable each year and whales have not been identified previously (Calambokidis *et al.*, 1994). This is different, however, for whales seen in northern Puget Sound, where four of six whales identified were known from sightings in past years. All four of these whales had been identified multiple times since 1990 or 1991. Whales seen in northern Puget Sound generally have been seen from March through May and then move to other unknown areas.

During 1998, whales that had been identified in previous years were seen more times (mean of 10.6 versus 4.7, $t = 4.73$, $p < 0.001$) over a longer period of time (61 versus 21 days, $t = 6.32$, $p < 0.001$) (starting earlier and extending later) than whales that had not been identified in previous years (Table 5). This was partly a function of the lower proportion of whales known from previous years in areas like California, Oregon and Puget Sound where resightings within 1998 were less common. Even with the elimination of this regional bias, however, this general trend remained within the three best-sampled regions (northern Washington and southern and central Vancouver Island).

Although only four whales were identified in southeastern Alaska in 1998 (and none previously), one of these was seen in past years off Washington. Although it was not seen elsewhere in 1998, it had been sighted 18 times in five of the previous six years off both the Washington outer coast and in the Strait of Juan de Fuca. Despite the small sample size, the movement of this whale suggests either the range of this feeding aggregation extends farther north than the primary effort of this study, or that there are other feeding aggregations with some interchange among them.

Seasonal patterns in resighting rates

Whales were identified from 12 March to 19 November 1998 and whales identified early and late in the season included animals seen over extended periods in 1998 and in previous years. There were, however, seasonal differences in the resighting rates of animals in 1998 (Table 6). Less than 50% of whales identified early (March and April) and late (November) in 1998 were known from previous years compared to 57% to 81% for those seen in previous years for May to October (Table 6). These whales were

November	14	5	36	3	21
By season					
Spring (Mar. to May)	25	7	28	13	52
Summer (Jun. to Aug.)	107	45	42	72	67
Fall (Sep. to Nov.)	74	44	59	46	62
All seasons	155	45	29	86	55

disproportionately sampled in Grays Harbor and in Puget Sound so this could partly be the result of regional differences. It also likely reflects the increased probability of sampling migrating whales closer to the time of the migration past the Pacific northwest.

Geographical recruitment

Although it appears that many whales consistently spend most of the feeding season in Pacific northwest waters, it is not known how they are recruited into this group. This is a critical question for evaluating how exploitation would impact this group (Quan, 2000). Some of the sightings in 1998 provide insight into one possible mechanism for the means by which animals adopt this alternate feeding area.

To examine the role that maternally-directed site fidelity plays in whales feeding in the Pacific northwest, some of the sighting history of identified cows and calves was examined. Although females with calves were sighted infrequently, three of the whales sighted in 1997 or 1998 were known reproducing females, plus one was a returning calf. One whale identified off Washington and British Columbia (ID# 43) has been seen in many years since 1984, including every year from 1992-1998. It was documented with a calf in July 1994 (ID# 107) and the calf was seen independently off Washington in three following years, 1995, 1997 and 1998. In the two other cases (ID# 67 and ID# 105), adult females known from multiple years (between 1992 and 1998) had a calf one year (1994 or 1995) that has not been resighted. In at least one of these two cases, the calf photograph was of marginal quality and there is a chance it would not have been recognised even if it had returned.

Estimation of abundance

The sample from 1998 provides a minimum estimate of the total number of whales feeding in summer months from northern California to southeastern Alaska. Although a total of 155 whales were identified, only 137 of these were seen after 1 June, outside the timing of the northern migration (Table 7). Mark-recapture estimates using annual samples from 1998 and either 1996 or 1997 yielded estimates of 181 and 179, respectively (Table 7).

Table 7

Petersen capture-recapture estimates for gray whales identified between June and November 1998 in the Pacific Northwest. See text for explanation of violations of assumptions and biases.

Sample 1		Sample 2				
Year	*n*	Year	*n*	Match	Est.	CV
1997	29	1998	137	22	179	0.09
1996	24	1998	137	18	181	0.10

DISCUSSION

While the presence of gray whales feeding during summer months in the Pacific northwest has been reported, there has been only limited research on the abundance and range of movements of these animals. Darling (1984) reported resightings of whales off Vancouver Island over an eight-year period. He documented movements of animals between different areas of up to 80km in the same season and 150km between seasons and estimated that the Vancouver Island area was occupied by 35-50 whales each summer. There were gaps, however, in the sighting histories of these whales, with some individuals not identified in the study area for several years.

This study shows that these whales inhabit a broad region during the spring, summer and autumn extending from at least northern California to southeastern Alaska. Within this range, gray whales can move widely both within and between years. The use of this broad area by these whales provides one explanation for why many of these individuals would not be seen in specific areas in some years. Even with the broad field effort reported here, only relatively small portions of the potential areas of use by these animals are being searched (Fig. 1). The interval of three months between sightings of one individual during which it moved from northern Vancouver Island to California without being sighted in intermediate areas of British Columbia, Washington and Oregon, demonstrates the limited survey coverage. Animals not seen in a particular year could inhabit neighbouring areas where there was no research coverage.

This sample provides both a minimum estimate of abundance based on the number of identifications and an estimate of total abundance using mark-recapture. The estimates using the Petersen mark-recapture method require several assumptions (e.g. Hammond, 1986) that are not totally satisfied by the current sampling.

1. The population is closed

There would have been some natality and mortality between annual samples, although this should be small. There also may be emigration or immigration of animals with the overall ‘population’ of gray whales.

2. All animals have an equal probability of capture in at least one of the samples

The 1998 sample is the most complete sample obtained and covers a broad geographic area. Even in 1998, however, effort was not systematic and some areas were covered far more thoroughly than others; there was no effort in some portions of the known range of these animals.

3. The two samples are independent of each other such that animals caught or not caught in one sample both have equal probability of being caught in the other sample

The 1996 and 1997 samples are clearly geographically biased and are based on identifications made in a relatively small area (northern Washington, Strait of Juan de Fuca and southern Vancouver Island). Since there is also some bias in the 1998 sample and animals do not appear to redistribute randomly, this would create heterogeneity of capture probabilities.

4. All matches, if present, are found and there are no false matches

There is little probability of false matches because only matches based on photographs showing multiple markings and verified by a second observer were used. Some matches could have been missed although this was kept to a low number by only including good quality photographs and requiring all comparisons to be made by two matchers.

Violations of assumption No. 1 and the probable violation of No. 4 (missed matches) would both bias the estimate upward while the violations of No. 2 and No. 3 would bias the estimate downward. Since violations of No. 1 and No. 4 are likely small, it is possible that the most significant bias would be a downward one caused by the unequal sampling. This would mean the estimates are likely underestimates. Multiple-year samples that more completely and evenly sample the range of this feeding aggregation are needed to refine the estimate.

The gray whales in this feeding aggregation are a relatively small proportion of the overall gray whale population. The total gray whale population was estimated at 26,365 (95%CI 21,800-32,400) in 1997/98 based on censuses conducted on the southbound migration (Hobbs and Rugh, 1999; IWC, 2000). The few hundred animals identified from photographs and based on mark-recapture estimates would make up less than 1% of this population.

The timing of the arrival and departure of the gray whales described in this study coincided with the timing reported for the overall gray whale migration past the Pacific northwest. Initial sightings of these whales that stayed through the season occurred in March, during the peak of the northward migration past the Pacific northwest as determined by Herzing and Mate (1984). Similarly, resightings of whales identified in the summer were made through late November, when the last field effort ended. This is close to the December/January peak of the southward migration (Herzing and Mate, 1984). Since migratory animals could be present through May (Herzing and Mate, 1984), it is hard to distinguish early in the season which whales are migrating through and which would remain in the region. Given this potential overlap, mark-recapture estimates were made excluding animals identified only before 1 June.

Some species of baleen whales show a high degree of maternally-directed site fidelity to specific feeding areas. This has been examined in detail for humpback whales (*Megaptera novaeangliae*) in both the North Pacific and North Atlantic. In the western North Atlantic, humpback whales breed at one primary wintering ground but during the spring disperse to a number of distinct feeding areas in the North Atlantic; interchange among these North Atlantic feeding grounds is limited (IWC, 2002). There are differences in mtDNA among some of these areas (Palsbøll *et al.*, 1997). Similarly, humpback whales in the North Pacific use a number of distinct feeding areas with little interchange among them (Calambokidis *et al.*, 1996; 2001), although interbreeding among these groups does occur to some degree on the wintering grounds (Darling and McSweeney, 1985; Baker *et al.*, 1986; Calambokidis *et al.*, 2001). As in the North Atlantic, maternally directed site fidelity to specific feeding grounds has resulted in pronounced mtDNA differences between these areas (Baker *et al.*, 1990; 1998).

Only limited genetic studies have been done on gray whales. Steeves *et al.* (2001) compared mtDNA from a sample of 16 summer ‘resident’ whales from Clayoquot Sound, Vancouver Island and compared them to whales from the overall population. They detected no significant differences in mtDNA patterns between these two groups. The lack of a difference could result from one or more of the following: small sample size, too short time frame for isolation to develop detectable differences, or lack of isolation of this group. The power to detect differences genetically could be limited as exemplified by comparisons between eastern and western North Pacific gray whales. Despite the generally accepted separation of these two populations, differences in the proportion mtDNA haplotypes, while significant, do not allow reliable separation of individual animals from these two populations (LeDuc *et al.*, 2002).

The degree to which the gray whales in this feeding aggregation should be managed as a unit separate from the overall gray whale population is unclear. Treating two sub-populations as one when dispersal between them is less than several percent per year could result in depleting one of these sub-populations (Taylor, 1997). There is some evidence from whaling data to support the existence of sub-populations of baleen whales on a relatively small geographic scale that were depleted and failed to recover (see discussion in IWC, 2001). The gray whales from the Pacific northwest feeding aggregation appear to migrate to Mexico each winter and therefore are part of the larger breeding population of gray whales. Depending on the stability of this group and how they are recruited, they may represent a unit that should be managed separately. While there are some parallels in the site-fidelity to feeding areas between humpback and gray whales there are some clear differences. The low proportion of gray whale calves documented and the possible evidence for a male bias in this group (Steeves *et al.*, 2001) are different from humpback whale feeding aggregations. Additionally, the overall gray whale population migrates past the Pacific northwest *en route* to their main feeding grounds in the Bering and Chukchi Seas. This would provide a mechanism for animals to encounter productive feeding areas on this migration and potentially adopt this alternate feeding area.

The results also indicate that early in the season it could be difficult to determine with certainty which whales were migrating through the region and which were part of the feeding aggregation that remained in the region. This could be an important management concern related to aboriginal takes of whales in the Pacific northwest. During the migration it would be expected that the overwhelming majority of whales in the migratory corridor would be migrating animals based on the large size of the overall gray whale population and the low numbers of whales estimated in the group that stays in the region. However, some of the gray whales identified in this study as early as March (during the gray whale migration) were animals that had been seen in previous years and stayed through the summer and autumn. The most reliable way to select migratory animals would be based on a combination of season (as close as possible to the time of peak migratory passage), location (in the migratory corridor and away from known feeding areas) and behaviour (animals travelling and not milling in an area).

This paper provides new information on the range, movements and abundance of gray whales utilising the waters of California to southeastern Alaska as a feeding area. While this approach does provide valuable new information, a multi-year effort, currently underway, will provide more accurate estimates of inter-year resighting rates and interchange, and abundance estimates.

ACKNOWLEDGEMENTS

The overall comparison of the 1998 photographic collections gathered by individual research groups was funded in part by the National Marine Mammal Laboratory of the National Marine Fisheries Service, and we thank Jeff Laake (NMML), Joe Scordino (NWRO) and Robert DeLong (NMML) for arranging this support. Support for the individual research efforts in different areas came from a variety of sources including the National Marine Mammal Laboratory, Olympic Coast National Marine Sanctuary and Cascadia’s whale adoption programme. Lisa Schlender, Jennifer Quan, Emily Walton, Joe Evenson, Jane Truman and Hanna Smith conducted photographic matching. Lisa Schlender, Jennifer Quan and Kristin Rasmussen assisted in data entry for surveys, identifications and sighting reports.

A number of people assisted in conducting field work with Cascadia Research in 1998: Joe Evenson, Todd Chandler, Kristin Rasmussen, Lisa Schlender, Hanna Smith, Aaron Huston, Bonnie Martin, Heather Harding, Heather Medic, Nicole Stagner, Natasha Bodorff and Megan Hess. We thank the skippers and staff of the whale watch boats in Westport, WA, the *Victoria Express*, the *Deluxe* and the *Lucky Pierre*, which allowed us to collect data and obtain identification photographs from their boats.

A number of people assisted in the fieldwork and matching effort at collaborating institutions. The National Marine Mammal Laboratory acknowledges the help and assistance of the Makah Tribe and Makah Tribal Fisheries, including Larry Cooke who assisted with fieldwork. Assistance to the effort by the Coastal Ecosystem Research Foundation was provided by Deb Randall, Kristyn Gray and Nathan Witherly, who did most of the photograph matching and the CERF photographers, crews and volunteers, who collected the data. Humboldt State University acknowledges the full support of the interns and graduate students within the Marine Mammal Education and Research Program (MMERP) and thank Captain Al Vanderford and Jim Sinnott of Tradewinds Charter Company for their full support in Oregon waters. The Whale Research Lab at the University of Victoria acknowledges the help of Dave Duffus and Anna Bass for taking photographs and the interns who assisted in photograph matching. Steve Diggon assisted in photography for the West Coast Whale Research Foundation. We thank Graeme M. Ellis and John K.B. Ford for contributing funds and logistical support for Volker Deecke’s surveys. John Ford obtained the photographs of gray whales in Boundary Bay and additional photographs from the southern Vancouver Island coast were provided by Carol Churchward, Szylvia Nagy, Andrea Pyrlik and Jane Watson. The manuscript was reviewed by Dave Duffus, University of Victoria; Gary Duker, Northwest and Alaska Fisheries Science Center; Jeff Laake, National Marine Mammal Laboratory; and Gretchen Steiger, Cascadia Research Collective.

TABLE OF CONTENTS

ABSTRACT

A collaborative effort to photographically identify of gray whales in the waters of the Pacific Northwest from California through Alaska from late spring through fall was conducted from 1998-2003. This report summarizes these results and provides new insights about the movements, abundance and survival of gray whales in the Pacific Northwest. Each year between 1,159 and 1,499 photographic identifications of gray whales were obtained. Surveys were most numerous along the south and west coasts of Vancouver Island and just north of Vancouver Island, British Columbia. Using all identification photographs, 600 unique whales were identified. We focused our analysis on 477 gray whales identified after 1 June to exclude whales that were seen during the course of the northward migration to the Bering Sea. Individual whales were commonly photographed in more than one region of the Pacific Northwest during the same year and between years including movements from the southernmost sampled areas of California and northernmost areas around Kodiak, Alaska. Gray whales were most likely to be re-sighted in adjacent regions indicating fidelity at a scale smaller than the entire Pacific Northwest but larger than a single region for most whales. Assessing the degree and scale of site fidelity is further complicated by its dynamic and temporal nature. Whales that were seen in more years were seen in more regions, so our ability to assess fidelity is limited by the timeframe of the observations.

Abundance of gray whales in the Pacific Northwest and sub-regions was estimated with closed and open population capture-recapture models. The well-known Petersen estimator for closed populations was used with adjacent years of photographs. The annual estimates for northern California to SE Alaska ranged from 261 to 298 and for Oregon to British Columbia (excluding Alaska and California), 197 to 256. Analysis of data collected from northern California to northern British Columbia (PCFA – Pacific Coast Feeding Aggregation) using open population models demonstrated a lack of geographic and demographic closure. Most whales seen for the first time were transients and were never seen again probably because they never returned (rather than mortality). Whales were more likely to return in a following year if they stayed for a longer time in their first year as measured by minimum residency tenure (MRT) (*i.e.*, time between first and last dates photographed within a year). MRT was also a useful predictor for the probability that a “returning(resident)” whale would be seen the following year. We propose that the mechanism for these relationships is related to foraging success or failure of whales. Whales visiting this feeding area during and following the migration may join the feeding aggregation depending on the success they have in locating food. The average annual survival rate of resident (returning) whales was 0.97 (SE=0.012). Annual abundance estimates of gray whales in the PCFA ranged from 200 to 225 during 2001-2003. An analysis of data from Oregon to southern Vancouver Island yielded lower estimates of abundance for this smaller region from 137 to 153 during 2001-2003.

INTRODUCTION

The existence of gray whales that spend the spring, summer and fall feeding in coastal waters of the Pacific Northwest has been known for some time. Starting in the 1970s, photographic identification demonstrated that along the west coast of Vancouver Island there was a core group of individual animals returning each year (Darling 1984). The resumption of the aboriginal hunt of gray whales by the Makah Tribe in northern Washington in the 1990s made determination of the status and number of these individuals of greater importance to management.

Beginning in 1998, a collaborative effort among a number of research groups was initiated to conduct a range-wide photographic identification study of gray whales in the Pacific Northwest (Calambokidis et al. 2000, 2002a, 2002b). Findings from 1998 demonstrated there was considerable movement of individual whales from northern California to southeastern Alaska and also provided initial estimates of abundance (Calambokidis et al. 2002a). The ability to look at movements and employ more sophisticated capture-recapture models, however, was restricted by the lack of multiple years of data with broad geographic coverage.

The collaborative effort to collect photographic identifications of gray whales from California through Alaska has continued since 1998 and these data now covers six years (1998-2003). This report summarizes this dataset and the new insights it provides about the movements, abundance and survival of these whales.

METHODS

Gray whales were photographed during small boat surveys conducted from California to Alaska by Cascadia Research, National Marine Mammal Laboratory and collaborating researchers between 1998 and 2003. Details of identifications obtained by the different groups are briefly summarized below and are listed in Tables 1-2. Principal study areas are shown in Figure 1.

- **National Marine Mammal Laboratory**: NMML obtained identification photographs of 754 gray whales representing 235 unique individuals sampling all years from 1998 to 2003 from a variety of locations from northern California to Kodiak, Alaska. Identification photographs were mostly taken while conducting dedicated surveys for gray whales.

- **Cascadia Research:** Cascadia obtained identification photographs of gray whales on 856 occasions representing 285 unique individuals. Surveys were conducted in all years using 5.3m RHIB at a wide range of locations from California to SE Alaska.

- **Humboldt State University**: HSU conducted surveys primarily off northern California from 1998 to 2002 and obtained 316 identifications of 127 unique whales.

- **Brian Gisborne, Juan de Fuca Express**: Brian Gisborne obtained identification photographs every year from 1998 to 2003 along the West Coast trail of southern Vancouver Island during daily trips of this region. He obtained 3,391 identifications of 199 unique whales during the trips from Port Renfrew to Bamfield.

- **Jim Darling, West Coast Whale Research Foundation**: Jim Darling provided identification photographs obtained during surveys along the west coast of Vancouver Island primarily from Clayoquot Sound to Barkley Sound in 1998, 2001, and 2002. These yielded 99 identifications of 59 unique whales.

- **Coastal Ecosystems Research Foundation**: CERF conducted regular surveys from 1998 to 2003 off British Columbia north of Vancouver Island primarily in the vicinity of Cape Caution. Identification photographs were obtained on 1,442 occasions representing 77 unique individuals.

- **University of Victoria:** UVIC obtained identifications photographs from Clayoquot Sound north along the west side of Vancouver Island every year from 1998 to 2003 except 2001. Identification photographs were obtained on 759 occasions of 108 unique individuals.

- **Volker Deeke:** Volker Deeke obtained identification photographs of gray whales from 1998 to 2001 off British Columbia and in SE Alaska. He obtained 64 identification photographs of 39 unique animals.

Each year from 1998 to 2003, between 1,159 and 1,499 identifications were obtained of gray whales totaling 7,743 for the entire period (Table 1). These were conducted from March through November with most effort from June to September. Surveys were most numerous in British Columbia, along the south and west coasts of Vancouver Island and just north of Vancouver Island (Table 2).

Photographic identification procedures

Procedures during surveys by different groups varied somewhat but were similar in identification procedures. When a gray whale was found, the time, position, number of animals, and behaviors were recorded. Whales were generally approached to 40-100 m and followed through several dive sequences until suitable identification photographs could be obtained.

For photographic identification of gray whales, both left and right sides of the dorsal region around the dorsal hump were photographed when possible. Most identification photographs were taken with 35mm cameras and 200-300mm lenses. We also photographed the ventral surface of the flukes for identification when possible. The latter method was not as reliable as the sides of the whale because the gray whales did not always raise their flukes out of the water. Markings used to distinguish whales included pigmentation of the skin, mottling, and scarring, which varied among individuals. These markings have provided a reliable means of identifying gray whales (Darling 1984). We also identified gray whale using the relative spacing between the knuckles along the ridge of the back behind the dorsal hump. The size and spacing of these bumps varies among whales and has not changed over the years we have tracked whales.

Comparisons of whale photographs were made in a series of steps. First, all negatives of gray whales were examined and the best shot of the right and left sides of each whale (for each sighting) were selected and printed (7 x 2.5 inch). To determine the number of whales seen during the season, the prints were then compared to others to identify whales seen multiple days. Finally, a comparison was made to our catalog of whales seen in past years. Whale photographs that were deemed of suitable quality but did not match our existing catalog (compared by two independent matchers) were assigned a new identification number and added to the catalog.

Data analysis

Interchange and tenure of whales

Initially gray whale identifications were grouped into 14 regions representing clusters of areas of effort (Tables1-2, Figure 1). To model some of the intra- and inter-year movements of gray whales, we grouped the range into 6 broader regions dropping some of the peripheral areas with infrequent sampling and low rates of interchange with the core area (Alaska and southern and central California, and some of the inland Washington waters). These six broader areas were: 1) northern California (NCA), 2) Oregon (OR), 3) northern Washington/Strait of Juan de Fuca (NWA), 4) southern Vancouver Island (SVI), 5) western Vancouver Island (WVI), and 6) northern Vancouver Island/British Columbia (NBC). The NWA region corresponds roughly with the Makah usual and accustomed tribal area. In particular, to address the issue of site fidelity and the abundance of gray whales at risk of potential harvest by the Makah, we were interested in the probability a whale would be observed in the NWA region given it was observed in one of the other regions. The interchange probability was estimated for each region within year, between years, and overall (either within or between). The dependent variable was 1/0 (seen/not seen in NWA) given that it was seen in a particular region/year. We used generalized linear modeling for a binomial random variable with a logit link in the R statistical software (R Development Core Team 2003).

For within-year interchange, in addition to region, we examined models with NWA survey effort or survey year, and the number of years a whale was seen as explanatory variables for the probability a whale was seen in NWA. For between-year interchange, we examined models with region, survey year and the number of years a whale was seen as explanatory variables. Survey year represented the year the whale was seen in one of the five other regions. For example, the model would estimate the probability that a whale seen in Oregon in 2000 would be seen at least once in 1998-1999 or 2001-2003. While we were primarily interested in regional differences in interchange, we thought they might also differ in time due to shifts in distribution. We also looked at overall (inter and intra-regional) interchange with NWA. For each whale seen at least once in a region during 1998-2003, we examined the probability it would also be seen at least once in NWA during 1998-2003. For overall interchange, we only considered region and number of years seen. We did not consider survey year because the analysis pooled the 6-year period. In each case, we used AIC (Burnham and Anderson 1998) to select the most parsimonious model. An overall goodness of fit was conducted for the best model using a chi-square test. The data were collapsed into categories as needed to achieve a sufficient expected value in most cells to yield a valid chi-square test.

Abundance/Survival using open population models

Population abundance and survival of gray whales was estimated with open population models for two spatial scales: 1) PCFA- the Pacific coast feeding aggregation from northern California (NCA) to northern Vancouver Island/British Columbia (NBC), and 2) ORSVI- Oregon to southern Vancouver Island. Gray whales photographed and identified anytime during the sampling period between 1 June and 30 November within the defined region were considered to be "captured" or "recaptured". For each unique gray whale photographed in the region, a capture history was constructed using the six years of data from 1998-2003. For example, the capture history 010010 represents a gray whale photographed in 1999 and 2002. The same gray whale may have had a capture history 010000 for the smaller spatial scale ORSVI or may not have been seen at all (000000) in ORSVI and would not be used.

Multiple "detections" of a single whale within the sampling period were not treated differently than a single detection. A "1" in the capture history meant that it was detected on at least one day during the sampling period. However, multiple detections within a region in the same year were used to construct an observed minimum residency time (MRT) for each whale. MRT was defined as the number of days between the earliest and latest date the whale was photographed with a minimum of one day for any whale seen. MRT for a whale seen on only one day was by definition 1 day and a whale not seen was assigned 0.

The capture history data for each region were fitted to a range of models using the POPAN model structure with the computer software MARK (White 2004). The POPAN model structure (Schwarz and Arnason 1996) provided a robust parameterization of the Jolly-Seber model structure in terms of a super population (N), the probability of entry (immigration), capture probability (p), and survival/permanent emigration (S). Models with constant and time-varying S were considered. We also considered models with different survivals for newly seen whales and previously seen whales allowing for the possibility of "transients" (Pradel et al. 1997) which are individuals that pass through (are seen once and then permanently emigrate) and do not return regularly. In addition, MRT for a newly seen whale was considered as a potential explanatory variable for permanent emigration (S) before the next sampling period.

The assumed parameter structure for capture probabilities (p) was important for estimation of abundance (N) particularly due to the limitations of the spatial scale. Clearly whales that typically returned to the PCFA or ORSVI could feed outside of these regions in some years. Thus, a whale may not have been photographed because it did not return to the region (temporary emigration) or it returned to the region at some time during the sampling period but was simply missed. Burnham (1993) has shown that abundance estimation is unbiased if the temporary emigration is random; however, we did not believe it was plausible to assume random temporary emigration for all whales. Instead we assumed that we photographed all whales that were within the defined region at sometime during the sampling period and whales were only missed because they did not return in that year. Thus, all newly seen whales (not seen in a previous year) were considered new immigrants to the "population" in that year and by assumption could not have immigrated in a previous year and been missed. While this assumption may not have been entirely true, it would result in an under-estimate of abundance that would be consistent with a risk-averse strategy in setting a harvest quota for the Makah. This approach was implemented within the POPAN model structure by creating a cohort/group for the newly seen whales in each of the six years. The probability of entry was fixed such that all of the whales in the cohort immigrated immediately prior to the sampling period in which they were seen and their capture probability (p) was fixed for the first occasion to be 1. Thus, the estimate of the initial size of the cohort was the number seen (*i.e.*, by assumption none were missed). Models with constant and time varying capture probabilities beyond the first occasion for each cohort were examined. In addition, we considered models in which the observed MRT for a whale on occasion *t* was used as a predictor variable for capture probability of the whale on occasion *t*+1. The abundance estimate for the population at time *t* was the number of newly seen whales at time *t* and the predicted number of surviving whales from previous cohorts. Surviving meant they were alive and did not permanently emigrate. Thus, the total abundance estimate at time *t* only includes possible transients from the newly seen cohort at time *t*. By excluding the size of the newly seen cohort, we constructed an estimate of abundance of non-transient whales from previous cohorts.

Our analysis could have also been done with the Cormack-Jolly-Seber (CJS) model structure in program MARK by treating each cohort of newly seen whales as a released cohort. However, MARK does not derive estimates of abundance for CJS because it is used primarily for survival estimation. However, we did use Test 2 + Test 3 results from the CJS structure (Lebreton et al. 1992) as a general goodness of fit for the global model and as a measure of possible over-dispersion creating the lack of fit. We used AICc for our model selection criterion (Burnham and Anderson 1998) for selecting the most parsimonious model for estimation. Model averaging was used when two or more models were within a ΔAICc of 4.

RESULTS

Good quality identifications were obtained of gray whales totaling on 7,743 occasions for 1998-2003 and these yielded 600 unique animals (154-254 per year)(Tables 1-3). These included identifications from early in the season during the migration as well as peripheral areas (see following sections).

The proportion of gray whales identified that had been seen in more than one region or more than one year (in any region) varied dramatically by month with whales identified in March through May less likely to have been seen multiple years or in multiple regions than those seen June to November (Table 4). This was expected because the northbound migration of gray whales proceeds past Washington through May making it more likely that gray whales identified early in the season are whales still migrating north. Resighting rates of whales seen after 1 June remained high through November.

Similarly, whales identified at the geographic ends of the sampled range (central and southern California and Alaska) as well as those seen in greater Puget Sound were also less likely to have been seen in multiple years and regions (Table 4). In some of these regions, such as Puget Sound, many of these whales were seen in the spring and may represent migratory animals. Even with exclusion of these early season animals, only a low proportion of the whales seen in Washington inside waters and at the north and south end of our sampled range had been seen multiple years or in more than one region. Gray whales in northern Puget Sound had a higher inter-year resighting rate than those in other parts of Puget Sound, but these whales were seen primarily only in spring and then were generally not resighted, indicating they were moving on to some other area outside where we sampled.

We examined the rate of interchange among regions both within years and overall among years for the 1998-2003 period. Within-year interchange was extensive especially among the outer coast regions from northern California to British Columbia (Figure 2). The low rate of interchange and within-year movements between these areas and those in Puget Sound or at the north and south ranges of our sampling in areas California and Alaska can also be clearly seen (Figure 2). Interchange among specific regions regardless of year, shows that whales seen on one region are most likely to be resighted at regions close to there rather than farther away (Table 5, Figure 3). For each region examined there was a pattern of decreasing interchange with each jump farther to the north or south of that site (Figure 3).

Even though resightings in other regions were less common for the whales identified in the ore geographically peripheral areas like southern and central California and Alaska, some of these animals were resighted in other regions (Table 5). For example, two whales identified off Bodega Head in central California in August 2001 were both seen in 2003 off southern Vancouver Island. Similarly, 5 of 10 whales identified off southeastern Alaska and 8 of 46 whales identified off Kodiak, Alaska had been identified farther south. This includes one animal from each of these Alaska areas that was documented on feeding areas farther south in the same season as when it was identified in Alaska. Directions of movement were opposite, however, with one whale (ID#140) that moved from southeastern Alaska around September 1999 to northern California on 30 October 1999 and another whale (ID#691) seen off southern Vancouver Island from 9 June to 6 July 2003 and then off Kodiak on 9 and 11 August 2003. This latter movement would represent a minimum of 1,104 nmi (by most direct route) in no more than 34 days.

Because of the presence of large number of migrating whales in spring, we restricted our mark-recapture and other analyses to whales that had been identified after 1 June for 1998-2003 each year. This reduced the number of unique individuals identified from 1998 to 2003 from 600 to 477 (Table 3). Unless stated otherwise, all analyses through the rest of this report will only include identifications and effort after 1 June.

Relationships between interchange and tenure of whales

Some simple exploratory plots suggest some interesting relationships regarding tenure and movements of whales. Whales that were seen more frequently (more years) were seen in more regions (Figure 4). Also whales that were seen more frequently had longer minimum residency times in the first year they were seen (Figure 5). Whales with a minimum residency time of three weeks or more were twice as likely to be seen the following year as whales with a shorter minimum residency time (Figure 6).

The most parsimonious model of within year interchange of whales into NWA from the other regions was a function of region, the number of years a whale had been seen and the year (Table 6). The model fit the data reasonably well (χ^2 =94.9, df=78, p=0.09) with the number of years seen collapsed into three groups (1-2, 3-4, 5-6). The next best model replaced year with survey effort in NWA during that year. Observed interchange increased with increasing effort in NWA; thus, many whales may have passed through NWA but were not always seen. However, inclusion of year in the best model suggests that in addition to effort other annually varying factors (*e.g.*, annual variation in movements) influenced the interchange with NWA. As might be expected, regions closest to NWA (SVI, OR, and WVI) had the highest within year interchange with NWA and NCA and NBC on the fringes had much lower within year interchange (Figure 7). Whales seen more frequently were more likely to be seen in NWA and another region during the year (Figure 7) which was most likely associated with longer within-year tenures.

The most parsimonious model of between year interchange of whales into NWA from the other regions was a function of region, the number of years a whale had been seen and the year (Table 6). The model fit the data reasonably well (χ^2 =43.3, df=49, p=0.70) with the number of years seen collapsed into two groups (2-4, 5-6). Again whales seen in the closest regions were more likely to be seen in NWA (Figure 8). As expected, whales seen in more years were more likely to be seen in NWA (Figure 9), which was consistent with whales being seen in more regions (Figure 4).

For overall (within- and between-year) interchange with NWA, the most parsimonious model likewise included region and number of years seen (Table 6). The model fit the data reasonably well (χ^2 =26.3, df=24, p=0.34) using the number of years seen in the six separate groups. The overall interchange was greatest for OR and SVI which are the regions to the south and north of NWA. For whales seen in all 6 years, at least 30% would be expected to be seen in NWA from all regions in the PCFA and more than half were seen in NWA of those seen in SVI and OR.

Population estimates from closed models

Abundance estimates using a simple Petersen mark-recapture model with adjacent years gave fairly consistent estimates of abundance (Table 7). The five estimates from pairs of adjacent years ranged from 261 to 298 for northern California to SE Alaska. Using only sites from Oregon to British Columbia (excluding Alaska and California) lowered the estimates slightly to 197 to 256 (Table 7). These results are very similar to the past inter-year estimate conducted in this manner but using a more limited number of years and not as complete a sample as available for this analysis (Calambokidis *et al.* 2000, 2002a, 2002b). These estimates were consistent from year to year and had a high certainty (Coefficient of Variation of 0.03 to 0.06) reflecting the high recapture rates; estimates were based on up to 206 different individuals identified in a year and up 126 recaptures between years (Table 7).

PCFA open population models

From 1998-2003, 408 unique whales were photographed from 1 June to 30 November within the PCFA (NCA to NBC). Excluding the 24 newly seen whales in 2003, 49% of the whales were seen in only one year and 25% were seen in every year following their first encounter. The latter includes 49 whales that were seen in all 6 years. The minimum residency time in the first year seen was 1 week or less for 46% of the whales and greater than 2 months for 25% of the whales. Of 186 whales with a minimum tenure (MRT) of 1 week or less in their first year, 68% were seen during July-September, the middle of the survey period well outside the migration period.

The goodness of fit results for Test 2 + Test 3 (χ^2=251.6, 11 df, P<0.0001) demonstrated a strong lack of fit for a model with survival and capture probability varying by year but not cohort specific. The lack of fit was predominantly from test component 3.Sr (χ^2=212.0, 4 df, P<0.0001) due to differences between “newly seen” and “previously seen” animals as described by Burnham et al. (1987). We subsequently divided the whales into 3 groups for each survey period: 1) newly seen whales with their first MRT ≤ 3 weeks, 2) newly seen whales with their first MRT > 3 weeks, and 3) previously seen whales. The goodness of fit results for Test 2 + Test 3 (χ^2=28.9, 15 df, P=0.01) suggested some lack of fit for the model group-specific time varying survival and capture probabilities, although most of the lack of fit occurred in one component for occasion 5 (2002), 3.Sr5 (χ^2=13.4, 1 df, P=0.004), which most likely occurred because there was very little survey effort in WVI during 2003. We assumed the lack of fit was structural and there was little or no over-dispersion in the data.

Minimum residency time was an important predictor of “survival” for newly seen whales and capture probability of returning whales (Table 8). Survival of newly seen whales varied by year and was presumably dominated by permanent emigration. Survival of previously seen whales varied by year in the lowest AICc model but was constant in the next closest model (ΔAICc=1.8). In computing estimates we used model-averaging of models 1 and 2.

Estimates of first year survival and their standard errors (SE) were 0.85 (SE=0.04), 0.22 (SE=0.05), 0.57 (SE=0.07), 0.39(SE=0.07), and 0.54(SE=0.12) for cohorts of newly seen whales from 1998-2001 using the mean value of MRT for each year. This first year survival represents both mortality and permanent emigration. The predominance of permanent emigration in these estimates is demonstrated by a comparison of the 1998 cohort to the 1999-2002 cohorts. "Newly" seen whales in 1998 were different than those in other years because many whales first "seen" in 1998 may have regularly returned to the PCFA but were only "first seen" because that was the beginning of the dataset. This was evident in the mean MRT which was significantly greater for whales seen in 1998 (47.6 days, SE=3.7) than the average MRT for newly seen whales in 1999-2002 (24.6 days, SE=2.0) (z=5.44, P<0.0001). The "survival rate" for 1998 was higher because there was less permanent emigration from the 1998 cohort than 1999-2002. Excluding 1998, on average we could reasonably expect about 43% of newly seen whales will return in the following years. The odds of a whale remaining in the PCFA after being first seen nearly doubled (1.92 SE=0.40) for an increase of 30 days in their first MRT.

Annual survival of previously seen whales, presumably true survival, was estimated to be 0.97 (SE=0.012) in model 2. The model-averaged estimates of annual survival were 0.92 (SE=0.04), 0.99 (SE=0.02), 0.97 (SE=0.02), and 0.87 (SE=0.08) for 1999 to 2002.

Estimates of recapture probability were 0.79 (SE=0.04), 0.70(SE=0.05), 0.71(SE=0.04), 0.88(SE=0.03) and 0.74(SE=0.08) for 1999-2003 using the average MRT from the previous year (1998-2002) of whales seen through the previous year. If all whales present in the PCFA each year were observed (as we have assumed), then 12-30% of the regularly returning whales may have temporarily emigrated outside of the PCFA. The odds of a whale being seen in a year doubled (1.90 SE=0.35) for an increase of 30 days in MRT the previous year.

Estimated abundance increased from 129 in 1998 (count of new whales) to a peak of 225 in 2002 (SE=6.6) (Figure 10). By subtracting the newly seen whales, we obtained abundance estimates of returning whales that increased from 102 (SE= 5.7) in 1999 to a peak of 176 (SE=20.5) in 2003. The average annual increase of returning whales was 18.5 from 1999 to 2003.

ORSVI open population models

The patterns observed in this analysis were quite similar to the PCFA analysis because the data were a subset of the PCFA data; however, captures and measures of MRT were restricted to the ORSVI area. A whale newly seen in ORSVI may have been seen previously in the PCFA but not in ORSVI and it was treated as a newly seen whale. From 1998-2003, 260 unique whales were photographed from 1 June to 30 November within ORSVI. Excluding the 28 newly seen whales in 2003, 48% of the whales were seen in only one year and 19% were seen in every year following their first encounter. The latter includes 18 whales that were seen in all 6 years. The minimum residency time within ORSVI in the first year seen was 1 week or less for

41% of the whales and greater than 2 months for 26% of the whales. Of the 107 whales with a minimum tenure (MRT) of 1 week or less in their first year, 69% were seen during July-September, the middle of the survey period, well outside of the northward migration period.

The goodness of fit results for Test 2 + Test 3 (χ^2=106.4, 10 df, P<0.0001) demonstrated a strong lack of fit for the model with survival and capture probability varying by year but not cohort specific. As with the PCFA analysis, the lack of fit was predominantly from test component 3.Sr (χ^2=98.8, 4 df, P<0.0001). As with the PCFA data we divided the whales into 3 groups for each survey period: 1) newly seen whales with first MRT ≤ 3 weeks, 2) newly seen whales with first MRT > 3 weeks, and 3) previously seen whales. The goodness of fit results for Test 2 + Test 3 (χ^2=16.2, 12 df, P=0.18) suggested a reasonable fit for the model with group-specific time varying survival and capture probabilities.

Minimum residency time was an important predictor of "survival" for newly seen whales and capture probability of returning whales (Table 9). Survival of newly seen whales varied by year and was presumably dominated by permanent emigration. Survival of previously seen whales was constant in the lowest AICc model but varied by year in the next closest model ΔAICc=1.4). In computing estimates we used model averaging of models 1 and 2.

Estimates of survival and their standard errors (SE) were 0.82 (SE=0.05), 0.50 (SE=0.11), 0.69 (SE=0.10), 0.26(SE=0.07), and 0.64(SE=0.15) for cohorts of newly seen whales from 1998-2001 using the mean value of MRT for each year. This first year survival is presumably predominated by permanent emigration. This was evident in the mean MRT which was significantly greater for whales seen in 1998 (49.1 days, SE=5.0) than the average MRT for newly seen whales in 1999-2002 (27.5 days, SE=2.6) (z=3.86, P<0.0003). Thus there was less permanent emigration from the 1998 cohort than 1999-2002. Whales that are newly seen in ORSVI may not be new to the PCFA, thus we would expect that permanent emigration would be less as it was. On average we could reasonably expect about 53% of whales newly seen in ORSVI will return in the following years. The odds of a whale not permanently emigrating after being first seen, increased by 2.24 (SE=0.53) for an increase of 30 days in MRT.

Annual survival of previously seen whales was estimated to be 0.97 (SE=0.019) in model 2. The model-averaged estimates of annual survival were 0.95 (SE=0.04), 0.98 (SE=0.02), 0.98 (SE=0.02), and 0.94 (SE=0.09) for 1999 to 2002.

Estimates of recapture probability were 0.70 (SE=0.06), 0.55(SE=0.06), 0.80(SE=0.05, 0.58(SE=0.06) and 0.67(SE=0.10) for 1999-2003 using the average MRT from the previous year (1998-2002) of whales seen through the previous year. If all whales present in the ORSVI each year were observed, that would suggest that 20-45% of returning whales may temporarily emigrate outside of the ORSVI. These percentages were expectedly higher because whales may have returned to the PCFA but outside of ORSVI. The odds of a whale being seen in a year increased by more than 50% (1.56 SE=0.33) for an increase of 30 days in MRT the previous year.

Estimated abundance increased from 84 in 1998 (count of new whales) to a peak of 150 in 2003 (SE=20.5) (Figure 11). By subtracting the newly seen whales, we obtained abundance estimates of returning whales that increased from 61 (SE= 5.0) in 1999 to a peak of 122 (SE=20.5) in 2003. The average annual increase of returning whales was 15.2 from 1999 to 2003.

DISCUSSION

Gray whales annually migrate from their feeding grounds during summer/fall to the breeding grounds in Baja California during winter/spring. Most whales feed in the Bering Sea, but some whales regularly do not complete the migration north and remain in coastal waters along the Pacific coast and in the Gulf of Alaska during the summer/fall to feed. While all whales that migrate north to the Bering Sea pass through the region inhabited by the Pacific Coast Feeding Aggregation (PCFA), most northward migration occurs prior to 1 June.

The northward migration path along the Pacific coast provides a possible natural mechanism for recruitment to the PCFA. Northbound whales have traveled a long distance and may be in search of food to replenish fat stores that have been depleted during the migration. Whales that encounter adequate food along the Pacific coast may choose to remain there and not continue the migration northward. If they are successful in one year, they may continue this in future years. Other whales may not be successful in finding food and may stay a short while before proceeding northward or simply pass through. Whales that typically return regularly may choose to look elsewhere following a year in which they were less successful foraging in the PCFA.

This proposed mechanism for the dynamics of the PCFA whales is supported by the inclusion of minimum residency tenure (MRT) in the models for survival (emigration) and capture probability. It is important to recognize that the observed tenures are minimums and whales may have been within the PCFA longer and not seen because it was in a region that was not surveyed or sampled less frequently. Although whales with short tenures could have been seen as late spring migrants or early fall migrants on their way north or south, more than two-thirds of those with short tenures were seen from July- September.

Lower survival estimates for newly seen whales could reflect permanent emigration (whales passing through) or mortality. Mortality would be more likely in this group if whales in poor physical condition are more likely to stop along the Pacific Coast in search of food. The estimated annual average survival rate (0.97) of PCFA (returning) whales clearly includes very little to no permanent emigration and is consistent with natural survival for a long-lived species. The annual variability in survival of PCFA whales in model 1 may have resulted from some increased mortality in 1999 during the stranding event but also the lack of sampling in WVI during 2003 may have depressed the estimated survival rate for 2002. The evidence for annual variation in survival is equivocal as the model ordering flipped between the two analyses. The support for constant survival in the ORSVI analysis may be due to the smaller sample size, but it may also be a better approximation to reality because it would not have been affected by the lack of sampling in WVI during 2003.

Jolly-Seber capture-recapture models assume that the capture occasion is an instantaneous event. Although a 6 month-long sampling period violates this assumption, it is only practically important if there are losses or gains in the population during the sampling period. Any loss due to natural mortality (0.03) is unlikely to have any importance even if it occurs during the sampling period. And while there will be whales both entering and leaving the region during the sampling period, it should not affect our estimates of population size that conservatively assume that all whales in the region are seen and whales are only missed because they did not return.

We chose a very conservative approach to abundance estimation with the potential for under-estimating abundance. We did so to provide estimates that could be used to set harvest quotas that would be risk-averse. Also, our estimation approach for abundance is consistent with our proposed mechanism for the dynamics of the PCFA whales. We have assumed that whales are only missed because they are not in the PCFA during the year. Thus, the newly seen whales are all of the new immigrants of which some (50-60%) will never return. If they do not permanently emigrate, they may return some years but not others and this is assumed to be random based on the year and their MRT in the previous year as modeled by the capture probability. Thus the estimated abundance is the predicted number of returning whales (did not permanently emigrate) that have survived from each cohort of newly seen whales. This may under-estimate the number of immigrants but newly seen whales have shorter MRTs and thus would be less vulnerable to harvest. Returning whales have longer MRTs and are more vulnerable to harvest.

The abundance estimates from the open population models are lower than the Petersen estimates based on a closed model. There are two reasons for the difference. First, the Petersen estimator treats “newly” seen and “previously” seen the same with each having a capture probability of p. Whereas, we have assumed p=1 for newly seen and estimated p applies only to returning whales. Secondly, the Petersen estimate is only unbiased with an open population if there are only losses or only gains in the population. In this case, there are both and that can create a positive bias because some of the whales seen in year 1 do not return and some of those seen in year 2 were new immigrants that year. Both of these will underestimate p and overestimate abundance.

Selecting a region for estimation is a difficult problem because for any set of boundaries the population size is open to change due to shifts in geographic distribution. We know that even using the PCFA boundaries, some whales that typically return will go to southeastern Alaska or Kodiak or possibly the Bering Sea. There is also considerable interchange within the PCFA so regions within the PCFA will have substantial annual changes when whales shift their distribution in search for food. However, clearly there is some level of fidelity; otherwise the abundance estimates from ORSVI would have been the same as the estimate for the PCFA. We have shown that regions in close proximity have the highest interchange rate thus it is both logical and reasonable to use ORSVI as the region for abundance estimation in setting quotas for a harvest of whales from the NWA/SJF region.

ACKNOWLEDGEMENTS

This analysis would not have been possible without the collaborating organizations contributing identification photographs listed in Table 1. These include Humboldt State University (coordinated by Dawn Goley), Coastal Ecosystem Research Foundation (coordinated by William McGill), University of Victoria (coordinated by Dave Duffus and Christina Tombach), and the efforts of Brian Gisborne, Jim Darling, and Volker Deeke.

Support for the photographic identification reported here, the comparison of gray whale photographs and preparation of this report came primarily from the National Marine Mammal Laboratory. Some of Cascadia's field effort on gray whales was conducted incidental to humpback whale research for the Southwest Fisheries Science Center and the Olympic Coast National Marine Sanctuary. A number of individuals helped arrange support for this work including Joe Scordino, Robert DeLong, Jay Barlow, and Ed Bowlby. Permission to conduct some portions of this research was provided by the U.S. National Marine Fisheries Service and the Makah Tribal Nation. Nathan Pamplin provided advice on the analysis. Gretchen Steiger reviewed the report.

We thank the operators of the boats that allowed us to gather data from their boats including the Mosquito Fleet in northern Puget Sound. A number of people assisted in the field effort and in the printing and matching of photographs. We thank our volunteers and interns whose assistance in the field and in the processing of the photographic identifications was invaluable. Todd Chandler conducted some of the surveys off Washington, Oregon, and northern California.

TABLES AND FIGURES

Tables

1. Summary of identifications of gray whales by collaborating researchers for 1998-2003.
2. Summary of effort and gray whale identifications by region for 1998-2003.
3. Sighting histories of gray whales seen after 1 June each year for 1998-2003.
4. Frequency with which gray whales were seen in more than one year or region by month region.
5. Interchange of gray whales between regions for 1998-2003 for all year and after 1 June only.
6. Model selection results of analysis of within year, between year and overall interchange between NWA and the other 5 regions.
7. Petersen capture-recapture abundance estimates for seasonal resident gray whales.
8. Model selection results for open population models fitted to PCFA (N. CA to N. British Columbia) capture history data.
9. Model selection results for open population models fitted to ORSVI capture history data.

Figures

1. Study areas showing principal areas of effort.
2. Locations of all identifications of gray whales made 1998 to 2003 with lines connecting resightings of the same whale in the same year.
3. Interchange of gray whales among regions.
4. The average number of the 6 regions in which a whale was seen increases for each year it was seen. Error bars are 95% confidence intervals for means.
5. Relationship between number of years seen and the minimum residency time in the first year the whale was seen. Error bars are 95% confidence intervals for means.
6. Relationship between minimum residency time in year *y* and the proportion of whales seen in year *y* +1. Error bars are 95% confidence interval based on normal approximation to binomial.
7. Predicted proportions of within year interchange with NWA for the highest (1998 - most effort) and lowest (2002 - least effort) years and for whales seen 1-2 years and 5-6 years.
8. Predicted proportions of between year interchange with NWA for the highest (2002) and lowest (1998) years and for whales seen 2-4 years and 5-6 years.
9. Predicted proportions of overall interchange with NWA for each region and number of years seen.
10. Estimated annual abundance of all whales in the PCFA and returning whales in the PCFA (log-normal 95% confidence intervals shown).
11. Estimated annual abundance of all whales in ORSVI and returning whales in ORSVI (log-normal 95% confidence intervals shown).

Table 8. Model selection results for open population models fitted to PCFA (N. CA to N. British Columbia) capture history data. Survival for newly seen whales represents survival (and permanent emigration) for the year immediately following their first encounter. It varied by year (t) for all models while some models also included MRT. Survival for previously seen whales was either constant or varied by year (t). Capture probability models with variation by year and MRT in the previous year were considered.

	Survival		Capture Probability	# par	ΔAICc
	Newly seen	Previously seen			
1	t + MRT	T	t + MRT	16	0
2	t + MRT	Constant	t + MRT	13	1.8
3	t + MRT	T	MRT	12	8.5
4	t + MRT	Constant	MRT	9	16.5
5	MRT	Constant	t + MRT	9	43.9
6	t + MRT	Constant	t	12	66.7
7	t	Constant	t+MRT	12	107.3
8	t	Constant	t	11	133.8

Table 9. Model selection results for open population models fitted to ORSVI capture history data. Model numbers in correspond to ordering of models in PCFA analysis (Table 8). The same models were considered in both analyses.

	Survival		Capture Probability	# par	ΔAICc
	Newly seen	Previously seen			
2	t + MRT	Constant	t + MRT	13	0
1	t + MRT	T	t + MRT	16	1.4
3	t + MRT	T	MRT	12	8.6

ABSTRACT

Habitat utilization and prey species of Vancouver Island gray whales were investigated by (1) summarizing 26 yr of distribution and feeding data and (2) conducting intensive observations in Clayoquot Sound, Vancouver Island, from 1989 to 1996. Whale distribution and movements were monitored from March to November through systematic boat surveys and whale-watch sighting programs. Prey species were collected by suction hose and plankton net or determined through analysis of fecal samples. Gray whales utilized virtually all of the southern west coast of Vancouver Island over the 26-yr observation period. Distribution, prey species, and feeding behavior showed marked variability during any one season and between years. Some feeding areas were used on an annual basis, others with >10-yr intervals between use. Feeding occurred in shallow sand or mud bays, eel grass beds, kelp beds, in the open water column, and at the surface. Young whales appeared to utilize habitat and prey species differently than adults. Main prey species included herring eggs/larvae (*Clupea harengus pallasi*), crab larvae (*Cancer magister* megalops, *Pachycheles* spp. zoea), mysids (*Holmesimysis sculpta, Neomysis rayii, Acanthomysis* spp.), amphipods (*Ampelisca* spp., *Atylus borealis*), and ghost shrimp (*Callianassa californiensis*). The definition and relative importance of specific feeding grounds and the study of human impacts on this population are complicated by its broad and variable use of habitat and prey species.

Key words: gray whale, *Eschrichtius robustus*, prey, feeding patterns, habitat, Vancouver Island, oil.

The majority of eastern Pacific gray whales (*Eschrichtius robustus*) migrate annually between winter breeding grounds along the Mexican coast and summer feeding grounds in the Bering and Chuckchi Seas (Scammon 1869, Pike

1962, Rice and Wolman 1971, Rugh 1984). Small populations of gray whales inhabit portions of the North American coast from California to Alaska during the summer (Gilmore 1960*a,b*, Pike 1962, Pike and MacAskie 1969, Rice and Wolman 1971, Darling 1984, Nerini 1984, Calambokidis *et al.* 1991). A gray whale population occupying a summer range along the west coast of Vancouver Island, British Columbia, has been studied since the early 1970s (*e.g.*, Hatler and Darling 1974; Darling 1978, 1984; Oliver *et al.* 1984; Guerrero 1989; Duffus 1996).

The Vancouver Island gray whale population consists of 35–50 whales which occupy the region for 8–9 mo between northern and southern migrations, the period from approximately March to December. During the summer they range and feed over a distance at least the length of the central Vancouver Island coastline. Between the 1970s and the present, a number of individually identified whales returned to this location each year, suggesting that the area may be a "home summer range" of a specific group of animals. Adults were typically identified over multiple years, and small, very young whales were usually present for 1–2 seasons only (Darling 1984).

Several authors have described gray whale feeding behavior off Vancouver Island. They documented benthic feeding on amphipods, ghost shrimp, and possibly polychaete worms (Hatler and Darling 1974, Darling 1978, Oliver *et al.* 1984, Plewes *et al.* 1984, Kvitek and Oliver 1986) and planktonic feeding on mysids (Murison *et al.* 1984, Guerrero 1989). Collectively, these observations indicate gray whales exploit several types of prey off Vancouver Island.

In December 1988 the Nestucca oil spill resulted in substantial amounts of oil being deposited in gray whale feeding grounds off Vancouver Island (Canadian Coast Guard 1989).[1] In the follow-up assessment, JDD was asked by the Department of Fisheries and Oceans to investigate the impact of the spill on the gray whales feeding in the area. Limited knowledge about the patterns of utilization of feeding grounds and specific prey species obscured our understanding of the impacts of the spill. Such information is key to our ability to determine the impacts of human activity or natural phenomena on the whales. The purpose of this study was to document patterns of habitat and prey utilization by gray whales in the Clayoquot Sound region of Vancouver Island.

METHODS

Study Area

Vancouver Island (Fig. 1) is a 480-km long island approximately half-way between gray whale breeding areas in Mexico and northern feeding grounds.

---

[1] The spill of 875,000 liters of Number 6 Fuel Oil occurred off Oregon on 28 December 1988, and currents brought oil to Vancouver Island within a few days. Substantial amounts of oil washed onto beaches in gray whale feeding grounds. The majority of gray whales were on their winter migration south of Vancouver Island at the time of the spill.

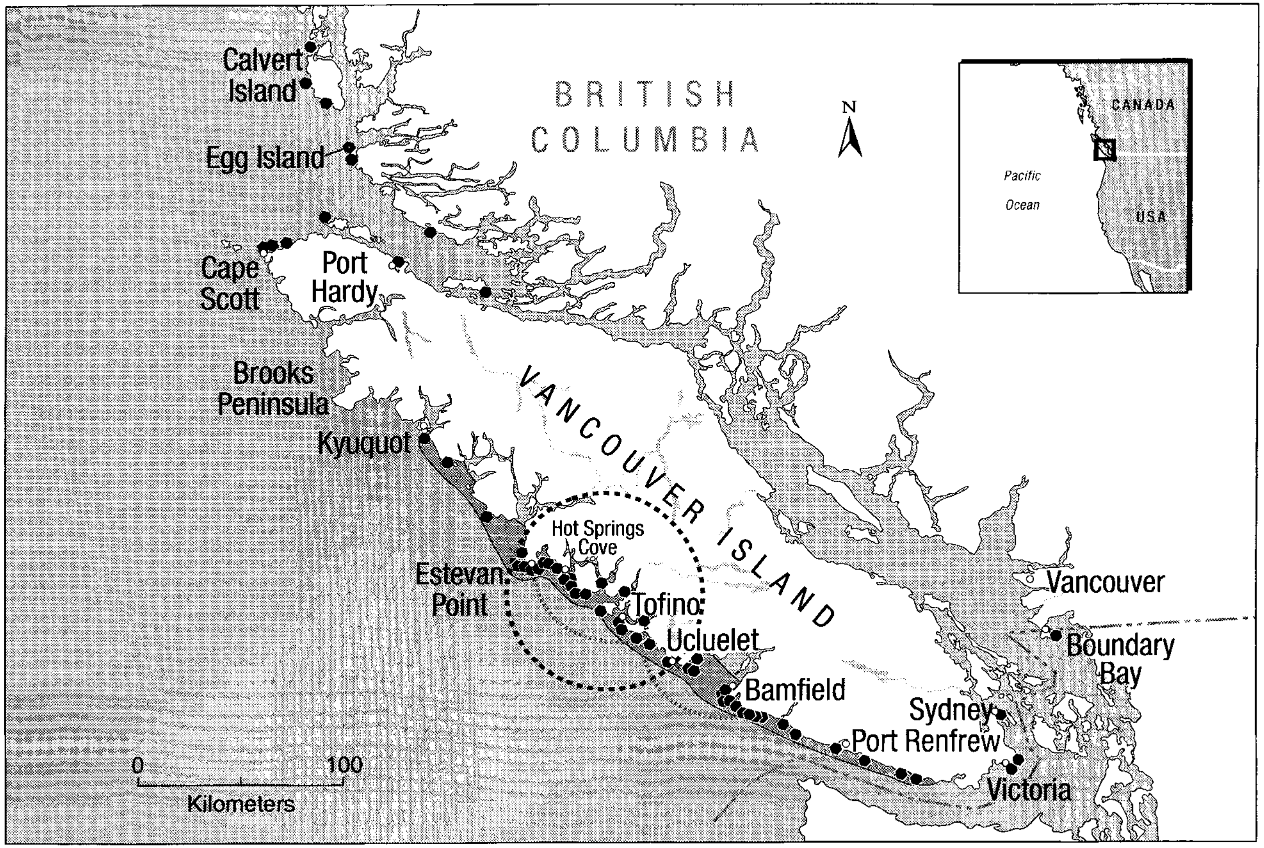

Figure 1. Vancouver Island, study area, and locations of feeding whales, 1971–1996. Primary study area indicated by circle. Dotted lines joining locations indicate actual movements of individuals within one summer and show study area smaller than summer range (Darling 1984).

Between 1971 and 1996, gray whale observations were conducted on the coasts of Vancouver Island between Victoria and Cape Scott and in waters northward on the British Columbia mainland coast. Most of the observations occurred along the 225-km central–southwest coast of Vancouver Island, with the primary study area in the Clayoquot Sound region, extending approximately 80 km from Wickaninnish Bay in the southeast to Estevan Point in the northwest (Fig. 1). Our primary study area is only a portion of the overall summer range of the Vancouver Island population (Darling 1984). This coastline is characterized by open, shallow, sandy bays with surf-swept beaches separated by rocky headlands, coastal islands creating protected inside waterways, and extensive fjords reaching up to 30 km inland.

Vancouver Island and Adjacent B.C Coast Sightings

Sightings were collected along the Vancouver Island and mainland British Columbia coast by JDD and other knowledgeable observers over the 26-yr period, 1971–1996 (Fig. 1). These were recorded in a series of field notebooks, and some have been previously published (Hatler and Darling 1974, Darling 1984).

Clayoquot Sound Observations

The majority of observations that focused on habitat use and prey species were made during an eight-year period from 1989 to 1996. Some of the observations presented originated from earlier work in the region by JDD. Habitat use information was gathered using both research surveys and whale-watch sighting programs. The research effort included systematic small-craft surveys of the study area at least weekly from May through October each year, 1992–1996. Additional surveys were conducted in March–April and November each year as weather allowed. Presence and absence of whales on known feeding grounds were documented. All whales were individually identified by photographs of natural markings on their sides (Darling 1984) and locations, behavior, and associates noted. Photoidentified whales were compared to those in an identification catalog developed over the last 20 yr for sighting histories. Changes in location and habitat use by whales were monitored through these surveys and from the daily whale-watch effort in the region.

Whale watching is a significant industry in the study area and provided an opportunity for an intensive documentation of whale distribution between early March and late October each year. Whale-watch boats searched for whales on a minimum of 175 d between these dates each year, leading to a total of over 1,400 d of observation, 1989–1996. Six–12 boats and one to three planes were involved on any one day, operating from dawn to dusk. A specific marine radio channel allowed all interested to be party to all sightings. Beginning in 1989, whale-watch boats were asked by JDD to record whale sightings. Forms with maps of the region were provided, and boat operators were asked to record trip time, locations, and whale activity (feeding, resting, traveling, rubbing). The majority of the boat operators had at least five years' experience with the whales and were proficient at determining behavior mode. Daily contact between whale-watch operators and researchers conveyed current whale activity, and boat operators contacted a researcher if unusual events occurred. The whale-watch activity amounted to an enormous sighting effort that was difficult to quantify due to variable participation and experience of specific operators. However, we cannot overemphasize the ongoing intensity of this effort, and we are convinced most whale activity in daylight hours in the region was recorded through this program.

The study effort for the years 1992–1996 was nested, with prey collections occurring within regular distribution and abundance surveys occurring within the ongoing whale-watching effort. Combined, these provided an accurate overview of activity in the area.

Prey Collection and Identification

In each feeding location the prey species was determined by collections, or, if needed, fecal analysis. Benthic samples were collected with a suction hose and fine-mesh net. A diver held the collection hose (PVC pipe) on the bottom in the close vicinity of feeding whales and, through use of a scuba tank to create a vacuum, suctioned the sediment/organism mixture into a fine-mesh net. Later, the predominant organisms were sorted and identified. When whales were feeding on deeper plankton or hyperbenthic organisms, collections were made using a plankton net with a cannonball weight attached to drop it to the bottom. It was towed within meters of feeding whales. Patches of prey were usually dense, and the net would often be filled beyond the collection cylinder within a few minutes of tow. When whales were feeding on the surface, the plankton net was used without the weight. If these techniques failed to catch organisms in quantities clearly indicating the prey species, the feces of the whales were collected and examined for body parts identifiable to species.

Once prey organisms were collected from a particular feeding event, the whales were monitored by researchers and whale-watch operators. Any change in behavior or feeding location warranted another collection of prey. Periodic collections were made whether whales had changed behavior or locations or not. This routine was followed throughout the May-November period, 1992–1996. In known benthic-feeding areas in which samples had been repeatedly taken over years (this study and others: *e.g.*, Kvitek and Oliver 1986), collections were made only to confirm prey species. It was presumed that when bottom feeding in these locations the whales were consuming benthic species known to inhabit the region.

Prey organisms were preserved in 5% formalin in seawater and identified by local identification keys such as Kozloff (1983) or by amphipod specialist E. Bousfield at the Royal British Columbia Provincial Museum.

RESULTS

HABITAT UTILIZATION

Vancouver Island and Adjacent B.C. Coast

Observations included both planktonic and benthic feeding activity (Fig. 1). Sightings ranged from Georgia Strait and Victoria on the southern tip of the island to Cape Scott in the north. Whales were also sighted feeding in the Inside Passage, between Vancouver Island and the mainland and along the B.C. mainland coast northwest of Vancouver Island. Research effort was considerably less over the northern half of the Vancouver Island west coast and the mainland coast; the fewer sightings in these regions compared to the southern Vancouver Island west coast, therefore, may reflect effort rather than habitat use. Gray whales occupied a variety of habitats when sighted, ranging from protected, shallow, mud-bottomed bays to exposed surf-swept bays and beaches, to stretches of sandstone shelf, or rugged rocky shoreline with extensive fringing kelp beds. Gray whales were not present in all locations each year, and some locations were more regularly occupied than others. However, the long-term records clearly indicate that virtually all of the central-southern outer Vancouver Island coastline was utilized by gray whales over the 26 yr.

Clayoquot Sound Region

Habitat types included feeding sites, divided into herring, benthic, and plankton feeding locations, and "rubbing" sites (Fig. 2). The whales made use of all of these locations and habitats over time, although not all locations were used each year. Some feeding areas were used regularly, and these are indicated as primary grounds; others were utilized irregularly, and these are shown as secondary feeding grounds (Fig. 2). Primary grounds were those where we observed feeding for at least some portion of the season in most years; secondary grounds included those in which several years separated periods of utilization. The status of sites could change from primary to secondary use over the long term.

Feeding Habitat

Herring sites—These sites could occur wherever herring spawned. Characteristics of herring spawning sites included eel grass or algae beds in semi-protected or protected waters. There was substantial annual variability in the timing, location, and size of the "spawn" and in gray whale use of herring spawn habitat. The most consistent location in the study area was Hesquiat Harbour, at the west end of Clayoquot Sound, a 6 × 10-km shallow bay fringed with eel grass and algae beds and protected from northwesterly seas and weather. Spawning sites within the bay varied somewhat year to year. Other herring spawning habitat utilized by gray whales included sites on the west and east shores of Flores Island and north and east shores of Vargas Island

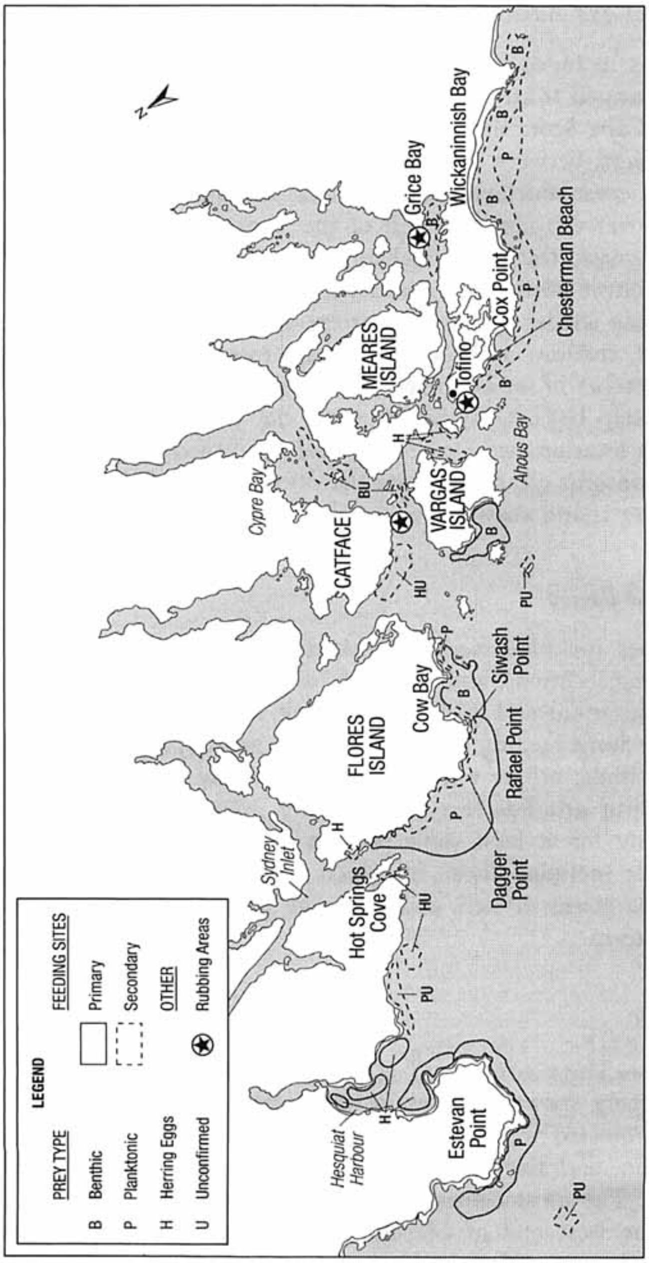

Figure 2. Gray whale habitat use and prey types in Clayoquot Sound, 1971–1996. Primary sites were those used regularly; secondary sites were those used irregularly. Wickaninnish Bay was primary site until early 1980s and now considered secondary site. "U" behind prey type indicates suspected but unconfirmed. Note rubbing areas off Tofino, Catface, and Grice Bay.

and adjacent shorelines (Fig. 2). Gray whale utilization of herring spawn areas occurred also at other locations along the Vancouver Island and Queen Charlotte Island coastlines (JDD, unpublished data).

Benthic feeding sites—Benthic feeding sites were the most definable and predictable of all feeding habitats. The primary sites included Cow Bay on the outside coast of Flores Island and Ahous Bay on the outside of Vargas Island (Fig. 2). Until the late 1970s, Wickanninish Bay and Chesterman Beach, approximately 20 km and 9 km, respectively, to the south of Ahous Bay (Fig. 2) would also have been considered primary benthic feeding sites. However, this has changed in recent years (discussed below). These are all relatively large, shallow, sand-bottom bays with feeding activity ranging from the intertidal zone to approximately 30 m of depth. Many smaller sandy bays in the region were used on occasion. An example of a secondary site was Cypre Bay, a protected passage between Meares Island and the Catface Range (Fig. 2). Several years passed without any extended gray whale use, but in some years this region was occupied by 6–8 whales for weeks at a time. Another important secondary site was Grice Bay, a protected mud-bottom bay so shallow that the majority of it is dry at low tide. It is reached through a 10-km long, narrow, inland passage from the entrance to the open sea at Tofino.

Plankton feeding sites—The plankton feeding sites most consistent over the period of this study were the section of coastline from Wickaninnish Bay to Chestermans Beach near Tofino, the entire outer Flores Island coast from its southern point around to the Sydney Inlet entrance, and the outer coast of Estevan Point (Fig. 2). Different sites within these larger regions were occupied for utilization of different prey species. The boundaries of these sites were quite flexible, with the prey and whales shifting with tide and current. Depending on prey species, the whales were found within and along kelp beds and in the surf zones of rocks (mysids) or slightly farther offshore in open water (crab larvae). Plankton feeding often occurred at locations distinct from benthic feeding sites, but overlap did occur.

Young Whale Habitat

Young whales generally tended to be separated from adult animals and were sometimes found together in small groups. This separation was subtle at times, with the younger animal(s) just several hundred meters away from adult assemblages, often inshore or in a kelp bed; or it was quite marked, when young animals occupied physically separate habitat with nearest adults 10+ km distant. The latter case is exemplified with the utilization of Grice Bay habitat. All sightings in this location over a period of 26 yr were of young whales. Between one and five whales spent months and in some cases a year or more in the bay, feeding benthically.

Sand Bar (Rubbing) Activity

Gray whales used specific habitat in Clayoquot Sound presumably for rubbing purposes. The whales regularly moved to sand bars and gravel spits in

Table 1. Prey species collected in Clayoquot Sound, 1989–1996.

Herring eggs/larvae	*Clupea harengus* pallasi

the region where they rubbed their bodies and "stood" on their tails with heads lunging above the water. This behavior occurred regularly at a sand bar in Templar Channel off Tonquin Beach at the south entrance to Tofino harbor and on a sand bar off Catface Mountain in Calmus Passage (Fig. 2). Whales moved into the area from feeding grounds, or from the migratory route, rubbed for a few minutes to several hours, then moved away again (Darling 1978). Some local observers have suggested that feeding occurs at these sites; however, we have no evidence either way. Whales periodically inhabiting Grice Bay were observed similarly rubbing on the gravel spit off Indian Island. It is possible this activity also occurred regularly on the bottom.

PREY SPECIES

Benthic species (Table 1) included amphipods (*Ampelisca* spp.) and ghost shrimp (*Callianassa californiensis*); planktonic or mobile species included mysids (*Holemsimysis sculpta, Neomysis rayii, Acanthomysis* spp.), crab larvae (*Cancer magister* megalops, *Pachycheles* spp. zoea), and mobile amphipods (*Atylus borealis*). Herring eggs and larvae (*Clupea harengus pallasi*) were also prey for gray whales off Vancouver island.

Appendix 1 gives the prey collection record from 1984 to 1996, including date, locations (Fig. 2), method of collection, and prey species. A total of 43 collections were made. The numbers of collections by species generally reflect only our need to confirm prey during ongoing monitoring and not the relative utilization of the different species.

The leveling off of the graph of "new" species (Fig. 3) indicates that the later collections produced species already documented as prey items. The last 16 collections in 1995 and 1996 and 27 of the last 28 collections since 1994 produced no previously unknown prey species. This suggests that the nine species identified to date made up the predominant prey species of gray whales in the study area during the period of observation. However, we do not wish to imply that this is a complete list. For example, highly suggestive but unconfirmed observations of gray whales feeding on juvenile rockfish and needlefish or sandlance have been made in the region.

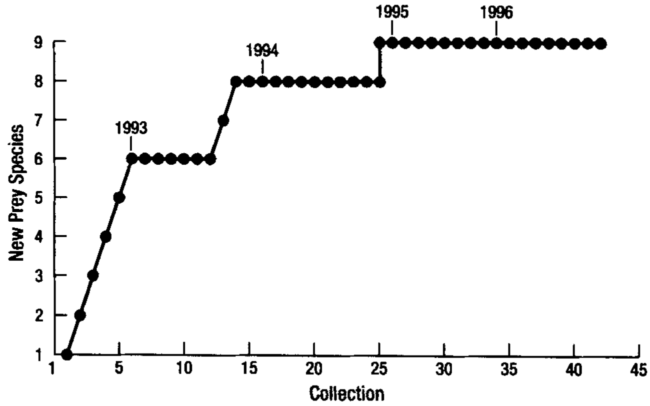

Figure 3. Discovery of prey species, 1984–1996. Leveling off indicates no new species found.

We observed several different feeding techniques and behavior patterns depending on type of prey, including feeding on the bottom, in the water column, and at the surface. Bottom-feeding activity, characterized by whales diving for several minutes and surfacing in approximately the same location streaming sediments from the baleen, and mysid feeding characterized by short dives and more random movements in kelp beds and within the surf zone of rock and islets, have been described by several authors (*e.g.*, Rice and Wolman 1971, Nerini 1984, Murison *et al.* 1984, Guerrero 1989). Feeding on crab larvae included skim feeding, with the whales moving along the surface, the upper jaw above the water, repeatedly "biting" down on the plankton streams along tide lines. When the crab larvae were deeper, the surface activity was similar to benthic feeding, except that the whales generally moved over a greater distance during dives. Feeding on herring eggs often occurred in water several meters deep, the whales on their sides with a flipper and half fluke above the surface. We presume that the whales used suction to engulf the egg masses but this has not been confirmed. A whale that died in the area in April 1997 was found to have its stomach filled with herring eggs (JDD, field notes).

FEEDING PATTERNS IN CLAYOQUOT SOUND

Early Season Herring Spawn Events

Each spring gray whales left the northward migration to feed on herring eggs recently deposited on eel grass and algae beds (Fig. 2). The location, time, and intensity of this activity varied substantially from year to year depending on the timing and abundance of herring. Hesquiat Harbour was the only site in Clayoquot Sound where this feeding occurred on an annual basis throughout the period of study. At Hesquiat the spawn and feeding activity occurred between mid-February and early April and usually lasted two to three weeks, with several separate spawns in some years extending this time considerably. During this period dozens to hundreds of whales utilized the site. It appeared the whales fed until the eggs hatched, which occurs approximately 10 d after spawning (Hart 1973), although we suspect they may also feed on the larvae in some circumstances. There can be an enormous volume of eggs, with egg drifts on beaches a meter or more high. Several other locations in the study area had smaller herring-related feeding events during one or two of the years between 1989 and 1996 (Fig. 2). When this occurred, whales moved into the area for a week or two, then departed. It is likely that herring provided the first food of the season to a portion of the migrating herd. Herring spawn times occurred progressively later along the coastal migratory route of the whales, just ahead of the migration itself. Herring-egg-feeding locations were not included in the annual feeding maps discussed below, as there is no confirmation at this stage that summer resident whales were involved in these events—although there is also no reason to believe they are not.

Summer Feeding Patterns

From observations conducted between 1989 and 1996, we have chosen four years to illustrate feeding patterns in detail: 1992, 1993, 1994, and 1995 (Fig. 4A–D). Observations from other years are referred to in relation to these examples. The terms early-season, mid-season, and late-season are used to generally designate the periods May–June, July–August, and September–November, respectively; and the terms "short-lived" and "extended", "minor," and "major" are arbitrary and used to describe the relative duration and number of whales participating in feeding events. A short-lived event was less than seven days; a major event involved more than ten whales.

1992 (Fig. 4A)—During the early- and mid-season there were several short-lived plankton-feeding events, including: (1) off Cox Point for one week in May (*A. borealis*), (2) north of Rafael Point in late June (*Pachycheles* spp.), and (3) off Estevan Point in mid-July (*Pachycheles* spp.). Beyond these events and through much of the summer, there were few whale sightings in Clayoquot Sound. There were occasional sightings of whales passing through or staying just a few days. On 18 August whales moved into Cow Bay and Ahous Bay and began feeding on benthic amphipods (*Ampelisca* spp.). This activity continued through the rest of the season. Numbers ranged from two to seven whales in Cow Bay through October and one to four in Ahous Bay through November. Noteworthy for this year is that sightings occurred over the period, 8–11 September, in the Cypre Bay region, a secondary ground with the last extended period of use in July–September 1982.

1993 (Fig. 4B)—An extended plankton-feeding event (*A. borealis*) occurred during the period from early May to early June along the coastline from Wickaninnish Bay to Chesterman Beach near Tofino, with up to seven to eight whales involved. During this time, and throughout most of the summer, whales were present in Ahous Bay and Cow Bay feeding on benthic prey (*Ampelisca* spp.). From June to October, one to six whales were periodically present in Ahous Bay. From May to November, one to eleven whales were present in Cow Bay. In the latter an obvious increase in numbers occurred in mid-August, leading to a constant seven to eight whales present through September. Whales also fed on mysids: (*N. rayii*) off Estevan Point in July and (*H. sculpta*) off Rafael Point for a period in July and August.

1994 (Fig. 4C)—This was primarily a plankton-feeding year. Whales were present for a week in early May in Wickanninish Bay (food unknown). From mid-May through late June up to 14 whales were involved in a major mysid-feeding event (*H. sculpta*) in the south Cow Bay area. By July most had moved to Rafael Point, where as many as eight whales fed on crab larva (*Pachycheles* spp.) through the end of August, although the number of whales present declined after 20 August. Whales were present off the Rafael Point–Siwash Point region feeding on plankton through September and October, but the prey species was not confirmed until 2 November: mysids (*N. rayii* and *Acanthomysis* spp.). The whales apparently shifted from crab larvae to mysid prey sometime during this period. Benthic feeding was not observed in the region until 2 November in Ahous Bay.

1995 (Fig. 4D)—Sporadic bottom feeding occurred in Ahous Bay from May to July, with one or two whales present for one or two days at a time. Similarly, sporadic bottom feeding occurred in Cow Bay in June, July, and early August, with one to four whales moving in and out of the area. In Ahous Bay, one to two whales were present continually by mid-September, five to six by early October, and seven to eight by late October. In Cow Bay from mid-August through September whale numbers were steady at three to four, and none were present in October. Through periods of July and August, two to five whales were present in the Rafael Point–Sydney Inlet area feeding on crab larvae (*Pachycheles* spp.), and in September a major feeding event occurred off Estevan Point with 10–15 whales also feeding on crab larvae. The Grice Bay secondary ground was utilized throughout the season, as described below.

Grice Bay utilization—During 1995, one to five young whales occupied the Grice Bay secondary ground from March through August feeding on ghost shrimp (*C. californiensis*). One of the same individuals was also present in the same area in June, July, and September 1996, also feeding on ghost shrimp. This feeding ground had been last utilized extensively in 1984–1985 by one or two young whales, and prior to that, in 1971, by one whale (Fig. 5; Hatler and Darling 1974). During the three documented periods of extended sightings since 1971, at least eight individual whales utilized this habitat for periods up to one year or more. The individual whale present in 1985 was one of the two animals present in 1984 and stayed the winter (JDD, unpublished data). No adults were sighted in the vicinity.

Between-Year Comparisons

It is clear that the differences between years are more striking than any repetitive patterns of occupancy or prey type (Fig. 6). For example, benthic feeding occurred throughout the season in 1993, was virtually non-existent in

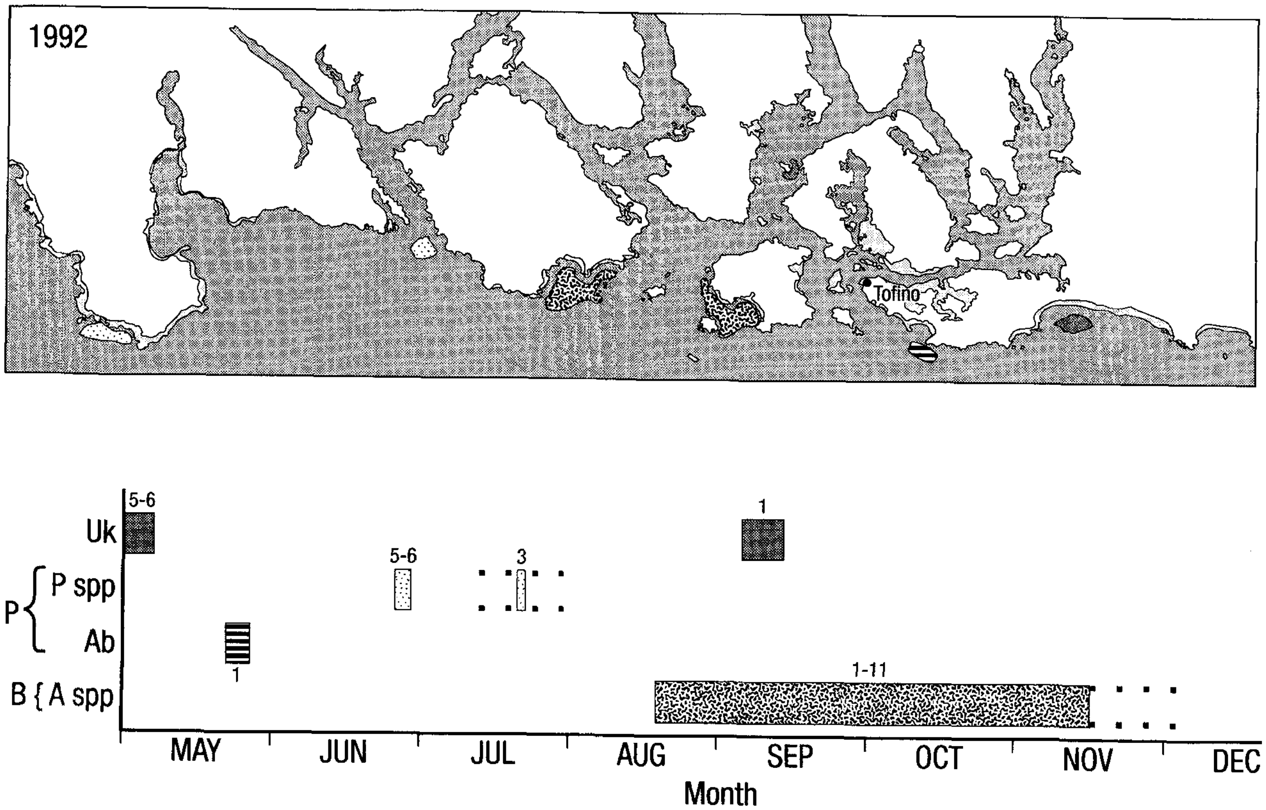

Figure 4. Patterns of habitat and prey utilization: (A) 1992, (B) 1993, (C) 1994, (D) 1995. P = plankton; B = benthic; Uk = unknown; Uk P = unknown plankton; Uk B = unknown benthic; A spp = *Ampleliscа* spp; Ab = *Atylus boralis*; Hs = *Holmesimysis sculpta*; Nr = *Neomysis rayii*; P spp= *Pachycheles* spp; Cc = *Callianassa californiensis*. Numerals indicate approximate number of whales involved in feeding event (determined by individual identification). Patterned circles inside "unknown" designation indicates likely prey (*e.g.*, 1993, 1994). Prey collections made within shaded areas.

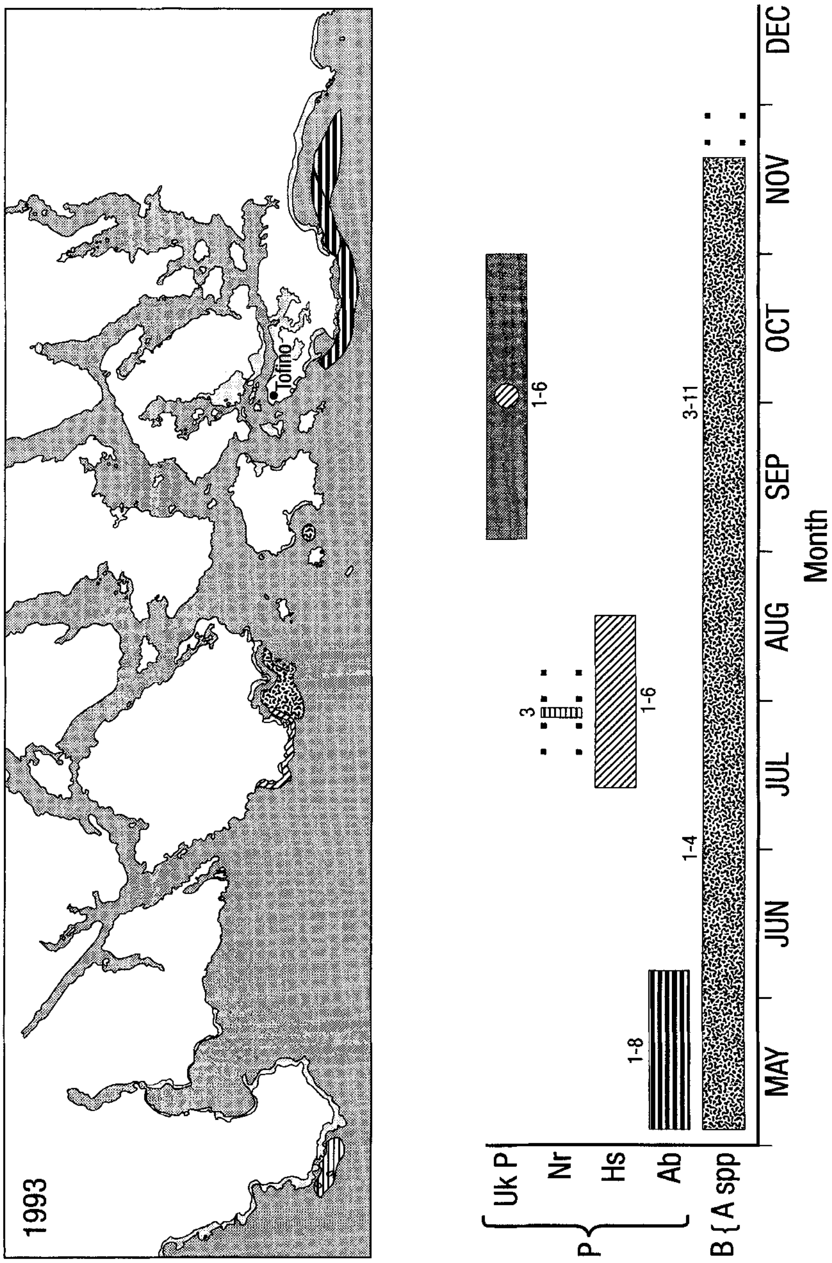

Figure 4. Continued.

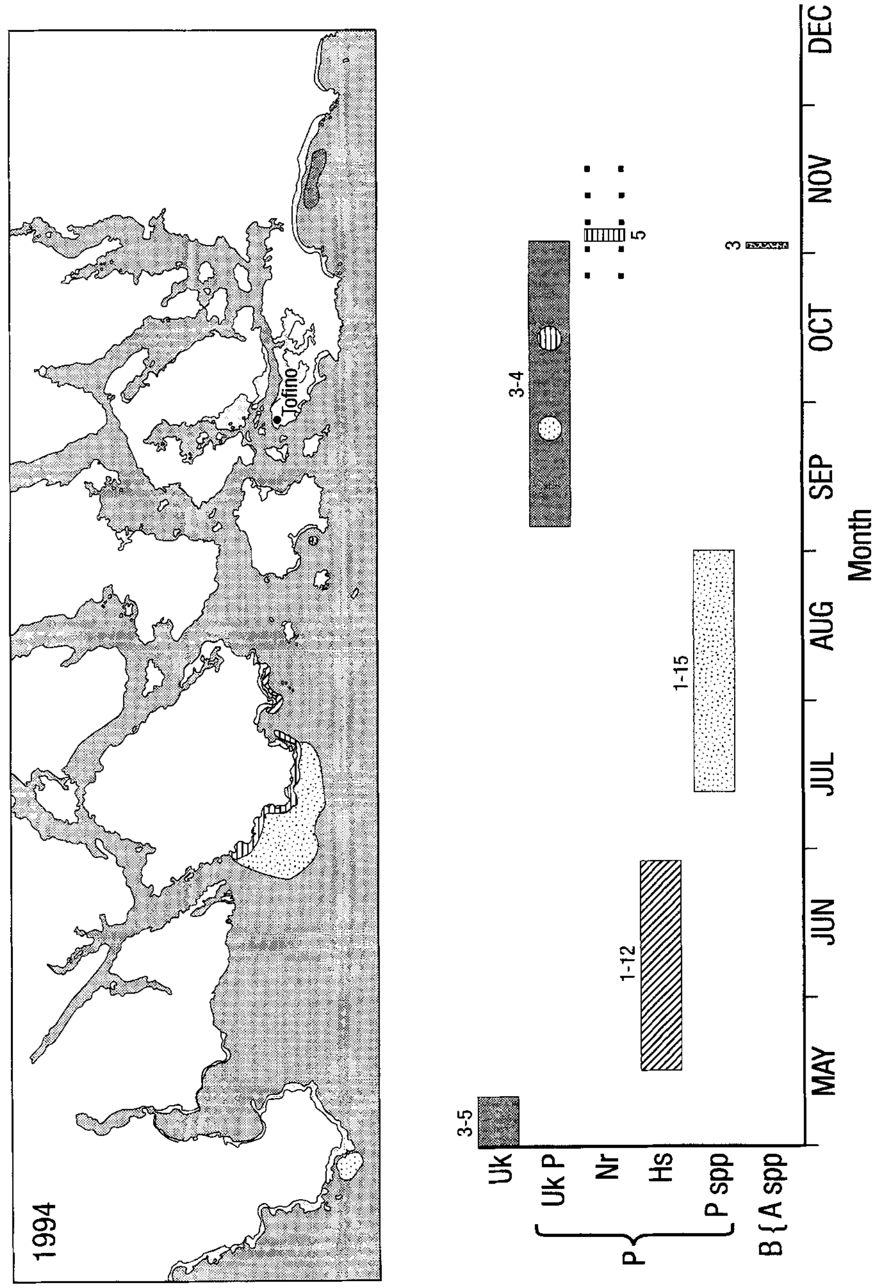

Figure 4. Continued.

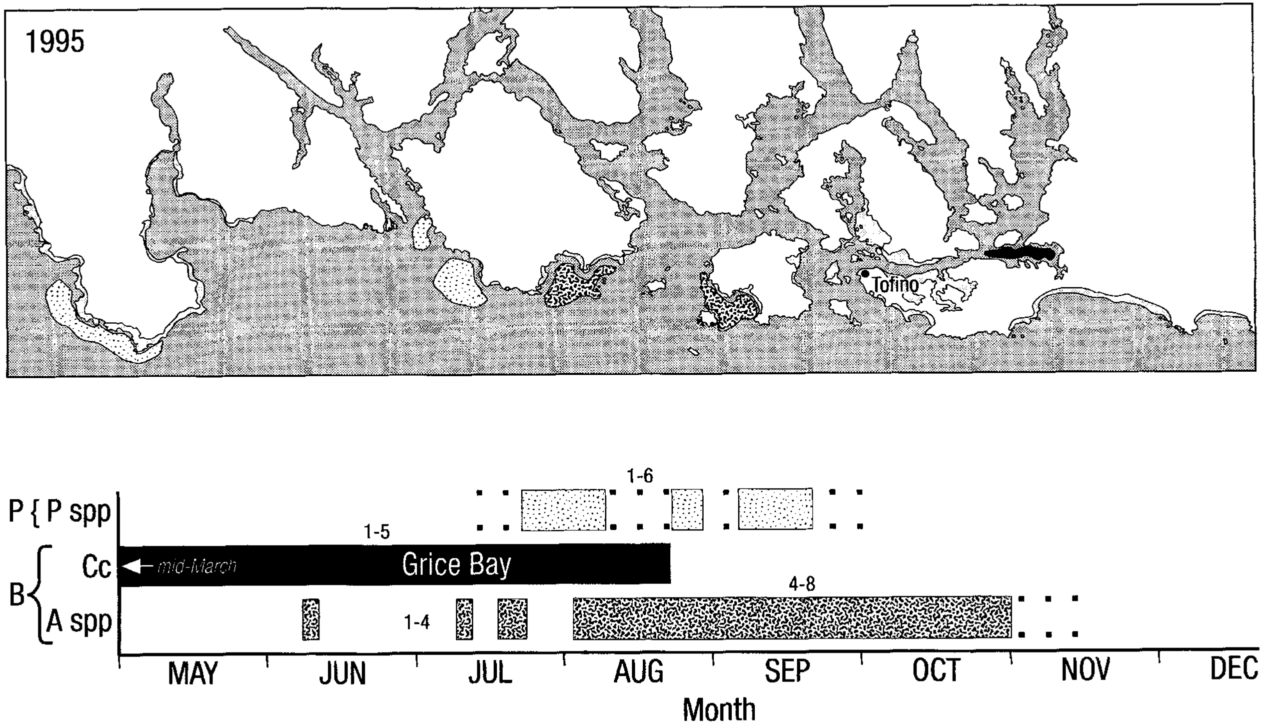

Figure 4. Continued.

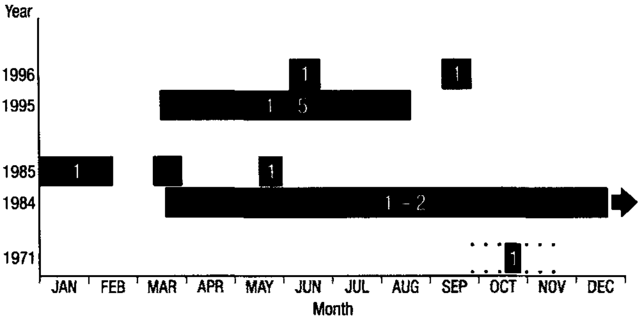

Figure 5. Utilization of Grice Bay, 1971–1996. Only young whales were found in this site in each occupation over 26-yr period, feeding on ghost shrimp (*Callianassa californiensis*). Whale present in 1985 was one of individuals present in 1984 and apparently stayed through winter. Whale present in 1996 was one of five present in 1995.

1994, and occurred for part of the summer in the other two years. Whales were present throughout the entire summer in 1994 due to successive plankton events, whereas in 1992 whales were rare for the first half of the season except for isolated, short-lived plankton events. Mysids were an important part of the prey for two years (1993 and 1994) but were not recorded as prey in the other two years. Early season mobile-amphipod-feeding occurred in essentially the same location for two years (1992, 1993) but over different lengths of time, then was absent in the following two years. Year-to-year variability in timing, prey type, and feeding location is the key feature of observations to date.

Several very generalized patterns may be emerging; these may or may not prove to be significant over the longer term. They are (1) a greater likelihood of feeding on benthic amphipods in the latter half of the season, (2) if there is steady whale-feeding activity in early and mid-season, it is more likely to be on plankton than benthic species, and (3) the Grice Bay ground may be

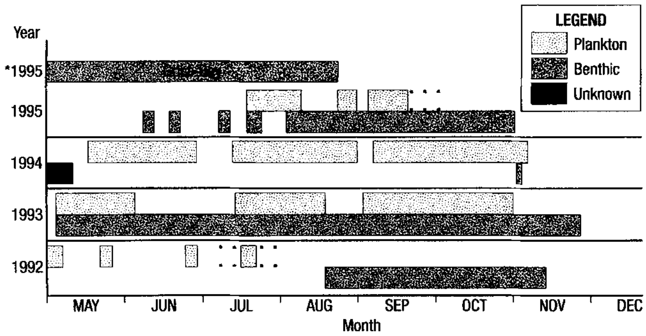

Figure 6. Comparison of gray whale presence and prey types between years, 1992–1995. All locations, except Grice Bay, combined; prey divided only into plankton and benthic types.

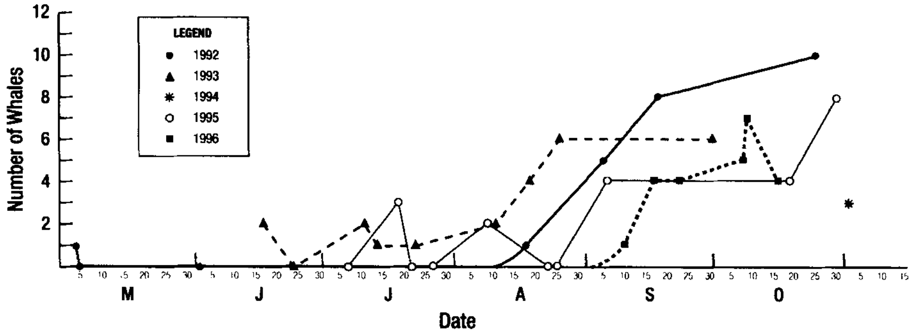

Figure 7. Number of benthic feeding whales in Ahous and Cow Bay combined, through seasons, 1992–1996. Note that in 1994 there was just one sighting of benthic feeding.

utilized by young whales steadily for one- to two-year periods separated by extended periods of non-use.

Our observations (Fig. 4) suggest that the predominant prey species for adult whales were crab larvae and benthic amphipods in 1992, swarming amphipods and benthic amphipods in 1993, mysids and crab larvae in 1994, and crab larva and benthic amphipods in 1995. It should be noted that our study area is only a portion of the animals' overall summer range.

Different Prey Species Utilized Simultaneously

On several occasions adult whales a few km from each other were observed feeding on different prey species. Examples are (1) on 11 August 1993 two whales were feeding on mysids (*H. sculpta*) in kelp off Rafael Point, and two whales were feeding on benthic amphipods (*Ampelisca* spp.) in Cow Bay, 4–5 km distant; (2) on 5 September 1996 two whales were feeding on mysids (*H. sculpta*) off Siwash Point and four to five whales were feeding on crab larvae (*Pachycheles* spp.) of Dagger Point 4 km distant; (3) on 19 October 1996 two to four whales were feeding on mysids between Siwash and Rafael Points, and two to eight whales were feeding on benthic amphipods (*Ampelisca* spp.) in Cow Bay, 3–4 km distant.

Changes in Density of Feeding Whales

The numbers of whales involved in each feeding event could vary substantially in a 24-h period (Fig. 4 A–D). Over the study period (1989–1996), at any one time and location, 1–14 whales were observed preying on mysids, 1–15+ on crab larvae, and 1–12 on benthic amphipods. Changing prey density could have been a factor but was not measured in this study.

A pattern repeated in several of the years was an increase in numbers of benthic feeding whales in late season (mid-August and later; Fig. 7). The numbers clearly increased after mid-August and remained high through the fall. An example of this increase in numbers occurred in 1995 in Ahous Bay. No whales were present through most of the year; then numbers increased from one or two in mid-September to seven to eight by the end of October. In 1994, the "odd" year in terms of benthic feeding, the only record of such feeding occurred in early November.

Longterm Change in Use of a Feeding Ground

Wickaninnish Bay is a 12-km-long open bay, with shallow sandy bottom at the eastern end of the Clayoquot Sound study area (Fig. 2). Sighting effort varied over the 30-yr period, ranging from intensive to sporadic in any one year (Table 2).

A change in use of Wickaninnish Bay as a feeding ground has clearly occurred over the last 30 yr. During the first decade of reports, from 1966–1977, whales were present throughout most summers. The period of most consistent observation was from 1972 to 1976, due to a whale-watch operation operating in the bay and Darling's (1978) observation that whales consistently used the area from May to September. From 1977 to 1979, whale presence became less consistent. From 1980 to 1996, gray whale utilization in summer was sporadic to absent. In some of these later years, whales utilized the area in May and early June. Since 1989 the whales in this region were observed feeding on plankton (crab larvae) or swarming amphipods more often than on benthic amphipods. Occasional bouts of benthic feeding occurred throughout this time, such as in April 1996, when several well-known resident whales (one of which was present in the 1970s when the site was used regularly) were observed in Wickaninnish Bay clearly bottom feeding. Nonetheless, consistent, season-long use has not occurred in the last 20 yr.

DISCUSSION

Broad Utilization of Coastal Habitat

Hatler and Darling (1974) speculated that "pockets" of gray whale habitat occur along the North American coast, and Votrogov and Bogoslovskaya (1980) and Bogoslovskaya *et al.* (1981) discussed "divisions" of gray whale habitat on the Asian coast, separated by empty areas through which whales passed rapidly. These terms were not defined or given scale and so may inadvertently leave the impression of discrete gray whale habitat within a section of coastline, say the length of Vancouver Island. Kvitek and Oliver (1986) described benthic feeding grounds of Vancouver Island as "discrete isolated habitats . . . separated by many kilometers of coast," leaving a specific impression of uneven coastal use. Our review of feeding locations over a 26-yr period questions the perception of an uneven use of coastal habitat by gray whales. At any one time, whales utilized discrete pockets of habitat depending on prey availability, but over the extended period virtually *all* of the southern half of the Vancouver Island west coast was used by feeding gray whales. We

Table 2. Utilization of Wickaninnish Bay by feeding gray whales, 1965–1996.

Years	Type of survey effort	Remarks
1965–1973	Park naturalist and whale watch reports	Present throughout summer in all years except 1966 and 1967 (Darling 1973, Hatler and Darling 1974)
1974–1976	Ongoing monitoring, regular surveys	Present throughout summer; no surveys without sightings (1–14) in May–September 1975–1976 (J. Darling, unpublished data; Darling 1978)
1977–1979	Regular surveys	Presence more sporadic: In 1977 present from May to September except for 6-wk period from July to mid-August. Long periods without sightings in 1978 until August. At least one sighting each summer month, but long periods of absence (J. Darling, unpublished data).
1980–1988	Sporadic surveys	Whales generally not present. In some years (1985, 1986) present in May and not thereafter. Occasional sightings in summer (J. Darling, unpublished data)
1989–1996	Present study	Whales present in May in most years but sightings rare throughout summer season.

suggest that the idea of a "foraging route or range" that covers extended sections of coastline provides a more accurate view of gray whale habitat utilization than the concept of discrete pockets of habitat.

Clayoquot Sound may provide a representative sample of the Vancouver Island gray whale foraging range. Virtually all of the outer Sound was used by gray whales over the study period. Different areas and habitat were used for different purposes, such as herring-egg feeding, benthic feeding, plankton feeding, and "rubbing." In one case, the use was by young whales only. Some habitats were used on a regular basis, often annually, others on some irregular basis that may have included ten or more years between use. Whales likely traveled between different habitats as prey availability and abundance, social behavior, or rubbing activity dictated. The specific function and importance of presumed rubbing behavior and hence habitat has not been investigated. The activity is common in specific areas and may serve a "grooming" or "recreation" function (Hatler and Darling 1974; Darling 1978, 1984).

Variety of Prey Resources: Benthic and Planktonic

Nerini (1984), in a definitive review of gray whale prey and feeding behavior, concluded that "the most extraordinary aspect of the gray whale's feeding ecology is its apparent dietary flexibility" and noted that with three modes of feeding (benthic suction, engulfing, and skimming) the gray whale has perhaps a greater range of foraging techniques than any other great whale. Benthic amphipods are generally considered the predominant prey species in northern seas, but numerous observations of gray whales feeding on fish and planktonic crustaceans exist throughout their range (Pike 1962, Rice and Wolman 1971, Nerini 1984, Kim and Oliver 1989). A review of examinations of gray whale stomach contents since 1874 indicated a broad array of some 70 genera of both benthic and pelagic organisms (Nereni 1984).

The most striking feature of our observations, consistent with Nerini's (1984) review, was the variety of prey and foraging techniques utilized by the whales. Since collections began, at least nine prey species supported the gray whale population in this region. Previous reports of gray whales feeding on benthic amphipods (Oliver *et al.* 1984, Kivetek and Oliver 1986), mysids (Murrison *et al.* 1984, Guererro 1989), and ghost shrimp (Plewes *et al.* 1984) are confirmed in this study. In addition, one species of mobile amphipod (*A. borealis*), at least two species of crab larvae (*C. magister* megalops and *Pachycheles* spp. zoea), and herring eggs and larva (*Clupea harengus* pallasi) were added to the list of Vancouver Island prey species. All three feeding techniques described by Nerini (1984) were utilized by the Vancouver Island whales to exploit these prey.

The polychaete worm, *Onuphis elegans*, has been discussed as a prey species off Vancouver Island in several reports (Darling 1977, 1978; Oliver *et al.* 1984; Kvitek and Oliver 1986; Kim and Oliver 1989; Weitkamp *et al.* 1992), but we do not believe this has been confirmed and therefore leave it in the unconfirmed category with juvenile rockfish and sand lance at this time. All of the prey species reported for Vancouver Island have been reported previously as prey of gray whales somewhere in their range, albeit in some cases from a single observation (Nerini 1984).

The current importance of planktonic prey off Vancouver Island *vs.* earlier observations of extensive bottom feeding (*e.g.*, Hatler and Darling 1974, Darling 1978) raises the question whether a change in prey species has occurred over the last 20 yr, or whether observations have simply become more complete. We lean towards the latter explanation for several reasons: most observations in 1960s and 1970s were in Wickaninnish or Ahous Bay, now well known as bottom-feeding grounds, and whales were documented in locations along the West Coast Trail (now known as a plankton-feeding area) as early as 1972 (Darling 1973). However, two points make us hesitant to entirely discount the idea that predominant prey species may have changed. These are (1) the virtual abandonment of Wickaninnish Bay and adjacent waters as a primary benthic feeding area by the early 1980s, and (2) Highsmith and Coyles' (1992) suggestion of the potential for long-term loss of amphipod habitat, and alterations of ecosystem structure, caused by feeding gray whales.

Overall, the literature has emphasized the benthic feeding behavior and prey of gray whales (Scammon 1869, Nemoto 1959, Pike 1962, Walker 1971, Rice and Wolman 1971). Nerini (1984) revisited this view and noted that observations of feeding in the water column were concentrated in southern regions, whereas whales feeding while migrating or summering along the northern half of the migration route were nearly always consuming benthic resources—that is to say, prey types could be region-specific. Kim and Oliver (1988) furthered this idea and proposed primary, secondary, and tertiary feeding grounds defined by location and predominant prey, with more planktonic prey species farther south in the range. Our Vancouver Island work suggests another view of gray whale feeding behavior. Rather than a region-specific prey regime (Nerini 1984, Kim and Oliver 1988), the whales utilize a variety of prey resources, both benthic and pelagic, within a feeding range. We propose they exploit the most suitable prey species at any one time, on a cyclic or otherwise recurring basis. In this view, pelagic feeding and prey may have equal importance to benthic feeding and prey overall. This clearly was the case on Vancouver Island during this study. Further, it may account for the numerous observations of plankton feeding and the variety of prey species found in gray whale stomachs in other parts of their range (Nerini 1984).

In related discussions, several authors have indicated that one or another prey species was the "most important" for gray whales. Benthic or near-benthic amphipods were often listed as the primary prey (Pike 1962, Rice and Wolman 1971, Nerini 1984) at least in northern seas, and Kivitek and Oliver (1986) and Kim and Oliver (1988) stated that mysids are the major prey along the coast of British Columbia. The species noted may well have been the predominant or most important prey at the time of collection or observation, but our study strongly suggests that such results should not be generalized over time and place. We propose that rather than a single species, it is an assemblage of species that is important to the whale. We speculate that the whales are attuned to natural patterns of abundance and absence occurring within this prey assemblage, and that different species play equal roles over a season or several years.

Variable Patterns of Utilization of Resources and Habitat

Gray whale feeding has been proposed as a major source of physical disturbance to the benthic community, with the activity being part of a cycle of exploitation, recolonization, succession, and maturing of the prey community (Nerini 1984, Oliver *et al.* 1984, Oliver and Slattery 1985). Periods of nonuse by whales are presumed to correspond to recovery and maturing of the prey species. Highsmith and Coyle (1992) and Weitkamp *et al.* (1992) raised the possibility that gray whale exploitation may, in some circumstances, be a one-way street and lead to permanent loss of the amphipod or other prey communities and, hence, changing feeding patterns. The virtual abandonment of Wickaninnish Bay as a primary benthic feeding area since the 1980s may be such an example, although it should be noted that the current status of prey species there has not been investigated.

An additional explanation for variable use of benthic grounds arises from the idea that an assemblage of prey species is potentially available and utilized over a season. A whale may change location and habitat to exploit the "optimum" prey species at any one time. The optimum prey is probably determined by factors such as abundance, density, size, caloric content, and predation pressure, all which may vary throughout the season and year to year, depending on environmental factors and life cycles. This study suggests that a progression from one prey species to the next may occur through the season. A generalized progression of gray whale prey in Clayoquot Sound from spring to fall was seen (herring eggs, mobile amphipods, mysids, porcilid crab larvae, and benthic amphipods), as each presumably became the optimum species to "harvest." A shift from one habitat and prey species to another may not necessarily reflect the loss of the initial prey, only that a better option has developed.

Several authors have noted differences in caloric content among gray whale prey species and within species at different times of their life cycles, especially in relation to reproductive condition. This information combined with bioenergetic considerations in foraging effort may well explain variable use of resources (Guerrero 1989, Highsmith and Coyle 1992, Weitkamp *et al.* 1992). For example, in the Bering Sea, the dry weight, energy content per unit weight, and caloric content of the benthic amphipod, *Ampelisca macrocephala,* increased significantly throughout the summer, with highest values in September–November (Highsmith and Coyle 1992). If the *Ampelisca* spp. in the study area grow similarly, this may explain the later-season progression to this prey species in Clayoquot Sound.

Our observation that patterns of utilization of resources and habitat were highly variable refers to utilization of a specific prey species and its habitat. However, if the assemblage of prey species is considered as a whole, the observation changes substantially. Utilization of the prey assemblage and its overall habitat was remarkably consistent and resulted in the highly predictable presence of gray whales in the region each summer. We speculate that it is the assemblage of prey species that allows the ongoing use of a specific feeding range over time.

Whale Age a Factor in Habitat or Prey Use

Very young whales, apparently ranging from several months in age and recently weaned to a 1-yr-old, made up a portion of the Vancouver Island population each year (Hatler and Darling 1974; Darling 1978, 1984; Oliver 1984; Rice and Wolman 1971; JDD, unpublished data.) The relationship of these whales with other adults in the area is yet to be determined. Darling (1978) noted "small whale characteristics" off Vancouver Island, including occupation of areas not frequented by larger feeding whales and an apparent affinity for kelp beds. Since then, some degree of separation of young whales from adults has been a recurring observation each year (JDD, unpublished data). The periodic use of Grice Bay by young whales best illustrates the apparent age-specific utilization of habitat (Hatler and Darling 1974, Plewes *et al.* 1984, this study).

Zenkovich (1937) suggested that specific areas along the Russian coast may be permanent feeding grounds for younger, apparently recently weaned, animals. Almost all whales captured in these areas were less than two years old, an observation from which he concluded that young gray whales form separate schools at weaning. Bogoslovskaya *et al.* (1981), from investigations in the same region, suggested that such separation does exist but may not be so well defined. Our observations of separation of adults and young, at times very distinct and at other times subtle, are consistent with these reports.

The reason for different habitat utilization patterns by young animals is not known. The Grice Bay young whales were feeding primarily on ghost shrimp at the same time that adults were feeding on other prey species in other parts of the study area. Weitkamp *et al.* (1992) suggested from a study of gray whale predation on ghost shrimp in Puget Sound that, due to density of this species, less foraging time was necessary than with benthic amphipods to obtain comparable bioenergetic gain. If true, this may be of significant benefit to young whales that are possibly learning how to feed and which may have high energy requirements. However, to complicate this view, young whales were commonly sighted in kelp beds in the general vicinity of adult whales feeding on mysids and in benthic grounds near whales feeding on benthic amphipods, and were observed to skim feed crab larvae (JDD, unpublished data). Oliver *et al.* (1984) reported that the small whale he observed was feeding on the benthic *Ampelisca* community. Apparent attributes of Grice Bay are shallow water, protection from storms, and possibly increased protection from predators, as well as abundant food supply. This is also true of kelp beds. Perhaps young whales seek out these relatively protective and productive habitats after weaning.

Management Considerations

1. The determination of the relative importance of specific locations and habitat to gray whales is complex. It is confounded by the whales utilizing different locations and habitat at different times within one season and from year to year. A coastal foraging route extending over hundreds of kilometers may be the appropriate view of gray whale habitat use. Certainly some locations are utilized more regularly than others, but at any one time or season the lesser-used locations may be critical to the survival of the whales, when food in the prime area is less abundant or if used for other purposes such as young whale care. Therefore, efforts to designate priority gray whale habitat within the overall coastline for management purposes may not be meaningful.
2. Determination of impacts of pollution or other human activity on gray whales is complicated by the highly variable patterns of specific habitat and prey utilization. The apparent potentially high natural variability in prey status due to normal environmental and biological fluctuations will likely lead to a corresponding variability in the distribution and behavior of the whales. The separation of natural and human impacts on the whales' distribution and behavior with current knowledge will be difficult below the lethal stage.
3. The ability of gray whales to exploit a variety of prey species, combined with a feeding range that may extend over hundreds of kilometers, may enhance the population's chances of surviving temporary catastrophic impacts on specific prey species or highly localized and contained pollution events or other disturbances. However this "enhancement" relies on the chance that the species or habitat affected is not critical at the time of impact.
4. The variable utilization of habitat and prey resources by gray whales over a large section of coastline strongly indicates that information from partial-season and single-site research projects must be taken in context. Such studies may well determine what is occurring at the particular time or place, or in a specific age class, but they may not be adequate to draw general conclusions about the entire population over time. These limitations should be noted when considering some of the inferences and conclusions in Oliver *et al.* 1984, Kivetek and Oliver (1986), and Duffus (1996).[2]
5. The information presented provides a broad-stroke, preliminary outline of feeding patterns in Clayoquot Sound. Several avenues of research would significantly further our insight into gray whale behavior in the region. These include (1) studies of factors influencing prey life cycles, distribution, and abundance; (2) quantitative studies of prey density and quality (in terms of caloric content) in relation to whale utilization patterns; (3) studies of the means by which whales locate prey, including potential communication between animals; and (4) investigation as to how social factors such as age, status and genetic relatedness may govern feeding distribution and behavior.

---

[2] Duffus (1996) studied gray whales in Clayoquot Sound and reported on "shifts" in whale distribution and prey from 1992–1994. He then proposed a pattern of whales moving away from Tofino and the center of "commercial" activity. His observations were limited in time and area and led to different interpretations than would occur with a broader database.

ACKNOWLEDGMENTS

We gratefully acknowledge the numerous people and organizations who assisted with this study over the years. We thank all whale-watch operators in Tofino, including Don Travers and Kati Martini at Remote Passages; Richard Beaupied at the Whale Centre; Joe and Carl Martin and Mike Woods of Clayoquot Whaler; Jamie Bray and Nora Christianson at Jamie's Whaling Station; Rod and Sharon Palm, Leigh Hilbert and John Forde at R & S Tours; Mike Hanson and Earl Thomas at Chinook Charters; Wilfred Atleo of Clayoquot Sound Adventures; Didier Midavaine at Sea Trek Tours; and Gary Richards, Doug Banks, and other pilots at Tofino Air. Many individuals contributed substantially to different aspects of the study. We thank Rod Palm, who assisted in collecting benthic samples; Phil Lambert and Ed Bousfield at Royal B.C. Provincial Museum for assistance with identification of prey species; Peter Buckland, Dave and Diane Ignace, and Steve Charleson who relayed observations from Hesquiat; Josie Cleland, Tom Stere, Kara Shaw, Scott Rogers, Steve Diggon, Marnie Egan, and Chiemi Ogawa at the Clayoquot Biosphere Project who assisted in the field and office; and many residents of Tofino and Clayoquot Sound who provided sightings. Special thanks to Leah Gerber for offering suggestions on the draft of the manuscript. The work was funded by a variety of sources: organizations supporting the Clayoquot Biosphere Project programs including Kendall Foundation, Alton Jones Foundation, Bullitt Foundation, Rockefeller Brothers Foundation, and B.C. Ministry of Environment (E-team); Jamie's Whaling Station; Whale Centre; West Coast Whale Research Foundation; and Department of Fisheries and Oceans.

Although the Bering and Chukchi seas are commonly cited as the principal summer feeding grounds of Eastern North Pacific (ENP) gray whales (*e.g.*, Highsmith *et al.* in press, Swartz *et al.* 2006), records indicate that this population actually feeds opportunistically throughout its range from the lagoons of Baja California, Mexico, to Alaskan waters (Nerini 1984). Specifically, recent reports suggest that whales may routinely feed in the Gulf of California (Sánchez-Pacheco *et al.* 2001) and Bahia Magdalena, Baja California Sur (Caraveo-Patino and Soto 2005), whereas Clapham *et al.* (1997) noted that feeding gray whales occurred offshore California even in the 1920s when population numbers were very low. The dynamic nature of foraging in this population is best described from coastal study sites along the southeastern shore of Vancouver Island, Canada, where whales shift among pelagic, epi-benthic, and benthic prey within and between years (Darling *et al.* 1998; Dunham and Duffus 2001, 2002).

In the 1980s the southern Chukchi Sea and the Chirikov Basin in the northern Bering Sea were considered the primary feeding grounds for ENP gray whales, based on reported high densities of both whales (Braham 1984, Kim and Oliver 1989, Moore *et al.* 2000) and their ampelicid amphipod prey (Grebmeier *et al.* 1989, Highsmith and Coyle 1990). However, by 2002, benthic productivity in the Chirikov Basin had declined precipitously, due to either whale foraging (Highsmith *et al.* 2006), ecosystem change (Grebmeier *et al.* 2006), or both, and only the southern Chukchi Sea supported dense aggregations of gray whales (Moore *et al.* 2003). Indeed, the

decline in benthic biomass in the Chirikov Basin (Highsmith and Coyle 1992) was suggested as causal to the 1999–2000 gray whale mortality event (Le Boeuf *et al.* 2000), although other factors, such as disease, could not be ruled out (Moore *et al.* 2001).

Since 1999 gray whales have been observed feeding year-round near Ugak Bay, Kodiak Island, Alaska, in the course of surveys for pinnipeds (Wynne 2005). These "Kodiak" gray whales have not been described in terms of distribution, relative abundance, behavior, or diet. One reason for this oversight is that waters southeast of Kodiak Island have long been considered simply a portion of the migration corridor for gray whales passing to and from northern seas (*e.g.*, Braham 1984) and not a part of the feeding or overwintering range. Conversely, the distribution and feeding behavior of the Pacific Coast Feeding Aggregation (PCFA; formerly called "summer resident" whales) have been investigated offshore Vancouver Island, British Columbia since 1984 (Darling *et al.* 1998; Calambokidis *et al.* 1999; Dunham and Duffus 2001, 2002). The PCFA has been the focus of photo identification surveys extending from northern California to southeastern Alaska, with mark-recapture estimates of 261–298 whales from photos taken from 1998 to 2003 (Calambokidis *et al.* 2004).

Here we present a compilation of opportunistic gray whale sightings noted between 1999 and 2005 in waters southeast of Kodiak Island, Alaska, accompanied by results from 6 days of benthic sampling conducted in 2002 near feeding whales at the entrance of Ugak Bay. Although these data are limited in scope, they provide evidence of year-round occurrence and a noteworthy feeding area for ENP gray whales in the northern Gulf of Alaska. Building a record of seasonal distribution, relative abundance, and feeding areas is key to interpreting the response of this population to environmental variability and carrying capacity.

Gray whale sightings were recorded opportunistically during aerial surveys for Steller sea lions (*Eumetopias jubatus*) and harbor seals (*Phoca vitulina*) conducted in the Kodiak Island archipelago (Fig. 1: inset). Monthly surveys of Steller sea lion haul-outs were conducted throughout the archipelago from September 1999 through July 2005, whereas surveys of harbor seal haul-outs focused on the east and south side of Kodiak Island and were conducted only in late August each year from 1993 to 2002 and in 2004. Although the sea lion and seal survey routes differed somewhat, both included waters between Long Island and Cape Barnabas along Kodiak's southeast coast, including the entrance to Ugak Bay. In addition, on 25 July 2000, a single aerial survey was conducted along a transect southwest and roughly parallel to Kodiak Island (Fig. 1: inset) to search for North Pacific right whales (*Eubalaena japonica*). This survey was flown in a high-wing aircraft with two primary observers seated at bubble windows and a downward looking high-format camera aboard to photograph whales (for details, see Perryman *et al.* 2002).

All pinniped surveys were conducted from a fixed-wing aircraft at altitudes between 220 and 472 m (700 and 1,500 ft) and speeds of 165–200 km/h (90–110 km). One to three observers (plus the pilot) scanned for blows and whales at the surface ahead of and on either side of the aircraft. When whales were seen, the plane was diverted to (1) confirm species identity; (2) mark the location, either *via* a global positioning system or a position relative to coastal landmarks; (3) estimate number

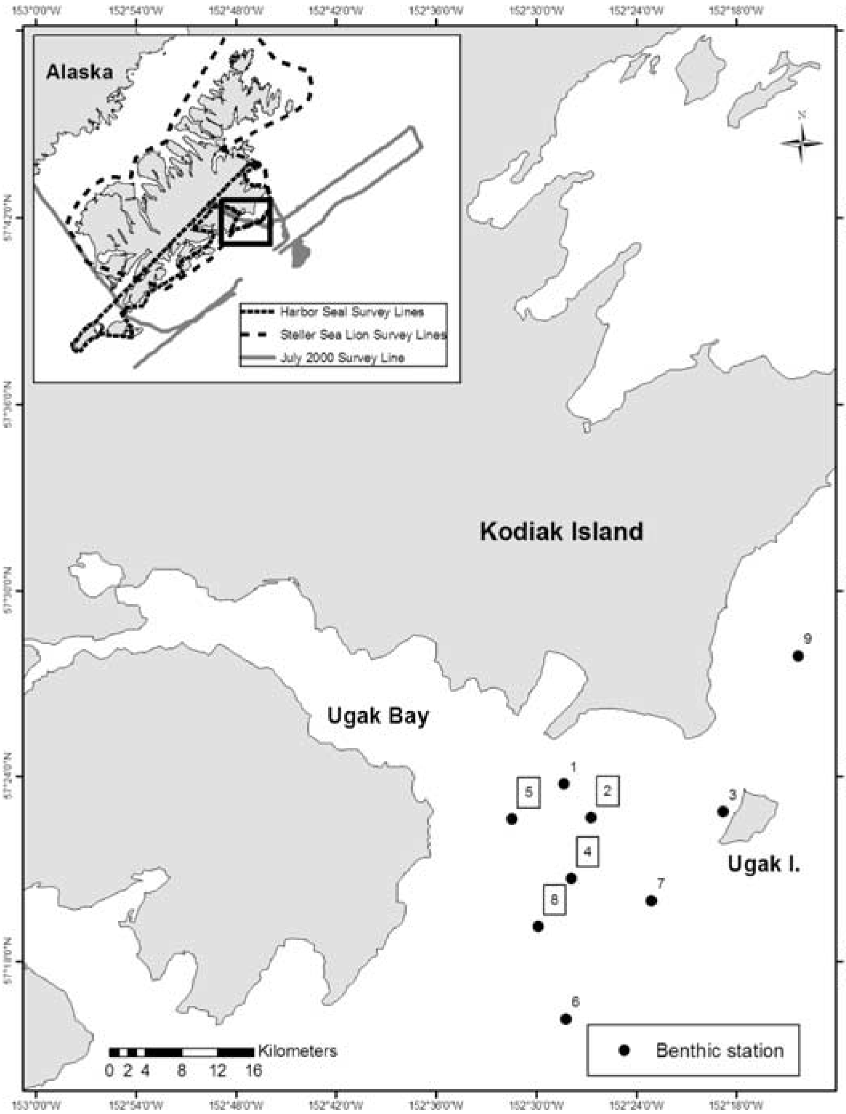

Figure 1. Benthic sampling stations near the entrance to Ugak Bay. Boxes indicate stations with extremely high cumacean densities (see Table 1). Inset: Routes for aerial surveys for pinnipeds around Kodiak Island (Wynne 2005), and trackline for the July 2000 aerial survey offshore the southeastern coast of Kodiak Island, Alaska. Gray whale sightings were recorded opportunistically during surveys for Steller sea lions (dashed line) and harbor seals (solid line) from September 1999 through July 2005.

of whales; and (4) determine general behavior—feeding was recorded whenever mud plumes were seen near whales. Sighting locations were subsequently plotted by season: winter (December–February), spring (March–May), summer (June–August), and autumn (September–November) and "rough-order" sighting rates (number of sightings/survey hour) calculated by dividing the number of gray whale sightings by the average time spent surveying between Long Island and Cape Barnabas on the pinniped surveys. These indices must be considered provisional, as there was no attempt to account for variable survey conditions, nor counts of individual whales in the derivation of sighting rates. In addition, due to the opportunistic nature of these surveys, no effort was made to delineate the full extent of gray whale distribution, detail behavioral interactions, or to derive population estimates from the sightings.

Gray whales were seen year-round along the east side of the Kodiak Island archipelago, most frequently and in greatest numbers near the entrance to Ugak Bay (Fig. 2). Whales were seen with mud plumes in each month, suggesting year-round feeding. Seasonal sighting rates were highest from September to November, declined during December to February and March to May periods, and reached lowest levels during the June to August period. Monthly sighting rates exceeded 100 sightings/h in January, June, September, and November, with >20 sightings/h in all other months except March (Fig. 3A). Annual sighting rates were highest in 2000 and 2001 (>70 sightings/h), lowest in 2003 (<20 sightings/h), with rates >30 sightings/h in 2002 and 2004 (Fig. 3B).

Roughly 350–400 gray whales were counted along the aerial survey transect flown on 25 July 2000. Distribution extended from the mouth of Ugak Bay, where 40–50 whales were seen, to roughly 100 km east-southeast of Ugak Island (Fig. 2: June–August). Overall, the feeding aggregation covered roughly 240 km^2 (*ca.* 80 km × 30 km); actual limits to the distribution were difficult to determine due to low fog over portions of the survey area. Whales were clustered in groups of 10–20 animals, with most associated with conspicuous mud plumes and surface feces trails indicative of active feeding. Most whales appeared to be large adults, with one trio involved in sexual behavior; no small juvenile whales or calves were noted.

To investigate gray whale prey availability, benthic samples were collected at nine stations where whales were seen feeding near the entrance to Ugak Bay (Fig. 1), from 15 to 20 August 2002. Four grab samples were collected at each station using a 0.1-m^2 van Veen grab weighing 88.7 kg (including a 32-kg lead weight), except for station 3 where only one sample was collected due to very large sediment grain size. Each sample was placed on a screen with mesh size of 1 mm and washed with seawater to remove sediment. Samples were preserved in 10% seawater buffered formalin for post-cruise laboratory analysis. To investigate gray whale prey selection, ten fecal samples were collected using a modified small-mesh plankton net with a cod end, attached to a fishing dip net by an extended handle. Samples were collected from the benthic sampling vessel by trolling through water where whales had deposited fecal plumes. One additional fecal sample was collected using a plastic bucket.

Thirty-six benthic samples were collected (Table 1), with potential gray whale prey summarized by station as abundance (individuals/m^2) and carbon biomass (g C/m^2). Cumaceans (*Crustacea: Diastylidae*) were the dominant fauna (93.6%–98.4% of the sampled abundance) at stations 2, 4, 5, and 8 (Fig 1: boxed stations), where biomass ranged from 31 to 67 g C/m^2. Abundance and carbon biomass measures were roughly an order of magnitude lower at stations 1, 6, 7, and 9 (Table 1). The single sample at station 3 revealed moderately high faunal abundance (33,060 individuals/m^2),

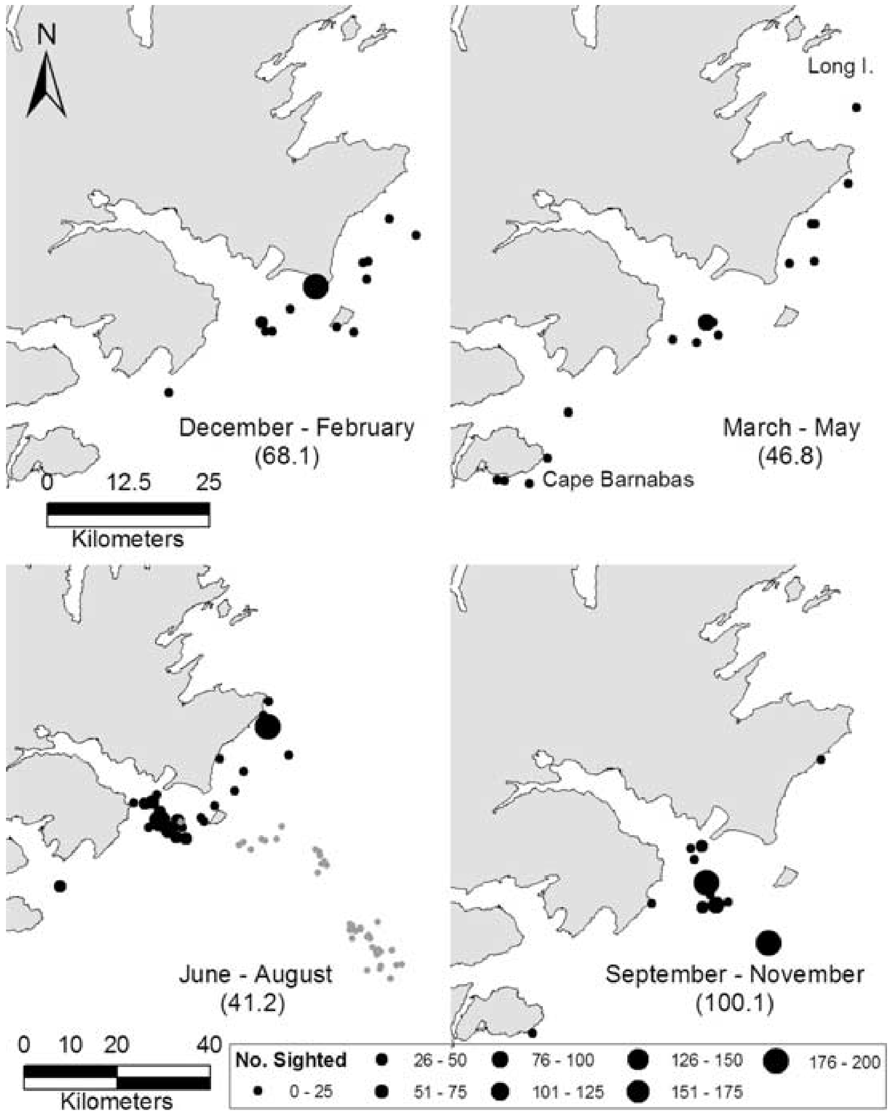

Figure 2. Cumulative gray whale distribution and provisional sighting rates by season: December–February (winter); March–May (spring); June–August (summer), and September–November (autumn). Note difference in spatial scale for the June–August panel, required to show data from the July 2000 survey.

consisting of polychaete worms (*Phyllodocidae* = 54.3%) and bivalves (*Tellinidae* = 33.6%), which resulted in the highest biomass measures (3,950 g/m^2; 125 g C/m^2) of all the stations. Evidence that gray whales were consuming cumaceans resulted from gross examination of the fecal samples, which contained voluminous quantities of (usually partially digested) Diastylidae. Notably, amphipods (*Ampelisca* spp.), a

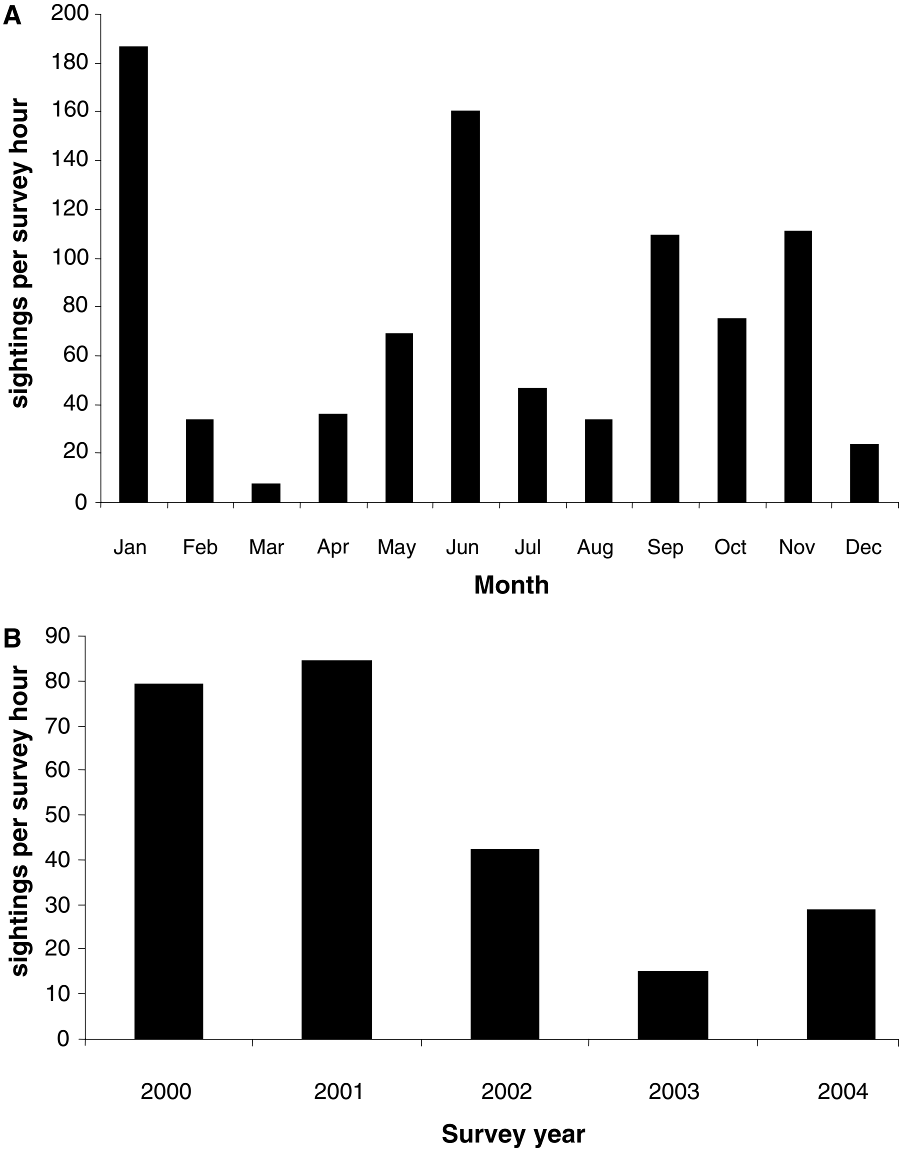

Figure 3. Provisional sighting rates for gray whales seen during pinniped-related surveys along southeastern Kodiak Island, by month (A) and year (B). Annual rates were not calculated for 1999 or 2005 because surveys were conducted only during part of those years.

common gray whale prey, were found only at station 2 and in low densities (0.7% of 57,210 individuals/m^2) and station 6 (15.6% of 1,105 individuals/m^2).

Although many of the gray whales seen near Ugak Bay since 1999 may be migrating through the area, some clearly stop to feed there, perhaps for much of the year. The

seasonal variability in gray whale distribution and sighting rates offshore Kodiak may be related both to migration timing (Rugh *et al.* 2001) and to whale responses to prey availability and composition, as demonstrated elsewhere on their range (Darling *et al.* 1998, Dunham and Duffus 2001, Moore *et al.* 2003). The high counts of gray whales near Kodiak in 2000 and 2001 may have been related somehow to the 1999–2000 mortality event (Gulland *et al.* 2005), or to feeding opportunities resultant from ecosystem responses to the 1997–1998 El Nino in the North Pacific, although specific mechanisms for this remains unexplored. We note that Benson *et al.* (2002) report gray whales feeding on large surface swarms of euphausiids (*Thysanoessa spinifera*) in Monterey Bay, California, during May 1999, which they interpret as a short-term response to prey availability linked to the 1997–1998 El Nino and 1999 La Nina.

The cumacean densities sampled at the entrance of Ugak Bay are among the highest reported anywhere in the world. Cumaceans are usually considered atypical gray whale prey (Nerini 1984, Darling 1998, Dunham and Duffus 2002) and have a low dry weight energy content (14.33 J/mg) compared to amphipods (16.37 J/mg; Cauffope and Heymans 2005). In a prey sampling effort co-located with feeding gray whales at fourteen sites along the Alaskan coast from Wainright south to Dutch Harbor, cumaceans were the dominant species only at Icy Cape in the Chukchi Sea (Kim and Oliver 1989). Core samples from that site resulted in wet weight biomass values of roughly 169 g/m^2, 51% of which was attributed to cumaceans. In contrast, at our sampling site 5 in outer Ugak Bay, wet weight biomass was 1024 g/m^2, 75% of which was attributed to cumaceans. Because sampling methods differed between the two studies, these specific measurements must be compared with caution; however, the extreme densities of prey suggest that the Ugak Bay site offered gray whales an exceptional opportunity to feed on swarming cumaceans, at least during August 2002.

Available records suggest pockets of gray whales can be found, often feeding, from Kodiak to northern California. These records include (1) gray whales reported here; (2) the report of approximately ninety feeding whales near Yakutat Bay in May 2000 (Moore, unpublished data); (3) summertime occurrence of roughly 30–50 gray whales feeding along the outer coast of Southeast Alaska since the mid-1990s;[2] and (4) whales routinely photo-identified at various sites between Kodiak and northern California (Calambokidis *et al*. 2004). Although the gray whales offshore Kodiak may simply represent a reoccupation of former feeding areas, there appears to be now some consistency in their use of these waters. When combined with observations of localized aggregations reported in Calambokidis *et al*. (2004), a pattern similar to that described for white-bearded wildebeests (*Connochaetes taurinus mearnsi*) is suggested wherein roughly 3,000 animals out of a population of 14,000 behave as "residents" that forage and breed in localized areas that are unused by the main migratory population (Estes 2006).

In summary, we suggest that (1) as flexible foragers, gray whales are responsive to feeding opportunities along their entire range; (2) an expanding ENP population may be meeting with new and more variable forage challenges in the wake of alteration of marine ecosystems associated with global climate warming; and (3) research focus on this population may provide novel insight into large whale population dynamics, behavioral ecology, and the capacity of a mysticete species to exploit disparate forage opportunities and respond to environmental changes.

ACKNOWLEDGMENTS

Support for this research was provided by the NOAA Alaska Fisheries Science Center, National Marine Mammal Laboratory (NMML). We thank Dr. Tom Loughlin (NMML, retired) for leadership and collaboration during the pinniped aerial surveys, conducted under NMFS permits 782-1768 and 1049-1718 (cetacean incidental takes). The pinniped surveys could not have been accomplished without the safe and professional services provided by pilots at Kodiak Air and Andrew Air in Kodiak, and the many volunteer observers, including Bree Witteveen

Hatler, D. F. and J. D. Darling. 1974. Recent observations of the gray whale in British Columbia. Canadian Field-Naturalist 88: 449–459.

Abstract. Observations of gray whales along the British Columbia coast confirm the occurrence of a peak in spring migration there during the first half of April, and provide further evidence that the animals follow a near-shoreline route while both north- and south-bound, especially along Vancouver Island. At Wickaninnish Bay on the central west coast of Vancouver Island, gray whales have been seen regularly, apparently feeding, during each of nine summers 1965–1973 except 1967, and similar sightings have been made each month between October and February in both 1971–1972 and 1972–1973. Among the gray whales recorded have been two females with young, one pair of which summered at Wickaninnish Bay in 1969, a pair engaged in mating or erotic play, a young animal apparently feeding in protected inlet waters, and a naturally marked individual that appeared at Wickaninnish Bay in 1970, 1972, and 1973.

Introduction and Methods

In their definitive work on the gray whale (*Eschrichtius robustus*), Rice and Wolman (1971) have drawn largely from data obtained along California shores, near the southern end of the eastern Pacific population's range. Information from farther north, particularly that relating to aspects of migration and feeding, has been provided largely by Pike (1962) and Pike and MacAskie (1969). During recent years we have had frequent opportunity to observe gray whales along the central west coast of Vancouver Island and have gathered additional information from knowledgeable residents of that area. Our data, given below, supplement the picture of migration given by the authors cited above, and introduce some previously undocumented aspects of the occurrence of the gray whale along this lower central portion of its annual range.

Most observations were made incidental to other work. While carrying out an inventory survey of mammals in Pacific Rim National Park (Hatler 1972), the senior author observed whales both from shore and from a small boat at irregular intervals in 1971 and 1972, and obtained additional information from local crab fishermen who regularly worked in the main whale-watching areas. The junior author observed whales throughout the summer of 1972 while conducting guided sea-mammal observation tours for a private concessionaire in Pacific Rim Park, and prepared a gray whale bibliography and status report for the park during the following winter and spring (Darling 1973). Observation forms were provided to several lightstations along the west coast of Vancouver Island in 1972, and personnel at some of these provided records of migrating whales during winter and spring 1972–1973, as weather and opportunity permitted. Observations, again at irregular intervals, continued through September 1973.

We are confident that most observations reported here involved gray whales and not other species. All were made within 1 mile from shore and most were within 1/2 mile. Pike (1962) has shown that such near-shore sightings rarely involve species other than gray whales, a conclusion which our observations support but which we did not accept complacently. We actively looked for other species, but rarely saw them. At Wickaninnish Bay especially, approaches to 100 m or less of observed whales was the rule, and under such conditions we nearly always saw the series of humps or "knuckles" along the posterior dorsum which is characteristic of the gray whale. The crab fishermen who provided data are keen observers who are thoroughly familiar with this and other common species, and among our respondent lightkeepers, at least two indicated their competence by noting "identification not certain" for some sightings they recorded on our observation forms.

Results

Migration

Counts and direction of movement of passing gray whales, as recorded by lightkeepers along the west coast of Vancouver Island, are shown in

Figure 1. As Pike (1962) has suggested, the paucity of observations of southbound animals along the Vancouver Island coast in winter has probably been due largely to the inclement weather and subsequent poor visibility typical of that time of year. He had just three significant winter observations from this area and a few more from other British Columbia locations, but from these he inferred that gray whales pass British Columbia shores in December and January with a peak in late December. Pike and MacAskie (1969) provided additional records including sightings of small groups of gray whales passing Langara Island (northwest Queen Charlotte Islands) in October–December 1960, peaking in December, and a count of 22 moving south past Kains Island, northwest Vancouver Island (see Figure 1), in December 1962. Our lightstation records (Figure 1) also indicate a rather strong southward movement in December. Despite the fact that weather conditions made observations impossible on 10–15 days or more, whales were seen on 7 days of that month at both Cape Beale and Pachena Point. We emphasize that these counts are minimal as the light personnel were not spending long hours looking for whales, but were simply recording them when they saw them.

Information received from marine mammal biologists M. Bigg and I. MacAskie (personal communication) includes a lightkeeper's sighting of 12 to 15 gray whales moving south past Cape St. James (south Queen Charlotte Islands) be-

FIGURE 1. Observations, by Vancouver Island lightkeepers, of apparently migrating gray whales, November through April 1972–1973. Closed circles indicate locations of Department of Transport Lightstations, including four from which no data were obtained (A, Cape Scott; B, Kains Island; C, Lennard Island; D, Amphitrite Point), but which are mentioned in the text. The three numbers shown for any given month and location are, respectively, the total number of whales counted during the month, the number of days on which whales were counted, and the maximum number seen on any one day. The arrows beneath the sets of numbers indicate the direction observed whales were travelling (left=north; right=south). The cross-hatched area is that shown at larger scale in Figure 2.

Explantory footnotes, tabular data:

[a] One whale moving north, it and one southbound animal not positively identified as gray whales;

[b] Single gray whales seen moving south on 22 and 26 February;

[c] Those seen probably gray whales, but not positively identified;

[d] All seen during the period 1–3 March; no other reports received from this station.

tween 20 December 1972 and 3 January 1973, and an additional 10 (not positively identified) on 7–9 January. Bigg saw about a dozen southbound gray whales during a flight along the west coast of the Queen Charlotte Islands in December 1971, and in a flight on 9 January 1973, the junior author saw six gray whales moving slowly southeast in Wickaninnish Bay (see Figure 2). December observations at three of our respondent lightstations occurred on the following days (numbers seen each day shown in parentheses):

Estevan Point:
5th (1), 7th (4), 8th (9), 10th (1);

Cape Beale:
2nd (1), 4th (2), 6th (2), 7th (1), 10th (1), 13th (1), 14th (1), 31st (1 found dead);

Pachena Point:
3rd (2), 6th (3), 12th (1), 17th (4), 21st (2), 29th (2).

Thus, during winter 1972–1973, gray whales moved steadily by the British Columbia shores throughout a 5- to 6-week period including all of December and early January. This result is in general agreement with the winter movement pattern suggested by Pike and MacAskie (1969), although these authors' conclusion that there is a peak movement in late December now seems less certain. Weather conditions may have obscured either this peak during our observations or the strength of the early December movement during theirs. Future observers may find that southbound gray whales do not peak in local occurrence to the extent that they do while heading north in the spring.

Among the April lightstation records, 56 of 74 whales counted at Estevan Point, 98 of 100 at Pachena Point, and 210 of 245 at Cape Beale were seen by the 15th of the month. Thus, our records precisely corroborate those of Pike (1962), who wrote that northbound whales appear on the British Columbia coast in February and peak during the first two weeks of April. Pike and MacAskie (1969) have later indicated that there is relatively little movement by Vancouver Island shores in spring until late March.

Our observations from Estevan Point, Cape Beale, and Pachena Point (Figure 1) along with earlier records from Lennard Island, Amphitrite Point (Pike 1962), and Kains Island (Pike 1962; Pike and MacAskie 1969) indicate that numbers of whales do pass close to the Vancouver Island shore, along most of its length, during both north- and south-ward migrations. This is contrary to the views of Gilmore (1960, 1969) who postulated a more pelagic route across the Gulf of Alaska, which resulted in most southbound animals' bypassing Vancouver Island in the fall. He felt that the first landfall occurred at about the Columbia River. The additional records given above for the Queen Charlotte Islands suggest that Pike (1962) was correct in concluding that most whales pass from the north tip of Vancouver Island to the west side of the Queen Charlottes. But the paucity of records from the mainland coast along the east side of Hecate Strait at this latitude may be reflective more of an absence of interested observers rather than an absence of whales. H. D. Fisher (personal communication) saw three gray whales moving north in Higgins Passage at the mouth of Milbanke Sound, mainland coast (52° 20′ N, 128°30′ W), on 11 April 1973.

At the south end of Vancouver Island, the relative lack of information at Carmanah Point (as compared to that from Pachena Point just 18 miles north) and the complete absence of sightings at Sheringham Point (see Figure 1) may indicate that most whales leave (and arrive at) the Vancouver Island shoreline somewhere between Pachena and Carmanah and cross the Strait of Juan de Fuca to (or from) Cape Flattery on the Washington Coast. We are aware of a single record from east of Sheringham, that of Carl (1967) who reported that one animal apparently summered in inside waters near Victoria during 1967.

Occurrence in Summer

Rice and Wolman (1971) acknowledge that not all gray whales migrate to the Arctic in the summer, and list a number of scattered and irregular summer sightings at locations from southern California to the Queen Charlotte Islands. It is common local knowledge, but it has not been documented previously, that gray whales are seen regularly each summer in the immediate vicinity of Wickaninnish Bay, a shallow sand-bottom bay adjacent to Long Beach in what was formerly Wickaninnish Provincial Park and is now Pacific Rim National Park (see Figure 2). The first significant observations on this regularity of occurrence were noted by provincial naturalists in reports on their summers in the area. Table 1 summarizes their information and that which we have gathered subsequently, providing coverage over nine summers from 1965 through 1973.

These data show that occurrence throughout the summer (roughly June through September) has been common, although a recurring feature (1965, 1966, 1973) has been a temporary scarity or absence in late July and August. Since most observations have been limited to Wickaninnish Bay, it is possible that these "absences" have been purely local. Gray whales have been seen, at times other than during migration, in Florencia Bay just south of the above area and in Schooner Cove, Cox Bay, and Ahous Bay (Vargas Island) to the north (see Figure 2). During the July period of apparent scarcity in 1973, gray whales were seen in Florencia Bay on at least one day (T. R. Bailey, personal communication). Another possibility is that these temporary disappearances and the nearly complete absence in summer 1967 have reflected changing feeding conditons in this area. The question of whether gray whales actually feed there is discussed later in this paper.

During the years of our observations, 1971–1973, the extent of our opportunity to record gray whale observations has varied considerably. In 1971 neither of us was present in the Wickaninnish Bay area after the April migration period until 1 August. On that date the senior author and park naturalist D. Foskett, conducting an aerial census of sea lions (*Eumetopias jubata*), counted four different gray whales between Sea Lion Rocks and the north end of Wickaninnish Bay. On 10 August and 26 September small-boat censuses of the same area by the senior author and an assistant, J. Biggar, yielded counts of five and three gray whales respectively. During this late summer period, sightings were common. Crab fisherman D. Arnet (personal communication) reported seeing as many as 10 whales (extent of duplication unknown) during a day's fishing on 13 September, but saw only two on 15 September. Vancouver Natural History Society members on charter boat tours near Sea Lion Rocks saw three, two, and three whales, respectively, on 18 and 26 September and 2 October (R. W. Campbell, personal communication), and Biggar saw four gray whales in Schooner Cove on 28 September.

TABLE 1 — Summer occurrence of gray whales in the vicinity of Wickaninnish Bay, Vancouver Island, British Columbia, 1965–1973

Year	Source	Remarks
1965	Buffam (1965)	Gray whales seen "virtually every day of the summer" but less commonly during the first three weeks of August than before or after this period
1966	Buffam (1966)	Seen until 15 July, but then disappeared and only one sighted from then through August
	Pike and MacAskie (1969)	One stranded in Florencia Bay in mid-August
1967	Campbell (1967)	Scarce all summer (19 June to 6 September), with only two sightings made: single whales on 24 June and 11 August
1968	Campbell (1968)	"At least six whales frequented Wickaninnish Bay the entire summer" (4 June through 2 September)
1969	Campbell (personal communication)	Gray whales again present throughout the summer
1970	Belton (1970)	Gray whales seen commonly during summer
1971	This study	Whales present at least through August and September (details in text)
1972	This study	Up to six or seven whales seen almost daily between 29 June and 4 September (details in text)
1973	This study	Apparently present throughout the summer but with temporary period of scarcity during last two weeks of July (details in text)

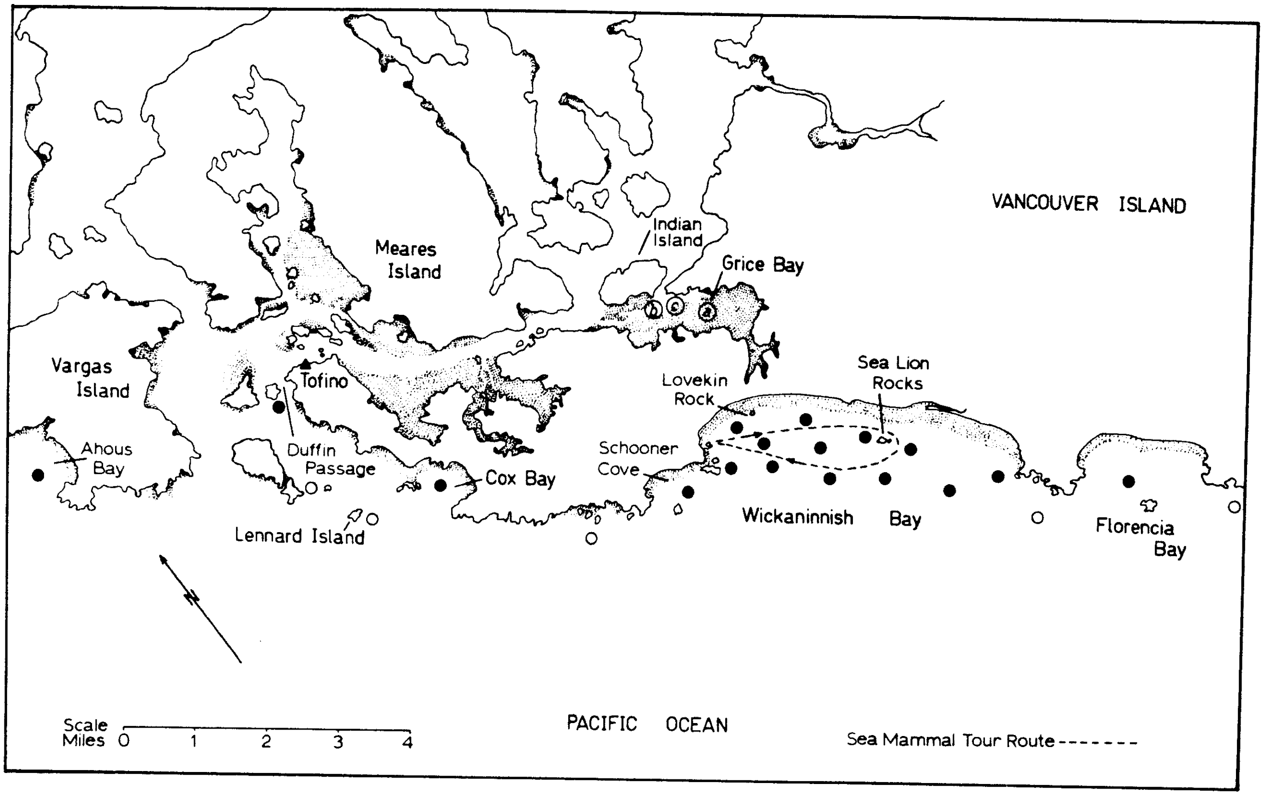

FIGURE 2. Observations of gray whales in the vicinity of Wickaninnish Bay, Vancouver Island, British Columbia, at times other than during migration. Closed circles represent approximate locations at which gray whales have been seen more than once, while open circles indicate single sightings. The three sightings in Grice Bay (labelled a, b, and c) were made on 27, 28, and 29 October 1971 respectively. Stippled areas indicate tidal mudflats (inside waters) and sand beaches (exposed waters). The entire area shown is indicated by a cross-hatched rectangle on Figure 1.

Our most intensive series of observations was recorded in summer 1972 when the junior author operated a commercial cruise boat for Pacific Rim Expeditions, Ltd. This firm's sea-mammal observation tours, run daily as weather permitted, covered an approximately 3-mile stretch of water between the north end of Wickaninnish Bay and Sea Lion Rocks (see Figure 2), and whales were seen only when they occurred on or near this route. From one to perhaps seven gray whales were seen each day of operation (29 June through 4 September) except on 14 and 24 August and 4 September. On these 3 days when no whales were seen, less than the full day of cruises was run owing to adverse weather conditions. The maximum count of six or seven (depending upon possible duplication) was obtained on 6 July; on 27 other days during which counts were possible numbers seen occurred in the following frequencies: one whale (5), two (2), three (8), four (5), five (6), six (1).

In 1973 our observations were again sporadic, but were sufficient to show that gray whales were present in the Wickaninnish Bay vicinity throughout the summer. Sightings of gray whales were a regular feature of nature walks conducted by park naturalists, and there were few days on which no whales were seen. The maximum count for any one time and place was seven, obtained by the junior author between north Wickaninnish Bay and Schooner Cove on 20 June. The apparent scarcity in late July, mentioned previously, was reported by the cruise-boat operators who were greatly disappointed at the fact, after having all but guaranteed visitors an opportunity to see whales. Sightings increased again in August, and the junior author counted four along the cruise route on 22 August and two just to the south on 4 September.

Among the summer observations, of particular interest have been sightings of apparent mother-young pairs. One cow and calf occupied

Wickaninnish Bay for most of the summer in 1969 (R. W. Campbell, personal communication). The senior author, on board a commercial cruise vessel near the north end of Wickaninnish Bay in July of that year, saw this pair but was unaware of the significance of the observation at the time, and more precise details were not recorded. There are apparently no published records of adults with young summering south of the Arctic feeding grounds, and even sightings during migration are exceedingly rare (Rice and Wolman 1971). We have one other probable record of a cow and calf gray whale: on an exploratory cruise with Pacific Rim Expeditions owner, J. Hudnall, on 29 June 1972, we were observing two feeding whales some 350 m northwest of Sea Lion Rocks (Figure 2) when a third suddenly blew just a few meters from the rocks and within 100 m of our boat. Attention was shifted to this third whale just as what appeared to be a very small whale surfaced and blew quickly, immediately beside it. Although it seemed evident that this was a mother-young pair, both disappeared seconds later and we were unable to find them again for confirmation. On 19 and 20 July a large and small gray whale pair, the two always side by side and blowing in unison, were seen at close range by the junior author and Hudnall. They were assumed to be a cow and calf, and may have been the pair glimpsed on 29 June.

Occurrence in Winter

Table 2 lists some of our gray whale observations between October and February in each of two winters (1971–1972 and 1972–1973). We have recorded whales at least once during each month of this period during both years, in partial confirmation of the remarks of longtime crab fisherman John Svoboda, Sr. (personal communication) who has told us that at least a few whales are always present. We stress that heavy surf, wind, fog, and rain are the rule at this time and on most days whales are not easily seen. We do not know where the whales weather out severe storms, but whales (presumably the same ones) may be seen in Wickaninnish Bay within a few days both before and after such storms, suggesting that they do not go far. During moderately rough weather, i.e., when observation is difficult but is still possible, whales may often be seen at the semi-protected north end of the bay, just north of Lovekin Rock (Figure 2).

Southbound migrants pass the Vancouver Island coast largely in December and perhaps early January, while some northbound animals appear

TABLE 2 — Observations of gray whales in the vicinity of Wickaninnish Bay, Vancouver Island, British Columbia, winters of 1971–1972 and 1972–1973

Date	Remarks[1] and Source[2]
27 Oct. 1971	At least one at north end of W. Bay[3] (dh)
5 Nov. 1971	At least three blowing near Lovekin Rock (dh)
15 Dec. 1971	One seen during sea-mammal census flight along Pacific Rim National Park shoreline, that in W. Bay (dh)
27 Dec. 1971	Independent reports from two crab fishermen that only one seen during day, that at south end of W. Bay (D. Arnet; J. Svoboda, Jr.)
13 Jan. 1972	One "feeding" among flock of sea ducks near Lovekin Rock (dh)
19 Jan. 1972	Two "feeding" 150–200 m out from Lovekin Rock (dh)
3 Feb. 1972	Four or five different animals seen in day's crab fishing at W. Bay (J. Svoboda, Jr.)
10 Mar. 1972	Two at Sea Lion Rocks and one north of W. Bay (D. Arnet)
24 Oct. 1972	Two in north half of W. Bay (dh)
1 Nov. 1972	One just south of Sea Lion Rocks (dh)
16 Nov. 1972	One "feeding" at north end of W. Bay (B. Campbell)
23 Nov. 1972	Two in north W. Bay; one behaving as though feeding (jd)
24 Nov. 1972	One apparently feeding in north W. Bay (jd)
2 Dec. 1972	Four in W. Bay near Sea Lion Rocks (J. Dyer)
7 Dec. 1972	One "breeched" twice in north W. Bay (jd)
11 Dec. 1972	Three near Sea Lion Rocks (J. Dyer)
13 Dec. 1972	Two at north W. Bay (jd)
14 Dec. 1972	Three apparently feeding near Sea Lion Rocks; observed at close range from a small boat for about one hour (jd)
28 Dec. 1972	One in north W. Bay (jd)
9 Jan. 1973	Two blowing at 3- to 4-minute intervals near Lovekin Rock; six moving slowly southeast just north of W. Bay (jd)
10 Jan. 1973	Several seen coming from the northwest into W. Bay (G. Trenholme)
6 Feb. 1973	Three near Sea Lion Rocks; diving pattern of two suggested feeding (jd)
7 Feb. 1973	One near Sea Lion Rocks (G. Trenholme)
23 Feb. 1973	One in south W. Bay blowing and diving in shallow water (B. Campbell)

---

[1] All observations by authors made on occasional visits to the area, as weather permitted.

[2] Source = observers. The initials dh and jd designate the senior author and junior author respectively.

[3] W. Bay = Wickaninnish Bay.

as early as February although they rarely show up in numbers until mid-March. This schedule would suggest that the vanguard of the northbound might meet the laggards of those moving south in our area, and it is difficult to determine the significance of our winter observations. As the remarks in Table 2 show, and as the discussion immediately following will indicate, we have seen gray whales apparently feeding in Wickaninnish Bay during January and February of two consecutive years, a time during which most of the population is supposed to be fasting in the warm waters off the coast of lower California (Rice and Wolman 1971). Since "feeding" animals have also been observed in the months preceding this period, it is tempting to speculate that some animals actually spend the winter at Wickaninnish Bay and do not make the full migration south. It would be necessary to have recognizably marked whales present in order to confirm this.

Feeding

Pike (1962) reviewed information on feeding and concluded that the gray whale "feeds little outside its arctic habitat." Gilmore (1969) stated flatly that gray whales do not feed on the southward migration, and Rice and Wolman (1971) support his statement for California shores with their analyses of 180 stomachs, none of which contained food. The stomachs of all but two of the 136 northbound whales examined by these authors were also empty, as were the stomachs of 10 animals taken in April off northwestern Vancouver Island (Pike 1962), although there were some intestinal contents in the Vancouver Island specimens, and Pike noted that these animals had "probably done some feeding." Later, reporting an observation of whales apparently feeding in Wickaninnish Bay in April, Pike and MacAskie (1969) generalized that some northbound animals do stop to rest or feed in British Columbia waters. More recently, three gray whales observed at Rose Spit, Queen Charlotte Islands, on 11 April 1973 were causing "upwellings of sand and mud from the bottom," i.e., perhaps feeding (H. D. Fisher, personal communication). Whether or not gray whales feed while migrating, it seems evident that those animals known to have spent all or much of the summer well south of the Arctic (including those listed by Rice and Wolman (1971) and those reported in this paper) must have sustained themselves by feeding locally.

Though there have been no whales collected in Wickaninnish Bay, thus making it impossible for us to demonstrate that they actually have food in their stomachs, we nevertheless are almost certain that they are feeding there, possibly throughout the year. Most of our summer observations, and many from other times of year, involve animals in water ranging in depth from about 5 to 15 m, and engaged in the following activity. Characteristically, a long dive of 2 to 3 minutes is followed by a series of short blows, usually three, the first of which is accompanied by the release of a brownish stain into the water (presumably waste material from the baleen). Following these short emergences, the animal arches forward in another deep dive, and during this motion it exposes most of its dorsal surface, although the flukes rarely appear. Whales engaged in this activity often worked back and forth through the same small area for long periods of time and the junior author, while piloting the cruise boat in 1972, noted that these could be encountered in the same general area on successive trips throughout one day.

Among our October–February observations, a number involved animals engaged in the above activity, our description of which matches the "feeding behavior" described by Wilke and Fiscus (1961). These authors have observed "seabirds" settling into the brown muddy patches produced by surfacing whales, implying that organic matter is included in the material released; we have seen gulls do the same at Wickaninnish Bay, and have noticed that "feeding" whales are often accompanied by sea ducks. On 19 January 1972, the senior author watched two whales apparently feeding near Lovekin Rock for over 1 hour. During this time two bunches of scoters (*Melanitta perspicillata* and *M. deglandi*) had divided from one large raft and each was following a whale. The whales moved back and forth over an area of less than 150 m^2 during the period of observation, changing direction frequently, and each group of ducks (most members of which were diving regularly and apparently feeding) maintained orientation with its respective whale. It was evident that either the scoters and the whales were exploiting a common food source or that the scoters were opportunistically snatching organisms stirred up by the whales.

In considering the rather well-documented concept that migrating gray whales do not feed, we are left with three alternative explanations for our observations. (1) The whales of our observations are not actually feeding. As indicated, we believe that they are; they at least appear to be trying. (2) These whales are not migrating. Because we have not been working with individually marked whales, there is little evidence either for or against this alternative and the question must be deferred at this time. Comments on one recognizable whale will be presented later. (3) Some or all migrating whales feed in suitable habitats along the migratory route, but there are few such areas south of the Arctic and perhaps none of significance south of Vancouver Island. This alternative seems reasonable and would explain the absence of food in the digestive tracts of animals off the California coast, where many of the absolutes of gray whale biology have been established.

Occurrence in Protected Waters

Gray whales occasionally enter the more protected waters of Clayoquot Sound, 10 miles north of Wickaninnish Bay (Figure 2). On 30 April 1969 the senior author observed one in Duffin Passage near the mouth of Tofino Harbour. The late R. Folker (personal communication) had seen gray whales "rubbing themselves" on a gravel bar at that location several times in the past. The most extreme inland record we are aware of occurred in October 1971. A Tofino resident had reported seeing a whale blow in Grice Bay (8 miles or more inland from Tofino; see Figure 2) on about 20 October, but had acknowledged that he had seen it at some distance and that it could have been a killer whale (*Orcinus orca*). This would not have been an unusual sighting, and the report was not followed up.

On 27 October, the senior author visited the area to carry out other biological duties and found a gray whale in 3–4 m of water in this mud-bottom bay. The animal was approached in a small boat to within 30 m to confirm identification, and was then watched for several minutes. It was a small animal, no more than 9 m in length, and it was apparently feeding. This whale was still present on both 28 and 29 October, but was working the deeper waters (6–10 m) near Indian Island on those days (locations plotted in Figure 2). Duties elsewhere made further observation of this animal impossible, and we do not know when it left Grice Bay. The earlier report from the Tofino resident suggests that it may have been present there for 10 days or more.

Possible Mating

On 26 April 1971, the senior author was attracted to a disturbance in the water about 1/2 mile offshore at the north end of Wickaninnish Bay. Through a 20-power telescope set up on a nearby knoll, he obtained a clear view of two gray whales engaged in vigorous activity. At least one of the animals frequently rolled over on its back with its flippers protruding from the water. There was much rolling and sounding, the latter frequently occurring with the flukes coming high out of the water and slapping the water surface with a large splash. Once both animals sounded, both sets of flukes showing at once and disappearing together.

Most often only one animal showed at the surface except when they were moving. Then one followed the other, both close to the surface and blowing often. These straight-line movements were usually only 50–75 m, at which time the trailing animal (perhaps the female judging from the observations of others (e.g., Sauer 1963)) initiated activity by speeding up, sounding, and coming up beneath the other. Frequently this started a series of rolls. On several occasions the male's conspicuously pink, erect penis showed clearly as the animal rolled over on the surface. Once the other animal's head emerged from the water and nudged the penis. Heads were seen frequently, but always only one at a time. These two whales maintained nearly continuous activity from 15:05 to 16:35 Pacific Standard Time. Observation was continued until 17:20, by which time no further activity had occurred. There were then five whales in the area, all apparently feeding, and there was no obvious pair among these, thus it was not evident which had been the original two. It was not possible to determine whether copulation had actually occurred, but the erotic nature of the activity was evident.

Rice and Wolman (1971) have provided sufficient histological evidence that reproductively functional breeding occurs before the spring migration. But they cite other records of apparent mating activity in northern areas, including observations from northern California, Washington, and northern Alaska. It may be that erotic play, and perhaps copulation, is a common recreational pursuit in this species.

A Naturally Marked Whale

Hubbs (1959) has called attention to conspicuous whitish patches, constituted by groups of epizoites and/or scars, which develop on the skin of gray whales. During the 1972 daily summer cruises at Wickaninnish Bay, the junior author was subjectively certain that he recognized some individuals repeatedly on the basis of these markings, but such information is difficult to document. One whale, however, was easily recognizable and we have obtained photographic proof that this animal has appeared in Wickaninnish Bay on more than one occasion (or perhaps over a long period of time). This whale possessed a large, rounded and distinctly orange-colored scar on its left side just below the "knuckles" on the lower back.

Figure 3 shows two views of this whale. The first photograph (A) was obtained by the senior author when the animal was first seen in October 1970. At this time it was "feeding" in company with two others near Sea Lion Rocks in Wickaninnish Bay. Without knowing that this photograph had been taken, the junior author first noted seeing this animal on 20 August 1972, recognizing it as one he had seen several weeks previously. We compared notes the following winter, and determined to watch closely for this whale. It appeared again during the summer of 1973, and Darling obtained the photograph of Figure 3B on 12 July.

The whale with the orange scar was seen again on 12, 18, and 20 August by cruise boat operator A. Oliver (personal communication), who had accompanied Darling when the animal was photographed on 12 July; on 22 August Darling obtained a third photograph of this animal. It was last seen during that summer on 2 September, by Oliver.

Thus, it is evident that at least one gray whale has been faithful to the Wickaninnish Bay area, returning to it in at least three of four summers between 1970 and 1973 and conceivably even residing there the year round during that time. Observation effort has been sporadic enough, especially during the winter months, that it could easily have been missed most of the time. In addition, as mentioned earlier, gray whales have been seen "feeding" in other areas within 10 or 12 miles of Wickaninnish Bay; if the naturally marked whale had occupied any of these areas, we probably would not have seen it, owing to our concentration of activities at Wickaninnish.

Another whale with a large white patch on its upper right side just below the rudimentary dorsal fin was photographed in Wickaninnish Bay on 14 December 1972. A photograph taken near Sea Lion Rocks on 22 August 1973 appears to portray this same animal, but we cannot generate the certainty, in this case, that is possible with the orange-scarred individual. The photos in Figure 3 have been reproduced from color transparencies; duplicate transparencies of these, of the 22 August (third) photo of the orange-scarred whale, and of the two photos of the white-scarred whale have been placed on file (PDF Number 320) at the British Columbia Provincial Museum, Victoria, British Columbia and are available for loan. Interested persons should write to Assistant Curator of Birds and Mammals, R. W. Campbell, at that institution.

Discussion

The annual migration route of the gray whale covers a distance, one way, of over 4500 miles (Pike 1962). Along this route, studies have been concentrated chiefly within the southernmost 500 miles, with occasional observations providing at least moderate knowledge of the species' occurrence as far north as Vancouver Island (about 1500–1700 miles north of the breeding area). As results reported in this paper indicate, our knowledge even at this latitude is fragmentary. Little is actually known of the species over the remaining (northern) two-thirds of its annual range, and many of the assumptions about its occurrence there (chief among which seems to be that it does nothing over most of this distance except swim) may be unwarranted.

We have found that gray whales may be seen, apparently feeding, during all months of the year at Wickaninnish Bay, Vancouver Island, British Columbia. This fact is somewhat at variance with previously published work, which has established that *most* members of the eastern Pacific population annually migrate between arctic waters where virtually all annual feeding is done, and lower California breeding grounds. If Wickanin-

FIGURE 3. A recognizably marked whale seen repeatedly in the Wickaninnish Bay area. (A) Photograph obtained when animal first seen, in October 1970. (B) The same whale, photographed on 12 July 1973.

nish Bay is the only area south of the Arctic which is occupied in the manner we have described, then our observations are of little consequence. But if small "pockets" of habitat between southern Vancouver Island and Alaska are regularly occupied by whales in this way, then it will be important to learn the nature of this occurrence. For instance, if it were found that certain classes of whales, such as first-year animals or non-breeders of one or both sexes, often do not make the complete migration to the breeding grounds, then the very sophisticated data on population dynamics obtained by Rice and Wolman (1971) could be badly biased. Having said this, we hasten to point out that we have no evidence that this is so; our data are sufficient only to suggest that further evidence may be required to demonstrate that it is not.

Perhaps the eastern Pacific population, having recovered from severe overexploitation relatively recently (Rice and Wolman 1971), is only now in the process of recolonizing feeding areas used previously. Perhaps the paucity of sightings outside migration periods has been due largely to an absence of observers. We received an unconfirmed report of four gray whales feeding near Nootka Island, 65 miles north of Wickaninnish Bay, in August 1973, and Pike and MacAskie (1969) report that "several gray whales [were seen] in late August and early September" along the northern Queen Charlotte Islands. Both of these areas are more accessible than many others one might name between Wickaninnish Bay and arctic Alaska, yet neither is regularly frequented by potentially reporting observers; therefore regular occurrence, if it occurs, could easily go undetected.

Clearly our own data, obtained incidentally and sporadically, are deficient. We know only that gray whales occur regularly in Wickaninnish Bay. We do not know certainly that the same whales occur throughout the summer. If as we suspect, some do, how far do they range? We do not know the extent of local turn-over, if any, during migration nor the extent, if at all, to which migrating whales feed in the area. What food organisms are available in Wickaninnish Bay? The sex, age, and condition of most whales frequenting the bay has been largely unknown. Are whales seen in January and February in Wickaninnish Bay among those seen the previous (or following) summer, or are they others which do not complete the southward migration, or are they successive sets of migrants all of which eventually pass by? What is the migration route north of Vancouver Island? Is Wickaninnish Bay the only regularly frequented feeding (resting, staging) area south of the Arctic? An important function of this paper is to suggest that though the answers to all of these questions are presently unknown, perhaps none are unknowable.

Acknowledgments

For providing records of sightings, we are grateful to lightkeepers F. Bergthorson, G. Britton, J. Bruton, O. Edwards, E. Kidder, G. Swaney, P. Thomson, and D. Weeden; crab fishermen D. Arnet, J. Svoboda, J. Svoboda, Jr., and G. Trenholme; Pacific Rim Park Staff, especially F. Bamber, B. Campbell, and D. Foskett; and numerous other whale-watchers including J. Biggar, J. Dyer, and A. Oliver. Special thanks are due J. Hudnall for transportation to Sea Lion Rocks on many occasions, to R. W. Campbell, H. D. Fisher, M. A. Bigg, and I. B. MacAskie for their generosity in sharing their special knowledge of gray whales along the British Columbia coast, and to Fisher and Ian McTaggart Cowan for reading and commenting on an earlier draft of the manuscript. Dr. Cowan also supported a substantial part of the cost of publication from his NRCC grants, and for this we are truly grateful. Finally, thanks to typist Rose Cella, and to Pearse Bowden Economic Consultants for loaning us her services.

Addendum

In late spring, 1974, the naturally marked (orange-scarred) whale reappeared in Wickaninnish Bay and reportedly stayed there throughout the summer. It was again photographed twice by Darling, on 19 May and 30 July.

Gray Whales off Vancouver Island, British Columbia

James D. Darling

Introduction

Each spring, gray whales (*Eschrichtius robustus*) migrate from calving lagoons in Baja, California, along the west coast of North America to feeding grounds in the Bering and Chukchi Seas (Scammon, 1869; Pike, 1962; Rice and Wolman, 1971). Although censuses conducted at Unimak Pass, Alaska (Hall *et al.*, 1977; Rugh and Braham, 1979; Chapter 10, this volume) indicated that the majority reached northern seas, sightings in summer off California, Oregon, Washington, and British Columbia suggested some whales terminate their migration far to the south (Gilmore, 1960; Pike, 1962; Pike and MacAskie, 1969; Rice and Wolman, 1971; Hatler and Darling, 1974; Darling, 1978; J. Sumich, cited in Chapter 13, this volume).

For waters off Vancouver Island, British Columbia (B.C.), three earlier studies demonstrated that (1) north- and southbound migrants pass along the west coast (Pike, 1962; Pike and MacAskie, 1969; Hatler and Darling, 1974; (2) gray whales regularly occur in summer along the outer coast (Hatler and Darling, 1974); and (3) at least one gray

ISBN 0-12-389180-9

whale, recognized in photographs by its unique natural markings, remained off the island throughout one summer and returned for several years (Hatler and Darling, 1974).

Techniques for identifying individual whales from photographs were developed in the early 1970s for southern right whales, *Eubalaena australis* (Payne *et al.*, 1981); for killer whales, *Orcinus orca* (Bigg *et al.*, 1976; Bigg, 1982); for humpback whales, *Megaptera novaeangliae* (Katona *et al.*, 1979); and, as described here, for gray whales. Such techniques have supported long-term studies of abundance and behavior by allowing repeated observations of the same individuals without the need for tagging.

This chapter describes the abundance, stability, distribution, and general behavior of gray whales that spend the summer off Vancouver Island.[1] It is based on direct observations and photoidentifications over the 10 years since the first individuals were identified in 1970–1973 (Hatler and Darling, 1974).

Methods

STUDY AREA

Vancouver Island (Fig. 1) is located approximately halfway between the Mexican calving lagoons and the northernmost Chukchi Sea feeding grounds. Its west coast is characterized by sandy bays and beaches (e.g., Long Beach, Wickaninnish Bay, is 11.3 km in length) separated by rocky headlands or long stretches of rocky coast and cliffs. Along the central west coast, a system of protected waterways exists between coastal islands.

Small craft surveys (1972–1976) initially centered on a 40-km stretch of the west coast (circled in Fig. 1). After 1976, these surveys were gradually extended to cover most areas accessible to small craft between the entrance to the Straits of Juan de Fuca and Cape Scott (Fig. 1). With cooperation from personnel at 10 Vancouver Island lightstations (Fig. 2), much of the west coast of the island was monitored during the migrations. All observation was coastal, within 4 km of shore; no offshore surveys were attempted.

MIGRATIONS

The present study was primarily concerned with gray whales which summer along the Vancouver Island coast. Therefore, migrations past the island were observed mainly to determine the interval between the spring (northbound) and winter (southbound) migrants. Lightstation personnel recorded the following data on gray whales that they saw between November and May: date, number of whales seen, direction of movement, and appropriate comments. Observations were incidental to their other duties, but reports did include records of any whales noticed and the number of days of poor visibility. The reporting lightstations from south to north, as indicated by triangles in Fig. 2, were Sheringham Point, Carmanah Point, Pachena Point, Cape Beale, Amphitrite

---

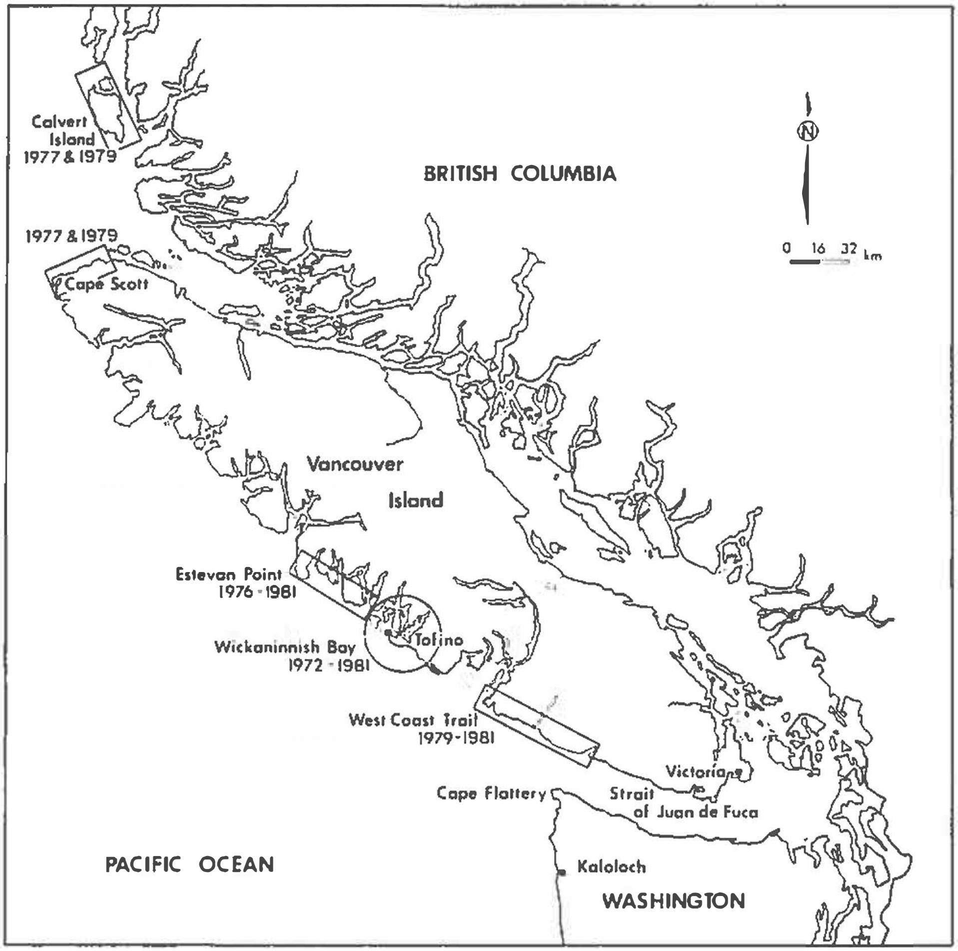

Fig. 1. *Vancouver Island, British Columbia, showing the central study area; areas surveyed frequently (circled) and areas reached less regularly (rectangles) in the years indicated.*

Point, Lennard Island, Estevan Point, Nootka, Kains Island, and Cape Scott. Lightstation records were used to monitor migrations in four seasons; 1972–1973 (reported in Hatler and Darling, 1974), 1973–1974, 1975–1976, and 1976–1977. In 1975 and 1976, the author also observed the spring migrations (February–June) from shore stations in the central study area and from small craft; the winter (November–January) migration was observed sporadically from shore; and incidental sightings reported by some residents of the area, particularly Pacific Rim National Park naturalists, were logged.

To establish timing of the migrations and indicate their peaks, all reporting lightstations were treated as one locus, that is, "the west coast of Vancouver Island." All sightings for each 2-week period, November 15 to May 1, from the four winters 1972–1973, 1973–1974, 1975–1976, and 1976–1977 were averaged. Intensive observations in the study area by the author, beginning in March of the years 1975 and 1976, allowed

further delineation of the northward migratory period; there were no comparable observations of the southward migration.

INDIVIDUAL IDENTIFICATION

Photographs were taken of pigmentation patterns on visible portions of whales' backs[2] with a 35-mm camera with a 200- or 300-mm lens, Kodak Tri-X Pan Film pushed

---

[2] Examinations of a cross-section of the skin of a dead whale indicated that these patterns were indeed pigmentation patterns and not superficial.

to 1600 ASA, and a shutter speed of 1000th/sec (cf. Bigg *et al.*, 1976; Bigg, 1982). Any scars or other prominent natural markings were also photographed.

Once photographed, the patterns were sketched on a data chart and corresponding film frames noted. These patterns were used for identification because for most animals they were the only part regularly seen. Most of the whales encountered were feeding in shallow water and rarely raised their flukes above the water surface. Therefore, identification by fluke patterns, as has been done in humpback whales (Katona *et al.*, 1979) was impractical.

The need to recognize individuals from side patterns complicated identification work because it required photographs of both sides to avoid duplication in counts. However, once photographs of both sides of an individual were on record, a picture of either side was sufficient. To avoid double counting in abundance analysis, when there were uncertainties about assignment of a photograph to an individual whale only photographs of the left side were used. Identification photographs were cataloged by year and records of repeat sightings established.

SUMMER POPULATION

During the summer, whales were located, observed, and photographed for individual identification from a small outboard-powered boat (5 m in length). Each whale's position, companions, and behavior were noted. Numerous reefs, islands, and other points in the study area allowed accurate positioning by landmark. Observations were made from within 100 m by the author and an assistant, usually during the 8 AM–1 PM period. Westerly winds beginning after noon are usual in the study area and make work after that time more difficult. Flights to locate whales were carried out weekly in 1976 and sporadically in other years. Behavioral observations were incidental to photo-identification and aerial survey work. Summer effort, summarized in Table I, varied from year to year.

Results

MIGRATIONS

Timetable

The first northbound whales passed Vancouver Island in February; numbers peaked the last 2 weeks of March then declined (Fig. 3 and Table II). Lightstation sightings were not reported after April 30. However, there were still some whales moving north in May and early June, as will be shown.

Southbound migrants pass Vancouver Island from November to late January with peak numbers during the last 2 weeks in December (Fig. 3 and Table II). From mid-January to mid-February, sightings were rare. The whales occasionally seen during this interval are discussed below.

Table I
Study Effort off the West Coast of Vancouver Island, B.C., 1972–1981

Year	Months of Observations	Methods				Number of Days Identification Photos Taken	Comments
		Boat	Aircraft	Shore	Lightstation

1974	May–Sept.	Occasional, May–Sept.	—	Sporadic	—	<10	Observations incidental to other work in the area
1975	Mar.–Dec.	Daily Mar.–May & Aug.–Oct. Frequent, June–Jul.	Occasional (opportunistic)	Regular Mar.–May	Nov. 1–Apr. 30, 1975–1976	53	In June and July, observations were incidental to other work in the area
1976	Mar.–Oct.	Daily	Weekly	Regular Mar.–May	Nov. 1–Apr. 30, 1976–1977	54	By boat as *weather allowed*
1977	June–Sept.	Daily	One survey flight of study region	Sporadic	—	39	Reached Cape Scott and Calvert Island Area (see Fig. 1.)
1978	July–Aug.	Occasional		Sporadic	—	9	Observations incidental to other work in the area
1979	June–Sept.	Daily	One survey flight of study region	Sporadic	—	18	Reached Cape Scott and Calvert Island Area (see Fig. 1.)
1980	June–Sept.	Occasional	—	Sporadic	—	9	Observations incidental to other work, plus one complete boat survey of south coast
1981	June–Sept.	Occasional	—	Sporadic	—	8	Observations incidental to other work, plus one complete boat survey of south coast

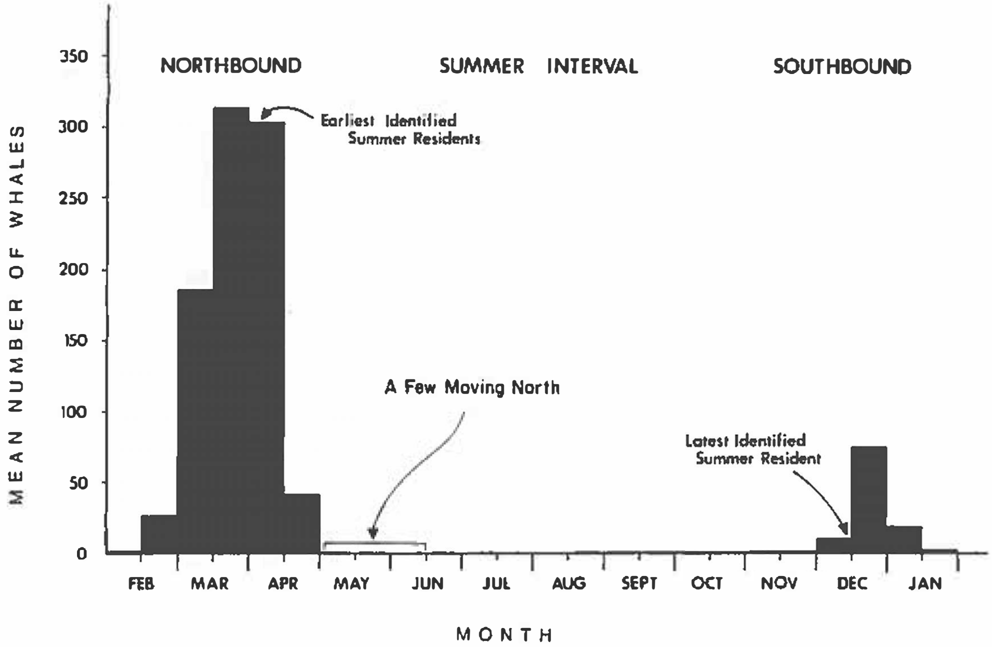

Fig. 3. *Timing of gray whale migrations past Vancouver Island based on lightstation sightings, 1972–1977 (data are unavailable for the period November 1974 through November 1975). See also Table I.*

Fewer whales were sighted during the southward migration than during the northward migration, probably reflecting poor winter weather rather than differences in numbers of whales passing. Two bits of evidence support this conclusion. A note received from the Kains Island lightkeeper in December, 1974 with his sighting forms for that month stated: "On about three days the visibility was clear enough to encourage us to glance out to sea and to see the odd whale . . . at least that is how it would appear from our fog alarm report." On those 3 days, they saw 26 whales. Also, in December, 1977, when weather was unseasonably good, significantly more whales were reported (Table II).

Intensive observations by the author allowed some further delineation of the spring migratory period (Darling, 1978). During this period whales were either (1) moving steadily north; (2) slowly and sporadically, but still obviously, moving north, or (3) lingering in the area. As was expected from lightstation reports, obvious northbound migrants were common through April, although they were fewer after mid-month. In May most whales observed were stationary and feeding; however, a few were still obviously migrating. A photographically identified cow and calf appeared in Wickaninnish Bay on June 2, 1976 and remained until June 5, 1976. They were observed to be feeding and were not traveling. They were gone on June 6 and had probably moved northwards as they were not seen again. This is the latest reasonably clear record of a migrant. Other whales identified in May and June were also not seen a second time, suggesting that they too had destinations farther north. Southbound migrants were sighted in Wickanin-

nish Bay in December and January, consistent with lightstation reports (Darling, 1978).

The winter interval between the last southbound and first northbound migrants was not clear cut. Lightstation reports indicate it occurs from approximately mid-January to mid-February, although in some years whales were sighted during that period.

Route

The migratory route observed during this investigation is shown in Figure 3. It conforms with the accounts of earlier researchers (Pike, 1962; Pike and MacAskie, 1969; Hatler and Darling, 1974). Northbound whales leave the Washington coast at Cape Flattery, head generally north until they reach Vancouver Island then change course to follow its west coast. All sightings were within 4 km of shore; most were within 1 km and many within 100 m. Occasional sightings of gray whales in the Straits of Juan de Fuca and Georgia Strait (Darling, field notes, 1975–1981) indicate that a few animals turn southeast at Cape Flattery.

INDIVIDUAL IDENTIFICATION

Approximately 5000 photographs were taken. Over 100 different gray whales have been identified off the west coast of Vancouver Island since 1970. Most markings were light, white or gray on a darker background. Extent, intensity, and location of identifying elements in the pattern varied dramatically (Figs. 4–6). They ranged from large portions of white, to varied combinations of white patches, slashes, dots, and speckles, to almost total black. Most individuals were immediately recognizable; all were distinguishable on close examination.

The longevity of observed patterns is suggested in Fig. 5, animal No. 741, pho-

Fig. 4. *Examples of pigmentation patterns used to identify individual gray whales.*

tographed over 5 years—in which there was no significant change in markings—and in Fig. 6, both sides of animal No. 756 over 2 years, 1975 and 1976—in which the smallest details of the patterns are constant (arrows). Some half-moon-shaped marks (circled) present on the left side of No. 756 in 1976 were not there the previous year. Similar superficial, nonpermanent marks noticed on some whales were not sufficiently large or common to interfere with identification. From a photograph of a near-term fetus with white skin patterns (see Rice and Wolman, 1971, p. 78), it appears whales are born with

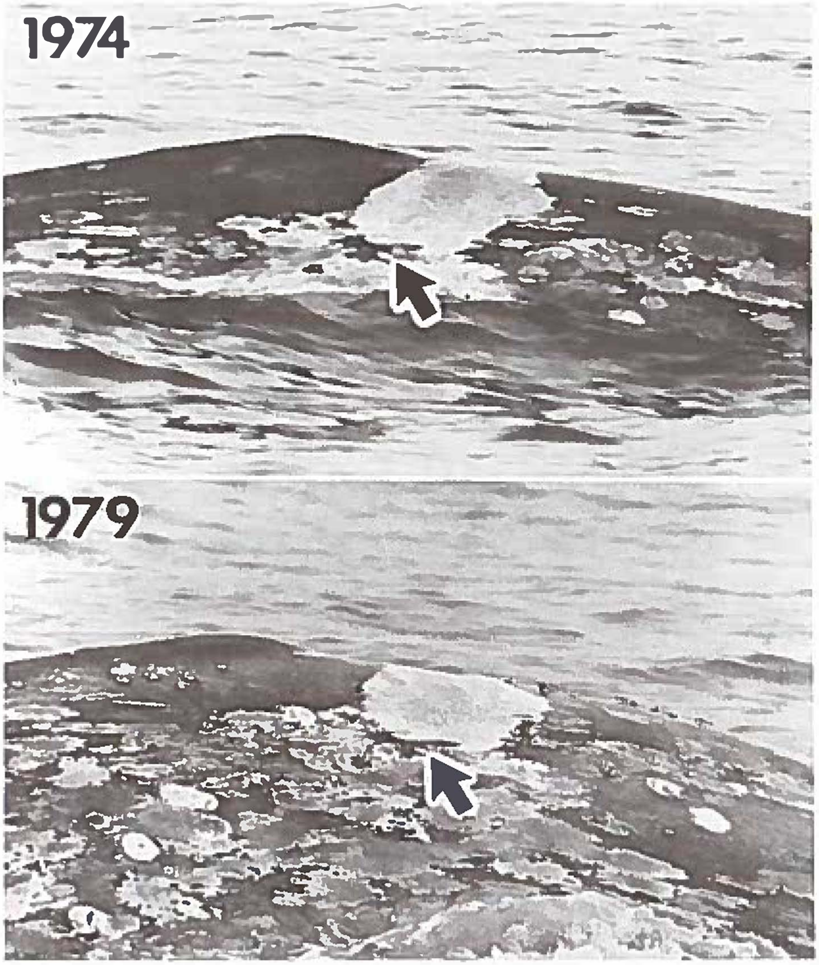

Fig. 5. *Photographs of whale No. 741 in 1974 and 1979. The photographs were taken at slightly different angles. Arrows indicate a common reference point.*

these patterns and maintain them throughout their lives although scratches or superficial growths may partially obscure them at times.

When a scar was the dominant marking, it was used as the basis for identification along with skin patterns. Such was the case with the scarred whale first described by Hatler and Darling (1974). The scar on this whale remained obvious from at least 1970 to 1975, the years it was recorded off Vancouver Island. No substantial change in the scar was noted.

Gray whales have patches of barnacles (*Cryptolepas rhachianceti*), especially on the head and the most anterior portion of the back, and cyamids (*Cyamus scammoni, C. ceti,*

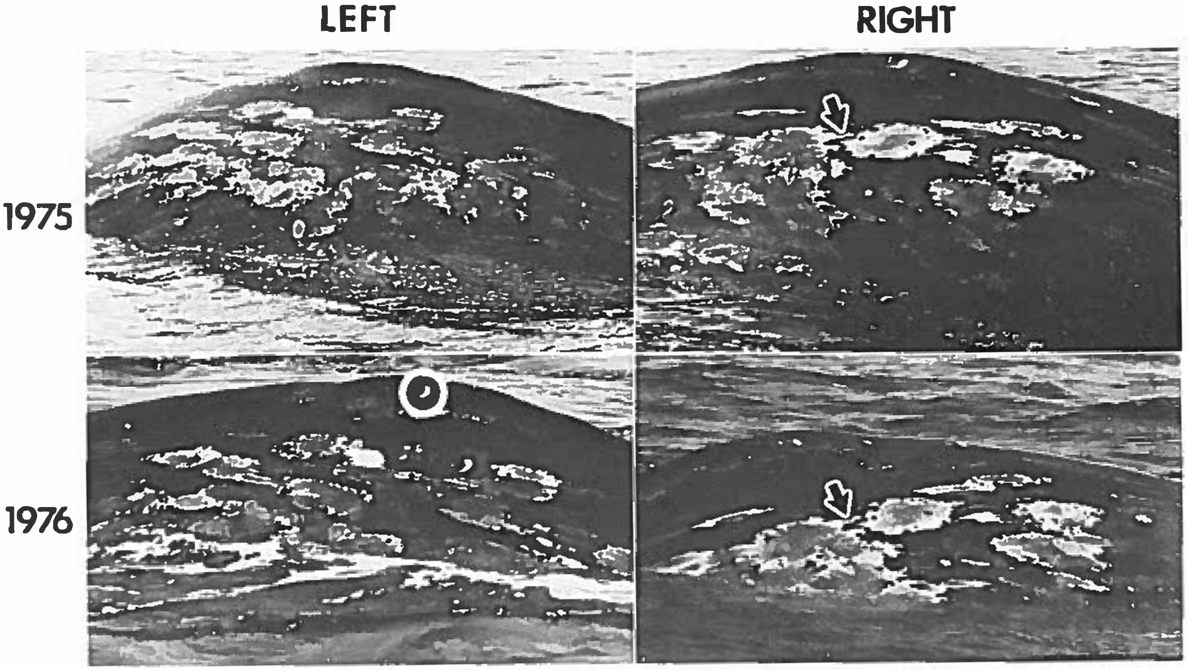

Fig. 6. *Pigmentation patterns of whale No. 756 in successive years. Note the half moon-shaped markings (circled) on the left side in 1976, which are not present in 1975. Arrows indicate a common reference point.*

and *C. kessleri*), particularly around the barnacles and on wounds (Rice and Wolman, 1971). Barnacles and cyamids were not used for individual recognition.

SUMMER POPULATION

Arrival and Departure of Summer Residents

As has been shown, the majority of northward migrants reach Vancouver Island between February and June. Summer residents, animals which remained in the area during the summer interval, were identified as early as April 8 (Whales #701, 721, and 752), April 11 (whale #7513), April 16 (whale #741, and April 17 (whale #754) in 1975, and April 12 (whale 754), and May 13 (whale #759 in 1976. Therefore, summer residents can be present in the area by the time of the local peak of the northward migration in late March and early April (Fig. 3).

Data indicating when summer residents leave for the winter are sketchy because day-to-day observation ended in September when many, if not all, identified whales were still present. The latest sighting of a positively identified summer resident was December 14, 1972 when whale #721 was seen feeding in Wickaninnish Bay. Other summer residents were identified as late as October 12, 1975 (whale #701) and October 23, 1976 (whales #759, 756, and 7511). Small craft searches were not made after these dates.

Apparently the duration of a whale's stay can be from peak to peak of the migrations or about 8–9 months (Fig. 3). The longest recorded stay of a single individual in 1 year was 7 months; whale #701 was first identified on April 8, 1974 and last identified on October 12, 1974.

Abundance

The largest number of resident whales identified in one summer was 34 in 1976 and 1977, the years of maximum effort (Tables I and III). Numbers identified in other years reflect effort level (Tables I and III). In both 1976 and 1977 previously unidentified whales were still being "discovered," albeit rarely, at the end of the season, indicating that not

Table III

D. Number of A seen only that year	7	9	11	5	11	3	10

all residents had been identified. It is not likely, however, that the maximum number of whales which summer in the area is much higher than 34. Aerial surveys carried out in the middle of summer did not indicate that large numbers of animals were "missed" in the identification effort. One of the best such surveys, considering weather and the amount of time spent searching for whales, was that on August 29 and 30, 1977, in which

804											x	x

the entire west coast of the island from Port Renfrew at the southern end of the West Coast Trail to Cape Scott was searched. Twenty-nine whales were counted, compared to 34 identified in that year. In 1979, in a survey from the Kaloloch on the Washington Coast to Calvert Island, north of Vancouver Island, we saw an estimated 30–40 whales; 22 individuals were identified that year. From the above, it seems unlikely that more than 50 whales range onto the Vancouver Island coast in any one summer, and a reasonable estimate might be 35–50.

In the six summers from 1975 to 1981, 93 individual whales were identified on this coast. This is the total of the 56 identified whales seen in only one summer [Table III, (D)] plus those 37 seen in more than 1 year (Table IV). It is thought that not all of these return to Vancouver Island each year.

Annual Returns

Since 1970, 37 whales have been seen in more than 1 year (Table IV). Whale #741 was seen for 8 years (1974–1981); whale #711, 7 years (1971–1977); whale #721, 7 years (1972–1978); and whales #701, #742, and #751, 5 years (1970–1975, 1974–1979, and 1975–1981, respectively) (Table IV). Among the animals identified each year there were those which had been identified in other years (average, 63%) and those which were seen only that year (average, 37%). In 15 cases (in Table IV), a whale was "missed" in one or more summers but seen in subsequent years.

Although some identified whales were resighted in the exact location in which they were identified the previous years (e.g., whale #701 in Wickaninnish Bay in 1970, 1973, 1974, and 1975), others were resighted in different years as much as 150 km from previous sighting location(s) (Table VA and Fig. 1).

Distribution and Movements

The combined locations where gray whales were found during the summers of 1975–1981 cover most of the Vancouver Island coast from Victoria to Cape Scott and

farther north off Calvert Island along the mainland B. C. coast (Fig. 7). The relatively larger gaps between sightings towards the north may well reflect the spacing of observers. The whales were feeding in all locations. All sightings were within 1 km of the shore; most were within 100 m. Apparently suitable habitat on exposed coast includes shallow sandy bays, areas along rocky coastlines and cliffs, and areas off sandstone shelves. Whales were repeatedly but less commonly seen feeding in protected waterways near Tofino.

Whales traveled among sites at least 77 km apart within a summer [Table VB; Fig. 7 (semicircle)]. The maximum distance traveled is not known but the six whales identified off Cape Scott, 220 km north of Estevan Point on July 20, 1977 were not among whales identified off southern Vancouver Island. Apparently, movements are among feeding

Table VB
Travels of Individual Whales along the West Coast of Vancouver Island, within One Summer

Whale ID Number	First Location and Date	Second Location and Date	Direction	Distance (km)
794	Wickaninnish Bay July 14, 1979 (traveling SE)	West Coast Trail Aug. 23, 1979 (feeding)	SE	77
7913	West Coast Trail Aug. 23, 1979 (feeding)	Wickaninnish Bay Aug. 28, 1979 (traveling NW)	NW	77
761	Wickaninnish Bay June 2, 1977 (feeding)	Estevan Point Aug. 17, 1977 (feeding)	NW	80
791	Wickaninnish Bay July 9, 1980 (traveling NW)	West Coast Trail Sept. 10, 1980 (feeding)	SE	77

areas, although traveling whales may not stop at the next nearest area and may bypass feeding whales en route. Whales were seen traveling alone, in pairs, in trios, and in patterns from slow and wandering to quick and direct. On occasion traveling whales moved to a riptide sand bar area where they remained for at least as long as 30 min to several hours.

In some areas whales remained only momentarily, and some animals had as many as four destinations in 1 week, covering a distance of approximately 40 km (whales #741 and 752 in August, 1975). At the other extreme, whales #701 and #754 each remained in Wickaninnish Bay for 80+ days in 1975 and 1976, respectively (Darling, 1978).

Discussion

MIGRATION TIMETABLE

Migratory times and peaks determined during this study generally agree with the observations of Pike (1962), Pike and MacAskie (1969), and Hatler and Darling (1974). The northern migration past the island begins in February, peaks in late March and early April, and continues through May or early June. There may be some slight variance in the timing among years. Based on sightings off Vancouver and Queen Charlotte Islands, Pike (1962) and Pike and MacAskie (1969) suggested the southbound migration occurs from late September or early October until early January, with a peak in the last 2 weeks of December. The sightings in September and October seem early for Vancouver Island. Sightings reported by Hatler and Darling (1974) occurred from the end of November through mid-January. Observations reported here confirmed that this migration occurs from November to mid-January with a peak the last 2 weeks in December. These findings are consistent with predictions from observations in other areas along the migratory route (Leatherwood, 1974; Reilly *et al.*, 1980; Chapters 10, 13, and 16, this volume).

The interval between the last northbound and first southbound migrants extends from mid-June to November. Summer residents were present off Vancouver Island throughout this period, confirming the speculations of Pike (1962) and Pike and MacAskie (1969) and reports by Hatler and Darling (1974). Many of the same identified individuals were seen repeatedly during the summer, as was one whale observed in 1971 (Hatler and Darling, 1974). Summer residents were present by early April, the peak of the northern migration, and stayed 8–9 months until December and the peak of the southern migration. Whales making the full migration to the Bering and Chukchi Seas must budget 2 months more traveling time than those resident off Vancouver Island, arriving in northern areas 1 month later and leaving 1 month earlier (Pike, 1962). They are left with only 6–7 months to feed. Many migrants do, however, feed sporadically while enroute north (Darling, 1978; Wilke and Fiscus, 1961).

The winter interval between the last southbound and first northbound whales is short and not always clear cut. To date there is no direct evidence that Vancouver Island summer residents migrate and in some years unidentified whales have been sighted in the area throughout the winter (Hatler and Darling, 1974). These authors note that it is possible the whales sighted during this period were successive groups of migrating animals, southbound and northbound. The degree of turnover of identified animals each summer suggests that some, if not all, join the rest of the herd.

INDIVIDUAL IDENTIFICATION

Several researchers have used natural markings to identify individual gray whales over the short term; Sauer (1963), describing apparent sexual activity off St. Lawrence Island, Alaska, stated that individual whales could be recognized by skin patterns. Leatherwood (1974) used natural markings to identify three gray whales on successive days off the California coast. Photographic identification work described in Hatler and Darling (1974) and in this chapter show the technique can be used as a basis for long-term studies in which every animal can be permanently identifiable. Swartz and Jones (1978, 1981) and Bryant and Lafferty (1980) have identified gray whales in Mexican calving lagoons and are constructing identification catalogs. Comparison of identified whales from different parts of the gray whales range may elucidate associations of the Vancouver Island whales with the rest of the eastern Pacific herd.

THE SUMMER POPULATION

Gilmore (1960) suggested that the whales lingering all summer on the northwest coast did so because they found themselves too far behind to reach the Bering Sea on time to store enough fat so stayed on more southerly feeding grounds. This explanation can be ruled out based on the facts that individuals return to Vancouver Island year to year, and that they are present at the peak of the northern migration.

Hatler and Darling (1974) speculated that "pockets" of habitat suitable for regular occupancy by gray whales occur between southern Vancouver Island and Alaska. Such "pockets" apparently do exist throughout the species range, off California (Dohl *et al.*, 1981), Oregon (J. Sumich in Chapter 13, this volume), Washington (Darling, 1979), and British Columbia (this chapter).

The Vancouver Island "pocket" is occupied by 35–50 whales each summer. These animals may well be part of a larger "northwest coast" population. Approximately 75 whales summer off Oregon each year (B. R. Mate, 1979, personal communication), so it is likely there are at least 100 in the British Columbia–Washington–Oregon area. This is a small part of the approximately 17,000 animals estimated in the eastern Pacific herd (Reilly *et al.*, 1980, Chapters 9 and 13, this volume).

Votrogov and Bogoslovskaya (1980) and Bogoslavskaya *et al.*, (1981) found gray whales unevenly distributed in "divisions" along the Asian coast. Between these were empty areas through which whales passed rapidly. Presumably these were not good feeding areas. These reports identify two apparent types of whale assemblage, small groups of 20–50 containing a high proportion of young, found mostly in shallow coastal waters, and larger concentrations of as many as 400 adults, feeding in apparently rich areas farther offshore. From observations of whaling operations along that coast in 1936, Zenkovich (1937) reported areas that he suggested may be permanent feeding grounds for younger, apparently recently weaned animals. Almost all whales captured in these areas were less than 2 years old, from which Zenkovich (1937) concluded that young gray whales form separate schools at weaning. Bogoslovskaya *et al.* (1981) suggested that such separation does exist but may not always be so well defined.

The "divisions" described above may equate with the "pockets" along the North American coast. The Vancouver Island summer population does include young animals, apparently recently weaned (Darling 1978). From individual sighting records reported in this chapter, others proved to be at least 8 years old. A more complete investigation of the age structure of this population is necessary; one tempting hypothesis is that the Vancouver Island summer assemblage is similar in age structure to the inshore "divisions" of predominantly young animals off the Asian coast.

The present observations suggest that a gray whale has a preferred location, extending over at least 150 km of coastline, to which it returns for at least part of its life. There are at least two plausible explanations for the variable turnover patterns of identified whales observed in the present study. The first is that they may result from incomplete and varying identification effort among years and mixing within a larger "northwest coast" population. The second assumes that the Vancouver Island whales are a distinct group and that the observed patterns are significant. Some animals return annually for a series of years (2, to at least 8) then go elsewhere, probably on full migration; others spend only one summer in the area. To speculate, the former group might well be immature whales and the latter related to the younger animals or attracted to the area by chance. This explanation suggests a dynamic relationship with the rest of the herd and is tempting because it is compatible with the observations by Votrogov and Bogoslovskaya (1980) and Bogoslovskaya *et al.* (1981) of separate assemblages of younger animals; however, it is far from proven.

The predominant behavior of the Vancouver Island whales is feeding (Darling, 1977, 1978). Feeding behavior and food of gray whales is discussed for the entire range by Nerini (Chapter 18, this volume) and for Vancouver Island by Murison *et al.* (Chapter 19, this volume). Three nonfeeding behavior patterns of note were observed off Vancouver Island in the summer: traveling, apparent resting, and rubbing at a sand bar–riptide area (Darling, 1978). Traveling, discussed above, essentially involves movement among feeding and riptide areas. Whales apparently resting were observed lying low and motionless in the water with just the top of the back above the surface and with wavelets breaking over them; they blew at regular intervals.

At the seaward entrance of several passages to extensive inlet systems in the study area, a "riptide" occurs with each tide change over a sand bar. Whales in these areas engage in stereotyped behavior; rising head-first out of the water and "falling" over backwards, clapping the jaws, spitting water, and apparently rubbing on the sand bar (Darling, 1978). This is probably "grooming" or "recreational," perhaps similar to the rubbing behavior described for killer whales (*Orcinus orca*) off the east coast of Vancouver Island (Ford and Fisher, 1983).

Summary

This study examines the abundance, distribution, and behavior of gray whales, *Eschrichtius robustus*, which are summer residents along the west coast of Vancouver Island, British Columbia. The migratory timetable was determined by observations during four winters from 10 west coast lightstations. The study of the summer population was based on individual identification of animals from photographs of natural markings, and on repeat observations of "known" whales for 10 years, 1972–1981. Direct observations were made from small boats and aircraft.

The northern migration begins in mid-February, peaks in late March, and continues through early June. It is followed by a summer interval lasting until November when the first southbound migrants pass; the southern migration peaks in late December and continues to approximately mid-January. Each year, 35–50 whales are resident in this area off British Columbia during the summer interval. An average of 63% of these returned for more than one summer; 37% were seen in 1 year only. Some individuals returned for at least 8 years. Whales were found feeding in numerous locations along the coast from Victoria to Cape Scott. Individual whales were identified in locations up to 150 km apart in different years, and within one summer they traveled between feeding areas at least 77 km apart. Feeding is the predominant behavior, although whales were also observed traveling, apparently resting, and rubbing at a sand bar–riptide area.

Acknowledgments

This work was funded by the Vancouver Public Aquarium, Parks Canada, The National Boat Show, Chevron Canada Ltd., the National Marine Fisheries Service, Marine Mammal Laboratory, Seattle, and research grants to Dr. J. McInerney, University of Victoria.

The support and assistance of many people are gratefully acknowledged. Special thanks are due to J. E. McInemey, R. S. Payne, M. Bigg, M. Newman, D. Hatler, S. Proctor, M. Tillman, K. Norris, F. ACKNOWLEDGEMENTS

A number of people assisted in conducting fieldwork with Cascadia Research in 1999: Joe Evenson, Hannah Smith, Heather Harding, Sheryl Lapp, Lindsey Fauss, and Annie Douglas. Additionally, Joe Evenson, Hannah Smith, Sheryl Lapp, Lindsey Fauss, Katy Segal, JR Veldink, Anne Nelson, Eileen Kelly, and Jane Truman assisted in data entry and photographic processing and matching. Dawn Goley and Caitlyn Toropova of Humboldt State University gratefully acknowledge the full support of the interns and graduate students within the Marine Mammal Education and Research Program (MMERP) at Humboldt State University in California. Student interns assisted the authors in photographic processing, data collection and data entry. The National Marine Mammal Laboratory (NMML) provided photographs collected as part of their research on gray whales. The National Marine Mammal Laboratory acknowledges the help and assistance of the Makah Tribe and Makah Tribal Fisheries, including Larry Cooke and Wilson Arnold who assisted with field work. A number of people contributed photographs of gray whales taken opportunistically including Dyanna Lambourn, Mike Felber, and Mark Sears. Gretchen Steiger provided comments on the draft report.

Research in 1999 was funded in part by the National Marine Mammal Laboratory, and we thank Jeff Laake, Joe Scordino, and Robert DeLong for arranging this support. The Olympic Coast National Marine Sanctuary provided support for some humpback surveys, which yielded opportunities to survey for gray whales. Some support came from Cascadia's adoption program and we thank those participating in this program. Humboldt State University Foundation and the Dean of Undergraduate Education also supported the research in California. We thank the skippers and staff of the whale watch boats in Westport, which allowed us to collect data and obtain identification photographs from their boats. We also offer our sincere thanks to Captain Al Vanderford and Jim Sinnott of Tradewinds Charter Company for their full support in Oregon waters. Permission to conduct this research was provided by the U.S. National Marine Fisheries Service, The Canadian Department of Fisheries and Oceans, and the Makah Tribal Nation.

EXECUTIVE SUMMARY

This report summarizes activities and results of gray whale photographic identification research conducted by Cascadia Research in collaboration with the National Marine Mammal Laboratory and Humboldt State University in 1999. This represents a continuation of photographic identification surveys for gray whales that have been conducted annually in the Pacific Northwest since 1991. These surveys are part of an ongoing research effort to study the abundance, movements, residence times and return rates of gray whales that feed in these waters in spring, summer, and fall (so-called "seasonal residents"). A broader ongoing effort has also been conducted in collaboration with researchers from a number of other organizations.

Research effort by the three groups centered in different areas. Between 14 March and 30 October 1999, Cascadia personnel conducted a total of 45 boat and land surveys for gray whales (dedicated and opportunistic) in the waters off northern California, Oregon, and Washington. Biologists from the National Marine Mammal Laboratory (NMML) provided identification photographs from surveys they conducted between 16 April and 23 November 1999 off the Washington outer coast, the western Strait of Juan de Fuca, northern Puget Sound and along the west coast of Vancouver Island, British Columbia. Identification photographs provided by Humboldt State University were from their work conducted off northern California and surveys off whale-watching boats out of Depoe Bay, Oregon from 7 July to 11 October 1999. On 516 occasions good quality identification photographs were obtained of 216 different gray whales. Individuals were seen up to 8 times with a mean of 2.4 (SD= 2.1). Overall 84 (39%) of the whales identified in 1999 were known from previous years.

There were dramatic differences in resighting rates among whales identified in different regions and time periods. Results off Vancouver Island were generally consistent with past years with large numbers of whales identified and high resighting rates both within season and between years. Identifications from other areas were more varied. Very few gray whales were seen off the Washington coast in the summer, but a limited effort in May (immediately after the Makah whale hunt) yielded identifications of a large number of whales that included a small number of known seasonal residents but mostly animals not previously identified. In Washington inland waters, unusually high numbers of gray whales were seen including sightings in areas where whales have not been generally observed previously. Other than six regular returning animals in northern Puget Sound, however, none of these animals were known from previous years and only a few were seen outside this region. Results from Oregon and California were more mixed, with a inter-year resighting rates high off Oregon but low off California.

Mark-recapture estimates of abundance made using annual samples (excluding identifications from early season and inland waters) from 1998 and 1999 yielded an estimate of 269 gray whales, higher than estimates made previously. One reason for the higher estimate was due to the 1999 sample from California, where only 9 of the 39 whales identified had been seen in a previous year. Exclusion of California data from the 1999 sample dropped the estimates to 222; more similar to the estimates obtained previously.

INTRODUCTION

This report summarizes activities and results of gray whale photographic identification research conducted by Cascadia Research in collaboration with the National Marine Mammal Laboratory and Humboldt State University in 1999. This represents a continuation of photographic identification surveys for gray whales that has been conducted annually in the Pacific Northwest (Calambokidis *et al*. 1994, 1999, Calambokidis 1996, Calambokidis and Quan 1997, Calambokidis and Schlender 1998). These surveys are part of an ongoing research effort to study the abundance, movements, residence times and return rates of gray whales that feed in these waters in spring, summer, and fall (which we refer to as seasonal residents in this report). Summer feeding aggregations of gray whales have been observed in a number of areas along the coasts of California (Patten and Samaras 1977, Mallonee 1991, Avery and Hawkinson 1992), Oregon (Sumich 1984), Washington (Flaherty 1983, Calambokidis *et al*. 1992, 1994, Wietkamp *et al*. 1992) and British Columbia (Darling 1984, Murison *et al.* 1984, Plews *et al.* 1985). Gray whales in these regions feed on a variety of prey including herring eggs/larvae, crab larvae, amphipods, mysids, and ghost shrimp, with locations of feeding often shifting from year and by season in response to shifting prey types and distribution (Darling *et al*. 1998, Nerini 1984).

The issue of "seasonal resident" whales has gained significance due to the resumption of whaling for gray whales by the Makah Tribe of Washington State. Although the whaling Management Plan calls for targeting migratory whales, there remains concern over the possible management implications of the hunt on seasonal resident whales (Quan 2000). Limited genetic testing has not revealed a difference in mtDNA haplotypes between seasonal resident and migratory gray whales off Vancouver Island although samples sizes were small (Steeves 1998). Genetic differences may not be detected even when sub-populations are distinct enough to warrant management as separate units (Taylor 1997).

In addition to the research reported here, other researchers continue photographic identification studies from British Columbia to southwestern Alaska. Starting in 1998, there has been a collaborative effort among these groups to conduct an expanded photographic identification comparison. In addition to the research reported here by Cascadia Research, the National Marine Mammal Laboratory, and Humboldt State University, other organizations participating in this broader comparison include: West Coast Whale Research Foundation, University of Victoria, University of British Columbia, Vancouver Aquarium, Department of Fisheries and Oceans, Coastal Ecosystem Research Foundation, and the operator of the Juan de Fuca Express (a coastal ferry service). Results of the larger effort from California to Alaska for 1998 (Calambokidis *et al.* 2000) have been summarized in a draft manuscript and efforts to complete this larger comparison for 1999 are planned.

METHODS

Surveys were conducted by three organizations from northern California to British Columbia (Figure 1). Between 14 March and 30 October 1999, Cascadia personnel conducted a total of 45 boat and land surveys for gray whales (dedicated and opportunistic) in the waters off northern California, Oregon, and Washington (Table 1 and 2). These surveys were conducted in a number of regions and utilized several platforms including:

- small boat surveys in southern and northern Puget Sound, the Straight of Juan de Fuca, and Grays Harbor, primarily using Cascadia's RHIB and other platforms of opportunity (including whale watch boats out of Everett and Port Townsend) on 14 days between 2 April and 13 August 1999,
- small boat surveys of the Washington Coast using both Cascadia's RHIB and some opportunistic effort in association surveys conducted with the Olympic Coast National Marine Sanctuary on 4 days between 20 May and 20 October 1999,
- small boat surveys using Cascadia's RHIB off Oregon including a search from Tillamook Bay to south of Newport on 5 days from 6 September to 13 October 1999,
- small boat surveys using Cascadia's RHIB off northern California in association with humpback whale effort on 5 days from 14 September to 30 October 1999,
- placing observers on the whale watch boat, the *Victoria Express*, operating out of Westport, WA on 12 days between 14 March and 25 April 1999,
- effort from land photographing gray whales in Discovery Bay, southern Puget Sound and near Neah Bay on 5 days between 1 and 18 April 1999,
- opportunistic photographs were also provided to us by other naturalists and researchers who opportunistically photographed gray whales in Puget Sound including Dyanna Lambourn, Mark Sears, and Mike Felber.

Biologists from the National Marine Mammal Laboratory (NMML) provided identification photographs from surveys they conducted between 16 April and 23 November 1999 (Tables 2 and 3). The photographs from NMML represent surveys from the Washington outer coast, the western Juan de Fuca Strait, northern Puget Sound and along the west coast of Vancouver Island, British Columbia.

Identification photographs were provided by Humboldt State University from their work conducted off northern California and Oregon (Tables 2 and 4). Identifications off northern California were primarily made out of Trinidad and Crescent City from 12 July to 11 October 1999 aboard a 16 ft inflatable. Identifications off Oregon were made primarily aboard Tradewind Charter company whale watch boats operating out of Depoe Bay from 7 July to 6 October 1999.

Procedures during Cascadia vessel surveys were similar to those used previously (Calambokidis *et al.* 1994). Effort data were recorded every 30 min and when there was either a course change or a change in the environmental conditions. We recorded time, position (latitude and longitude from GPS) and environmental conditions (sea state, visibility, precipitation, cloud cover, and swell height). When a gray whale was found, the time, position, number of animals, and behaviors were recorded. Whales were approached to 30-50 m and followed through several dive sequences until suitable identification photographs could be obtained. At the end of a sighting the time, location, and roll and frame numbers of photographs taken during each observation were also noted.

For photographic identification of gray whales, both left and right sides of the dorsal region around the dorsal hump were photographed when possible. *Ilford* HP-5 negative film was used with *Nikon* 35mm cameras with 300mm f4.5 lenses. We also photographed the ventral surface of the flukes for identification when possible. The latter method was not as reliable as the sides of the whale because the gray whales did not always raise their flukes out of the water. Markings used to distinguish whales included pigmentation of the skin, mottling, and scarring, which varied among individuals. These markings have provided a reliable means of identifying gray whales (Darling 1984).

We also utilized the relative spacing between the knuckles along the ridge of the back behind the dorsal hump. The size and spacing of these bumps varies among whales and does not change over the years we have tracked whales. Measurements were made based on coordinates marked on a scanned image of the whale and compared to a database of values for all the whales in our catalog. A computer program (developed by Joe Evenson) provided a prioritized list of potential matches and then the match was verified or rejected based on the pigmentation and other markings described above.

Comparisons of whale photographs were made in a series of steps. First, all negatives of gray whales were examined and the best shot of the right and left sides of each whale (for each sighting) were selected and printed (7 x 2.5 inch). To determine the number of whales seen during the season, the prints were then compared to one another to identify whales seen multiple days. Finally a comparison was made to our catalog of whales seen in past years. Whale photographs that were deemed of suitable quality but did not match our existing catalog (compared by two independent matchers) were assigned a new identification number and added to the catalog.

RESULTS AND DISCUSSION

On 477 occasions, good quality identification photographs were obtained of 216 different gray whales by Cascadia Research, NMML, and Humboldt State University in 1999 (Table 2). Whales were seen up to 8 times with a mean of 2.4 (SD= 2.1). Overall, 84 (39%) of the whales identified in 1999 were known from previous years. Identifications, including sighting history, are summarized by organization (Tables 3 and 4).

Resighting rates were different among whales identified in different regions and time periods (Tables 5 and 6). Results from off Vancouver Island were generally consistent with past years with large number of identifications and high resighting rates both within season and between years. The number of newly identified whales and the resighting rates from other areas were more varied than off Vancouver Island. Very few gray whales were seen off the Washington coast in the summer. A limited effort in May immediately after the Makah whale hunt, yielded identifications of a large number of whales which included only a small number of known seasonal residents; most of the whales during this time period had not been previously identified. In Washington inland waters (including Puget Sound and Hood Canal) there were unusually high numbers of gray whales and newly identified individuals. Furthermore, whales were concentrated in a number of infrequently used areas. Aside from six regular returning animals in northern Puget sound, however, none of these were previously identified animals and few were seen outside this region again. Results from Oregon and California were more varied, with inter-year resighting rates high off Oregon but low off California. The different findings by broad region are described in more detail below.

From matching photographs of identified animals, we documented the overall movement patterns throughout the study season in 1999 (Figure 2). While these patterns are partly biased by the timing of effort in different locations, they do reveal movements of some known individuals. In general, a northward shift in areas of use by some gray whales was noted from May to August with identified gray whales moving from the Washington coast, southern Vancouver Island, and the Strait of Juan de Fuca northward to areas off central and northern Vancouver Island. From August to October, movements in the opposite direction predominated with whales identified off Vancouver Island being photographed in the Strait of Juan de Fuca and off the Washington coast in August and September, and then off Oregon in September and October. Despite these overall patterns, there were also movements opposite to those described above, indicating variability in the behavior of animals and not a unified migration or shift.

Identifications off Vancouver Island

Identifications of gray whales reported here were obtained from along the western and northern Vancouver Island regions during two region-wide surveys conducted by NMML in early August and September as well as more frequent coverage of southern Vancouver Island. This report does not include results from survey effort along Vancouver Island obtained by other research groups affiliated with West Coast Whale Research Foundation, University of Victoria, University of British Columbia, Coastal Ecosystems Research Foundation, and Juan de Fuca Express. Because photographic matching between the samples reported here and those from these other groups have not been completed, the results for this region are preliminary.

These relatively few surveys yielded a large number of identifications from broad coverage of most of the outside coastal waters of Vancouver island. In total, 18 individual gray whales were identified off southern Vancouver Island, 48 from western Vancouver Island (from Barkley Sound to Cape Scott), and 10 from northern Vancouver Island. In all three areas, a high proportion of the animals (65-100%) were individuals identified in previous years including a high proportion (60-94%) identified in 1998 (Table 6).

Early season identifications off the northern Washington coast

A large number of identifications of whales came from an early season sample taken on a single day off the Washington Coast. A total of 71 identifications of 45 different individuals were made on 20 May 1999, 5 nmi north of La Push on the Washington outer coast. An estimated 50 to 100 gray whales were in this general area, a larger concentration than we generally encounter. This was less than 10 nmi south and a week after the successful Makah take of a whale. In past years, identifications were generally not made in this area early in the season because it is in the migratory corridor and would likely include migratory animals. This sample in 1999, however, is of interest because of the similar timing and location to the area of the Makah hunt.

Although this large group of whales was in the migratory corridor, their behavior was more suggestive of feeding than of migrating. Of the 60 groups (singles or pairs) of gray whales made that day, all but two groups were judged to be milling rather than travelling in a consistent direction. Surface direction of animals was recorded on 54 occasions and varied widely. Similar proportions of animals had a southerly direction (SW, S, or SE) compared to a northernly direction (35% vs. 44%). Similarly, multiple identifications of 15 of the 45 individuals photographed during the day indicated little movement with again a roughly equal split between those that had shifted slightly to the north or south.

Only 6 of the 45 (or 13%) identifications made off northern Washington in May were individuals known from previous years, a lower percentage than was found for most other areas. These six whales had been first identified between 1994 and 1998. Five were seen in 1998; four had been seen off southern and central Vancouver Island, two off Oregon, and one off the Washington coast. Even though only one was seen in 1998 off northern Washington, two others had been seen there in previous years. One of the six gray whales that we had identified from past years (ID# 191) was a whale seen only in 1996 once again in the early season but this time off Grays Harbor. This whale was identified six times between 7 April and 12 May 1996 in an area off Grays Harbor called the "Whale Hole". Although this spot is in the migratory corridor, it is an area where feeding whales, some of which are seen later in the season, have been identified (Calambokidis and Quan 1997).

Similarly, only 4 of the 45 whale identified off the Washington coast in May 1998 were seen later in the season in the effort by Cascadia, NMML, and HSU. All four of these whales were also whales that had been documented in previous years. Three of these whales were seen later in the season in July and August off central Vancouver Island and one was seen beginning in July off Oregon.

These findings indicate that seasonal resident whales are present during the time and in the area of the Makah whale hunt but are a relatively small proportion of the animals. There did not appear to be any clear way to distinguish between those whales that remained in the Pacific Northwest and those that moved out of the area. These results should be treated cautiously, however, since 1999 appeared to have been an anomalous year in a number of respects including unusually large numbers of whales apparently feeding in atypical areas and high observed mortality.

Identifications in Washington inside waters

A higher than usual number of whales was seen in a number of areas of Puget Sound in spring 1999 (Table 5). These included sightings of multiple whales in Discovery Bay, around northern and southern Puget Sound, around the San Juan Islands, and in Hood Canal. A total of 95 identifications of 33 different whales were made in these combined regions with only six known from previous years (Table 6).

Some of these sightings in inland waters were in unusual areas. In Discovery Bay, six whales were identified in April 1999 near Adelma Beach, an area where gray whales have not generally been seen in past years. None of these whales had been identified previously but several were seen in other regions later in the season. Two (ID# 350 and 396) were seen in Admiralty Inlet later in April and May; one of these was seen off west Seattle in June. Another whale (ID# 351) seen in Discovery Bay was later identified at the very end of Hood Canal near Belfair on 29 April and then was seen by NMML off Bajo Reef, off western Vancouver Island on 8 August.

Although spring-time sightings have been common in past years off Whidbey Island in northern Puget Sound, there were differences in the locations and resighting rates of animals seen in 1999 compared to past years. Many of these whales were feeding in shallow waters of the Snohomish Delta in April and May. Although our effort did not continue through the summer, gray whales were reported in this region through the summer. Five of the 19 whales identified in this region were animals that had been seen in this same areas most years since 1991, one other individual was known from a sighting in a previous year elsewhere and the remaining 13 had not been seen previously. Unlike the whales that we have identified in the past in this region, which we rarely see in other areas, four of these whales were seen elsewhere in 1999, one in southern Puget Sound and around the San Juan Islands, another off west Seattle, a third in Hood Canal and off western Vancouver Island, and a fourth off Oregon.

Sightings around southern Puget Sound were reported through the spring and summer and identifications were obtained of six whales between 4 April and 8 July. Two of these whales were seen near Purdy in early April. One of these was seen only once and the other (ID 459) was seen multiple times later in April and in May in northern Puget Sound and then in June in the San Juan Islands. Two other whales gathered considerable attention when they swam under the 4th Avenue bridge on 8 July and spent most of the day gathering crowds of several hundred people in downtown Olympia. Neither of these two whales has been seen at any other time.

Similarly, of the two whales seen off west Seattle in early June, one was not seen at any other time and the other was a whale seen prior to this in the Discovery Bay area.

The frequent sightings and identifications of a few gray whales in the San Juan Island area in 1999 were also unusual because gray whales have previously been uncommon in these waters. The 40 identifications made from 4 April to 18 June were all of five whales seen up to 20 times each. None had been seen in a previous year and only one had been seen in a different area (the animal mentioned above identified in southern and northern Puget Sound in April and May).

Many of the areas where we identified gray whales in inside waters were near areas where we had strandings of gray whales in 1999. Ten gray whale strandings were recorded between 18 April and 6 July 1999 in Washington inside waters including six in northern Puget Sound, two in the San Juan Islands, and one each in southern Puget Sound and Hood Canal. In many cases, suitable identification photographs of stranded animals could not be obtained and did not allow us to make a positive match between live and stranded whales.

In past years, high rates of gray whale mortality have corresponded with years of high numbers of animals sighted in inside waters (for example 1990 and 1991, Calambokidis *et al.* 1994). As in past years, of the stranded gray whales from which we could get suitable photographs, none matched those of previously known seasonal resident whales. The high mortality in 1999 in Washington State was consistent with elevated mortality of gray whales documented from Mexico to Alaska. We suspect that gray whales that came into many areas of Puget Sound were primarily stragglers from the migration that were not in good health.

Identifications in Oregon and California

Identifications by Humboldt State University and Cascadia yielded 31 unique animals from 51 identifications off central Oregon and 36 individuals from 59 identifications off northern California in July through October (Table 5). Identifications in Oregon were made from July to October with most made in October. A high proportion of the gray whales identified off Oregon were known from previous years (19 / 31 or 61%). Most of these had been seen in other regions with only five whales identified in past years off Oregon.

Results from California were different than from Oregon. Most of the whales were identified off California in July and August. Only six of the 36 (17%) were known from previous years and only two of these from California. Similarly, there was relatively little interchange with other areas documented with this region in 1999. Only five of the whales identified in California were seen in other areas that year and all these were whales that moved between northern California and central Oregon.

Estimates of abundance

Mark-recapture estimates of abundance made using annual samples from 1998 and 1999 yielded higher estimates than using previous years (Table 7). The 1998 sample encompassed broad coverage of a number of areas from California to southeastern Alaska gathered by a number of collaborating organizations (Calambokidis *et al.* 2000). Data from 1999, while not quite as large or as complete geographically, still provided broad coverage from northern California to north of Vancouver Island. To insure identifications were of seasonal resident whales, only identifications taken from 1 June or later were used and identifications from inland waters of Washington were excluded (see Table 7).

The abundance estimate based on 1998 and 1999 samples was 269 (Table 7). This is higher than the estimates of 169 and 175 obtained using 1996 and 1997 annual samples, respectively, in conjunction with 1998 (Calambokidis *et al.* 2000). One reason for the higher estimate using the 1999 data is the sample from California, where there were 39 identifications but only 9 matched a previous year. Exclusion of California from the 1999 sample dropped the estimates to 222 (Table 7). It is unclear why the 1999 California sample was so different. It could be part of the high mortality and unusual distribution of gray whales seen in 1999 resulting in an anomalous occurrence of whales that were stragglers from the main migration.

These mark-recapture estimates should be viewed as tentative until more is learned about the range and movements of these whales to allow testing of some of the assumptions behind mark-recapture estimates. The 1999 sample used here, does not yet include identifications from some of the other collaborating researchers participating in the 1998 comparison.

Updated analysis of abundance and population structure of seasonal gray whales in the Pacific Northwest, 1996-2015

John Calambokidis, Jeffrey Laake, and Alie Pérez

Abstract

We update the results of a 20-year (1996-2015) collaborative study examining the abundance and the population structure of these animals conducted over a number of regions from Northern California to British Columbia using photographic identification. Some 21235 identifications representing 1638 unique gray whales were obtained during 1996-2015 from Southern California to Kodiak, Alaska. Gray whales seen from 1 June - 30 Nov (after the northward and before southward migrations) were more likely to be seen repeatedly and in multiple regions and years;therefore only whales seen during those data were included in the abundance estimates. Gray whales using the Pacific Northwest in summer and fall include two groups: 1) whales that return frequently and account for the majority of the sightings and 2) transients seen in only one year, generally for shorter periods and in more limited areas. A time series of abundance estimates of the non-transient whales for 1996-2015 was constructed for the region from N. California (NCA) to N. Vancouver Island (NBC). The most recent estimate for 2015 was 243 whales (se=18.9). The estimated abundance increased in the late 1990s and early 2000s during the period when the eastern North Pacific gray whale population was experiencing a high mortality event and this created an apparent influx of whales into the area. The earlier estimates for 1996-1997 are biased low because the survey coverage area was much smaller but those data were included to improve estimates later in the time series. The abundance estimates since the early 2000s has been relatively stable but it has increased in 2013-2015.

1 Introduction

Beginning in 1996, a collaborative effort among a number of research groups was initiated to conduct a range-wide photographic identification study of gray whales in the Pacific Northwest (Calambokidis et al. 2000, 2002b). An initial publication of findings from 1998 demonstrated there was considerable movement of individual whales among sub-areas from northern California to southeastern Alaska (which we broadly refer to as the Pacific Northwest) and also provided initial estimates of the abundance of whales within that geographical area (Calambokidis et al. 2002a). The ability to look at movements and employ more sophisticated capture-recapture models, however, was restricted by the lack of multiple years of data with broad geographic coverage. A subsequent report by Calambokidis et al. (2004) characterized the group of whales feeding in these survey areas during the summer-fall period as a “Pacific Coast Feeding Aggregation” (PCFA). They proposed that a smaller area within the PCFA survey areas – from Oregon to Southern Vancouver Island (OR-SVI) – was the most appropriate area for abundance estimation for managing a Makah gray whale hunt (Calambokidis et al. 2004). Subsequently the IWC has adopted the term PCFG for Pacific Coast Feeding group so we will use PCFG in place of PCFA.

This report updates information through 2015 from a collaborative effort to collect photographic identifications of gray whales from California to Alaska has continued since 1996 and these data now cover 20 years (1996-2015) and span fifteen survey regions along the coast from Southern California to Kodiak, Alaska (Figure 1). We provide estimates of abundance for the summer-fall seasons (1 June to 30 November) during 1996–2015 for survey regions between Northern California and Northern British Columbia (NCA-NBC), the region chosen by the IWC to represent the PCFG. For the National Marine Fisheries Service development of an Environmental Impact Statement, we also provide estimates for the smaller regions between Oregon and Southern Vancouver Island (OR-SVI) and Makah Usual and Accustomed area (MUA) which includes the outer coastal area of the Olympic Peninsula (NWA) and the Strait of Juan de Fuca (SJF), even though this area is quite small relative to the observed movements of whales within the PCFG.

2 Methods

Gray whales were photographed during small boat surveys conducted from California to Alaska by collaborating researchers (Table 1) between 1996 and 2015. Gray whale identifications were divided into the following regions (Figure 1): 1) SCA: Southern California, 2) CCA: Central California, 3) NCA: Northern California, 4) SOR: Southern Oregon, 5) OR: central Oregon, 6) GH+: Gray’s Harbor and the surrounding coastal waters, 7) NWA: Northern Washington coast, 8) SJF: Strait of Juan de Fuca, 9) NPS: Northern Puget Sound, 10) PS: which includes southern Puget Sound, Hood Canal (HC), Boundary Bay (BB) and San Juan Islands (SJ), 11) SVI: Southern Vancouver Island, 12) WVI: West Vancouver Island, 13) NBC: Northern Vancouver Island and coastal areas of British Columbia, 14) SEAK: Southeast Alaska, and 15) KAK: Kodiak, Alaska. With some exceptions, research groups work primarily in one or two regions. Details of identifications obtained by the different research groups are are summarized in Tables 1-2.

2.1 Photographic Identification Procedures

Procedures during surveys by different research groups varied somewhat but were similar to one another in identification procedures. When a gray whale was sighted, the time, position, number of animals, and behaviors were recorded. Whales were generally approached to within 40-100 m and followed through several dive sequences until suitable identification photographs and associated field notes could be obtained.

For photographic identification of gray whales, both left and right sides of the dorsal region around the dorsal hump were photographed when possible. Most identification photographs were obtained with were obtained with 35mm cameras prior to 2004 and primarily with digital SLR after 2004 with both camera types paired with a telephoto lens (generally 200-300 mm). Researchers also photographed the ventral surface of the flukes for further identification when possible. The latter method was not as reliable since gray whales did not always raise their flukes out of the water. Markings used to distinguish whales included pigmentation of the skin, mottling, and scarring, which varied among individuals. These markings have provided a reliable means of identifying gray whales (Darling 1984). We also identified gray whales using the relative spacing between the knuckles along the ridge of the back behind the dorsal hump. The size and spacing of these bumps varies among whales and has not changed throughout the years these whales have been tracked, except with injury. Figure 2 shows typical photographs and features used in making gray whale identifications.

Comparisons of whale photographs were made in a series of steps. All photographs of gray whales were examined and the best photograph of the right and left sides of each whale (for each sighting) were selected. Identification photographs were initially compared within year to identify resightings and compared to the CRC catalog of whales seen in past years. Whale photographs that were deemed of suitable quality but did not match our existing catalog (compared by two independent persons) were considered “unique” identifications and assigned a new identification number and added to the catalog.

2.2 Data Analysis

The abundance of gray whales was estimated with open population models for three nested spatial scales consisting of contiguous survey regions (Figure 1; Table 3) 1) NCA-NBC: the coastal survey regions from Northern California (NCA) through Northern Vancouver Island/British Columbia (NBC) which matches the IWC definition of the PCFG, 2) OR-SVI: survey regions from southern Oregon through Southern Vancouver Island (SVI) identified in the Makah waiver request, and 3) MUA - survey regions NWA and SJF. Inland waters in WA (other than SJF) and in BC are excluded from the abundance estimates because these are used primarily by transient whales in the northward spring migration.

Gray whales photographed and identified anytime during the period between 1 June and 30 November (hereafter referred to as the “sampling period”) within the defined region were considered to be “captured” or “recaptured”. For each unique gray whale photographed, a capture history was constructed using 20 years of data from 1996-2015. For example, the capture history 00010010010000000000 could represent a gray whale photographed in 1999, 2002 and 2005 in the PCFG. The same gray whale may have had a capture history 00010010000000000000 for a smaller spatial scale such as OR-SVI or may not have been seen at all (00000000000000000000) and would not be used at the smaller spatial scale.

Multiple “detections” of a single whale within the sampling period were not treated differently than a single detection. A “1” in the capture history meant that it was detected on at least one day during the sampling period. However, multiple detections in the same year were used to construct an observed minimum tenure (MT) for each whale. MT was defined as the number of days between the earliest and latest date the whale was photographed with a minimum of one day for any whale seen.

We fitted open population models to the 20 yearly time series of capture history data for each spatial scale to estimate abundance and survival. Open models allow gains due to births/immigration and losses due to deaths/emigration. Using the RMark interface (Laake and Rexstad 2008) to program MARK (White and Burnham 1999), we fitted a range of models to the data using the POPAN model structure. The POPAN model structure (Schwarz and Arnason 1996) provides a robust parametrization of the Jolly-Seber (JS) model structure in terms of a super population size (N), probability of entry parameters (immigration), capture probability (p), and survival/permanent emigration (φ).

It is essential to consider the population structure and its dynamics to build adequate models. In particular, we know from previous analysis of a subset of these data (Calambokidis et al. 2004) that some whales were seen in only one year between 1 June and 30 November and were never seen again. Transient behavior is a well-known problem in capture-recapture models and it is often addressed using a robust design which involves coordinated multiple capture occasions within each year and typically assumes closure within the sampling period (June-November). Region-wide coordinated surveys may be possible but would be difficult with variation in weather conditions. Also, the closure assumption within the year would be suspect due to variable timing of whales arrivals and departures into the PCFG, so it would require nested open models. We know from prior analysis that whales newly seen in year (y) were less likely to return (i.e., seen at some year >y) than previously seen whales but also newly seen whales that stayed longer during their first year (i.e., longer MT) in the PCFG were more likely to return. Likewise, previously seen whales were more likely to be seen in the following year (y+1), if they had a longer MT in year y. Calambokidis et al. (2004) postulated that these observations were consistent with whale behavior that was determined by foraging success.

Transient behavior in which an animal is seen only once can be modeled by including a different "first year" survival (Pradel et al. 1997) for the newly seen animals. Survival in the time interval after being first seen is dominated by permanent emigration rather than true mortality. Survival in subsequent time intervals represents true survival under the assumption that animals do not permanently emigrate except in their first year. Pradel et al. (1997) were working with release-recapture data (Cormack-Jolly-Seber) where modeling this transient effect on survival is straightforward. For a Jolly-Seber type analysis where the first capture event is also modeled, the inclusion of a transient effect is less easily accommodated.

We divided the whales into cohorts based on the year in which they were first seen ("newly seen"). In the model, their first year survival could differ from subsequent annual survival as in Pradel et al. (1997). "Newly seen" is not a particularly useful concept for the first year of the study (1996), because all whales were being seen for the first time. The survey effort and coverage in 1996 and 1997 were not nearly as expansive as 1998 and later. We considered models that had three different first year survivals (1996&97, 1998, and >1998) and we also considered a model that allowed for a different first year survival for each year (cohort) to allow for different transient proportion in each year. The first year survival was also allowed to vary as a function of MT with a model in which the relationship was constant across years and varied for (1996&97, 1998, and >1998). We also considered models that allowed a different first-year survival for whales identified as calves under the presumption that their true survival might be lower but that their probability of returning to the PCFG might be higher. Discussion at the 2012 intersessional AWMP meeting led to consideration of an additional covariate which split whales into 2 groups for estimation of post-first-year survival. Whales seen initially as calves and any whale newly seen in 1998 or was in the CRC catalog because it had been seen prior to 1998 were put in one group and the remaining whales newly seen in 1999 or later were put in another group. The expectation was that the first group would have higher post-first-year survival because many of the newly seen whales that entered after the stranding event in 1999/2000 might eventually emigrate. When this covariate was included it made such a large improvement that any model without it would have no support. Therefore, it was included in all 10 models for survival (Table 4).

In Calambokidis et al. (2010) we estimated a cohort-specific super-population size for each cohort using the median MT covariate value for unseen whales but during the April 2011 AWMP meeting it became apparent that this may lead to bias in estimating abundance. Therefore, we used the method outlined in the 2011 AWMP report which is similar to the method used by Calambokidis et al. (2004) in that we assume that all whales in the PCFG for the first year are seen so the super-population size for each cohort is the number seen and thus there are no unknown covariate values. We fixed capture probability (p) and probability of entry (pent) to 1 for each cohort in their entry year. We are not interested in the number of transient whales so we used an estimator of abundance for non-transient whales (2011 AWMP report) which is a modification of the Jolly-Seber estimator which for any year can be expressed as:

$$\hat{N} = n/\hat{p} = (u + m)/\hat{p}$$

where $n = u + m$, n is the number seen in a year being composed of new animals (u=unmarked) and previously seen animals (m=marked), and $\hat{p}$ is the capture probability estimate. For the PCFG we are assuming that any new whale is sighted ($p = 1$) and we are only interested in estimating the abundance of whales that will remain part of the PCFG which is the portion of the new whales that do not permanently emigrate from the PCFG. We can modify the estimator for year j as follows:

$$\hat{N}_j = u_j\hat{\phi}_j + m_j/\hat{p}_j$$

where ϕ_j is the first year survival rate of "new" whales. When ϕ and p contain whale specific covariates like minimum tenure (MT) the estimator becomes:

$$\hat{N}_j = \textstyle\sum_{i=1}^{u_j} \hat{\phi}_{ij} + \sum_{i=1}^{m_j} 1/\hat{p}_{ij}.$$

To obtain an abundance estimate for 2015, we assumed that the parameter for first year survival intercept in that year was the same as in 2014. A variance-covariance matrix for the abundance estimates was constructed using the variance estimator in Borchers et al. (1998) for a Horvitz-Thompson type estimator with an adaptation for the first component of the abundance estimator for prediction of number of new whales that do not permanently emigrate. For the estimated capture probabilities (p) not fixed to 1, we fitted 3 models that varied by time (year) and/or varied by MT in the previous year (Table 4).

We used Test 2 and Test 3 results from the Cormack-Jolly-Seber structure (Lebreton et al. 1992) as a general goodness of fit for the global model and as a measure of possible over-dispersion creating the lack of fit. We fitted each combination of models for S (survival) and p (capture probability) and used AICc (Burnham and Anderson 2002) to select the most parsimonious model of the 30 fitted models. Model averaging was used for all models to compute estimates and unconditional standard errors and confidence intervals.

3 Results

The database contains 25580 records for whales photographed between 1996 to 2015 from California to Kodiak, Alaska; however 4345 are replicate identifications of whales on the same day. We define a sighting as one or more photographs of a whale on a day. The number of sightings varied annually from 131 and 1959 with a total of 21235 sightings of 1638 unique gray whales (Table 1). The average number of sightings/whale was 13 (range: 1-339). Identifications were made throughout the year but with most effort from June to September. Number of sightings were most numerous in NCA, SVI, WVI, and NBC and (Table 2). The number of uniquely identified whales was greatest in NCA, NWA, SVI and WVI (Table 2).

3.1 Seasonal Sighting Patterns

Whales have been photographed in every month of the year (Table 5) but with very few during December-February when most of the whales are in or migrating to Mexico and survey effort is reduced. Previous analysis of these data have always used 1 June - 30 November as the sampling period to describe the whales in the PCFG because whales seen prior to 1 June and after 30 November are more likely to be whales that are migrating through the region. The southbound migration starts in December and the separation between May and June is clearly supported by the data. For example, of the 1638 unique whales sighted from California to Kodiak, Alaska, 666 whales were only seen between 1 Dec - 31 May and 87.2% of those were only sighted once (one day). Of the 972 whales sighted between 1 June -30 November at some time, 38.8% were only sighted once (one day). If sightings in Alaska are excluded, then only 31.7% of the 833 were seen only once (one day).

The break between May and June is apparent in various measures such as proportion of whales sighted more than once, sighted in more than one region, and sighted in more than one year (Figure 3). However, the break is more apparent if we separate out SJF, NPS and SVI from the other survey regions (Figure 4). The difference across months is not as strong for inland waters of Washington and British Columbia (NPS, SJF) because these are whales that have diverted from the migration and are either more likely to remain after 1 June or demonstrate high year-to-year fidelity during spring such as with NPS. Also, even though Southern Vancouver Island (SVI) is in the main migration corridor and not an inland water, the pattern across months is also weaker because the sampling has been focused on the spring herring spawn in Barkley Sound (effectively an inland waterway) and has purposefully undersampled passing migrant whales (Brian Gisborne, pers. comm.).

The break between May and June is much more apparent for NWA and the other areas in the migration corridor which is consistent with the northbound migration of gray whales proceeding past Washington through May. Resighting rates of whales seen after 1 June remained high through November.

A large photo-ID sample of gray whales in the MUA was conducted in 2015 by Makah Tribal biologists. At the time of this report the full comparison of these whales to historical images had not been completed but in the future will provide a better indication of proportion of PCFG whales present prior to 1 June.

Capture (sighting) histories of whales seen at least once in the PCFG from 1 June - 30 November are provided in Appendix Table 1 which show sightings of whales in 1 Mar -31 May only, 1 June - 30 Nov only and in both time periods within a year.

3.2 Regional Sighting Patterns

There is considerable variation in the annual regional distribution of numbers of whales photographed during the sampling period (Table 6) which is in part due to variation in effort. Although not a true measure of effort, the number of days whales were seen (Table 7) does reflect the amount of effort as well as abundance of whales. In particular, in comparison to other regions, the large number of sightings in SVI partly reflects large numbers of sampling days by Brian Gisborne who has routinely sampled SVI from summer through fall on almost a daily basis. On the other hand, the decline in sightings in SVI during 2007 was not due to reduced effort but to the distribution of whales with many of the whales having moved to waters off Oregon and Washington (Calambokidis et al. 2009b). Similarly, there were 40 survey days in SJF in 2010 but only 4 whales were seen on 4 different days (Table 6, Table 7) so this drop relative to other years was not due to lack of effort.

Whales were sighted across various survey regions and the interchange of whales (Table 8) between survey regions during 1 June - 30 November depends on proximity of the regions (Calambokidis et al. 2004). During 1 June-30 November for 1996 to 2015, 793 unique whales were seen in the PCFG range and 68.6% (544 of the 793 whales seen in the PCFG range) were seen within the smaller OR-SVI region and approximately 36.3% (288 of the 793 whales seen in the PCFG range) were seen within the smaller MUA area; however, there is variation in interchange between areas in the PCFG and the MUA. Of the whales sighted in regions from NCA to NBC, from 39.8% to 59.6% of the whales were seen at some point within MUA (Figure 5). If we exclude transients (whales seen in only one year), the interchange rates with MUA are much higher but the pattern is similar (Figure 6) with a range of 47.7% to 77.5%. Appendix Table 2 provides capture histories using data from 1 June - 30 Nov of whales seen in the MUA at least once. For each year, the table shows whether the whale was sighted in PCFG but not in the MUA during that year, only seen in MUA that year, and seen in both MUA and another PCFG area in that year.

Whales seen in the PCFG exhibited a wide range of movement across and within years. The 143 whales seen in 9 or more years provide a useful example. None of those whales was seen exclusively in a single region, and 67.1% were seen in at least 4 of the 9 survey regions from 1996 to 2015. However, whales did regularly visit the same regions across years with 94.4% were seen in at least one of the regions during six or more of the years they were seen and 65.7% were seen in a region two-thirds or more of the years they were seen. SVI was the region with the maximum number of years seen for 65 of the 143 whales, which in part reflects the larger amount of survey effort in SVI (Calambokidis et al. 2004a, Calambokidis et al. 2013). Thus, some whales regularly visit particular regions more often than others, but they are seen across the other regions as well.

Some of the whales not seen in the PCFG in a year were seen in Kodiak and Southeast Alaska (Table 9). Of the 25 whales identified in Southeast Alaska and the 153 whales identified in Kodiak, Alaska, 14 (56%) and 24 (15.7%), respectively have been seen farther south in the PCFG.

If we look at latitudes of sightings of individual whales across the 20 years using whales that have been sighted on at least 6 different days (Figure 7), we see that sightings of some whales are highly clustered; whereas, sightings of other whales are highly dispersed across several regions. We defined each whales primary range by the 75% inner quantile which is the middle of the range that includes 75% of the locations. The length of the 75% inner quantile in nautical miles exceeded 60 nautical miles (or 1 degree of latitude) for 49.0% of the whales (Figure 8) and it was more than 180 nautical miles for more than 29.6% of the whales. Thus, it makes little sense to compute an estimate of abundance for any region that spans less than a degree of latitude.

3.3 Annual Sighting Patterns

The average number of whales identified in any one year was 156, 104, and 37 for the PCFG, OR-SVI, and MUA, respectively (Table 10). However, those numbers do not represent the total numbers of whales that use each of these areas because not all whales using a region in a year are seen, not all whales return to the same region each year, and not all of the whales return to the PCFG region each year. The annual average number of newly seen whales (excluding 1996-1998 when the photo-id effort expanded to cover all survey regions) was 37.2, 25.8, and 13.6 for PCFG, OR-SVI, and MUA, respectively. The annual average number of newly seen whales that were "recruited" (seen in a subsequent year), excluding 1996-1998 and 2015, was 14.9, 12.6, and 6.4 for PCFG, OR-SVI, MUA respectively. Thus, there were a substantial number of new whales seen each year and 40.6, 49.6, and 47 percent of those were seen again in a subsequent year in the 3 regions respectively. The number of newly seen whales and the number newly seen and recruited (i.e., seen in at least one more year after the initial year it was seen) (Table 11) are displayed as discovery curves in Figures 9 and 10.

Of the whales that were seen during June-November 1996-2015 in the PCFG (NCA to NBC) about half were only seen in one year and the whales that were seen in more years were sighted more often each year and therefore represented a large proportion of the sightings (Figure 11). Of the 750 identified whales first seen before 2015 between 1 June and 30 November in the PCFG range (NCA-NBC), 52% were seen in only one year and only represent about 5% of the sightings (Figure 11). Many of the newly seen whales did not return in subsequent years. Some whales were seen in every year with 9.3% that were seen in every year after their initial identification, including 5 whales first seen in 1996 that were seen in all of 20 subsequent years. The remaining 39% were seen more than once but not in every year.

Likewise, examination of MT in the first sighting year demonstrates that whales who stay longer in their first year were more likely to be seen in a following year (Figure 12). Whales “first” seen in the first few years of the study (1996-1998) includes some whales that were truly new to the PCFG in those years but many were only “new” because it was the first year of the study or as the surveyed regions expanded over time. This is evident (Figure 12) in the much higher proportions for 1996-1998 than for the other years. These relationships will be important in the capture-recapture models for abundance estimation because whales that do not return after their first year (a large percentage in this analysis) would appeared to have not survived because they have permanently emigrated (with a small fraction that died).

3.4 Open Population Capture-Recapture Models

If the yearly cohorts were pooled, Test2+Test3 statistics indicated a significant lack of fit for the PCFG and subsets (Table 12) primarily resulting from Test 3. This was expected due to the different “survival” rates of previously seen whales (true survival) and newly seen whales of which many never returned (i.e., permanently emigrated) (Table 13) . By separating the cohorts, survival for each cohort was time-varying and thus each cohort has a separate first year survival. The goodness of fit test (Test 2) demonstrated a lack of fit for NCA-NBC and OR-SVI (Table 12). For those regions, we estimated an over-dispersion values of $\widehat{c}$=2.29 and $\widehat{c}$=1.23 respectively to adjust AICc and estimated standard errors.

For all areas, the best fitted model (Table 14) was model 2 for p with capture probability varying across years and higher when MT was greater in the previous year. Likewise, for φ the best model was model 4 for all areas. Model 9 was the second best model. Both models 4 and 9 included a separate first year survival which depends on MT. Model 9 included a different calf first-year “survival” which gave a higher survival for calves than non-calves the first year seen (redundant for calves) because they are more likely to return. In models 9 and 4, there are 3 intercepts for first year survival (1996&97, 1998, >1998) and in model 9 the slopes for MT differ as well. These results were consistent with Calambokidis et al. (2004) who demonstrated strong support for the effect of MT on first year survival (Figure 13) and capture probability (Figure 15) in the following year. These results differ some from Calambokidis et al. (2010) who used an annual median-centered MT. Use of MT with median centering was necessary to construct open model abundance estimates in the manner described in Calambokidis et al. (2010). However, that was not necessary for JS1 and the use of MT without median-centering resulted in lower AICc values.

There was large year to year variation in capture probability. The values for NCA-NBC ranged from 0.42 to 0.98 depending on the year and value of MT (Figure 15). The lowest values were from 2007 which reflects the temporary emigration of whales from MUA and SVI to waters offshore of Oregon in that year. In contrast, for MUA capture probabilities were much lower ranging from 0.08 to 0.76 depending on the year and value of MT (Figure 16). The lower overall capture probability and weaker relationship between capture probability and MT reflect the transitory behavior of whales in such a small area. The lower estimates of of capture probability in 1999-2004 for MUA was due to decreased effort by NMML which spread their survey effort across MUA to WVI during 1999-2002, lost a vessel in 2002 and had no funding in 2004 (Figure 16).

First year survival estimates were dominated by permanent emigration. For NCA-NBC, the estimates varied from 0.30 to 0.81 for non-calf whales with MT=1 in their first year and from 0.69 to 0.95 for MT>80 in their first year (Figure 13). Calf survival is by definition a first year survival rate and potentially includes permanent emigration from the PCFG. Depending on the value of MT, calf survival estimates ranged from about 0.35 to over 0.90 (Figure 14). The average calf survival estimate was 0.63 (se = 0.090). There was some support for a different first year calf survival with model 9 being the second best model (ϕ in Table 14) because calves are less likely to permanently emigrate. Unfortunately there is no way to separate permanent emigration from mortality with the existing data.

Survival subsequent to the first year was assumed to be constant but was less for non-calf whales that were newly seen in 1999 or later. Post-first-year suvival for calves and whales present in 1998 or earlier presumably represents true survival assuming there was little permanent emigration after the first year. Those estimates were 0.967 (se=0.0062) and 0.967 (se=0.0066) for OR-SVI and NCA-NBC respectively. The post-first-year survival estimates for whales that entered in 1999 or later and not identified as a calf were 0.912 (se=0.0125) and 0.917 (se=0.0142) for OR-SVI and NCA-NBC respectively.

3.5 Abundance and Recruitment

For NCA-NBC, OR-SVI and MUA annual estimates of abundance were constructed with model averaged values for JS1 (Table 15-16). Estimates for NCA-NBC in Figure 17 are only shown for 1998-2015 with the open models $p = 1$ for 1996 so it will certainly be an underestimate and the survey coverage in 1996 and 1997 was not as extensive as the later years.

The value of N_{min} for 2015 is 228 for NCA-NBC (Table 15). To gain a sense for how these values might be relevant to estimating a possible level of removal (e.g., due to harvest) we computed the MMPA's Potential Biological Removal (PBR) (typically reserved for stock-level assessments). Using the PBR formula, with an Rmax of 6.2% and a recovery factor of 0.5 (Caretta et al. 2013), the PBR for NCA-NBC (PCFG) would be 3.5.

New whales that are not identified as calves have appeared annually and many of these new (non-calf) whales have subsequently returned and been re-sighted (Table 13). In NCA-NBC from 1999-2014, an average of 32.1 (range: 8.0, 68.0) new whales not identified as a calf were seen each year. Of these new non-calf whales, on average 11.8 (range: 1.0, 28.0) whales returned and were seen in subsequent years. It is unknown what proportion of the non-calves used the PCFG as a calf but were not seen in that year. Currently recruitment appears to be offset by losses (either mortality or permanent emigration) as the abundance estimates have been fairly stable since 2002 and recently increasing.

4 Discussion

The population structure of gray whales using the Pacific Northwest in summer and fall is complicated and involves two elements. One group of whales return frequently and account for the majority of the sightings in the Pacific Northwest during summer and fall. This group is certainly not homogeneous and even within this group, there is some degree of preference for certain subareas. Despite widespread movement and interchange among areas, some of these gray whales are more likely to be seen returning to the same areas they were seen before. The second group of whales are transients that are seen in only one year, tend to be seen for shorter periods that year, and in more limited areas.

The existence of these two groups in the study area and their dynamics complicate estimating abundance. While the JS1 estimator may not be optimal, it provides a practical way of handling transients in this open population. Excluding 1996-1997, the JS1 sequence of abundance estimates provides the most reliable assessment of trend for the non-transient abundance and the best estimate of current abundance in 2015.

Despite extensive interchange among subregions in our study area, whales do not move randomly among areas. Abundance estimates were lower when using more limited geographic ranges but these more limited areas do not reflect closed populations. While the use of geographically stratified models can be useful in cases where populations have geographic strata they use (see for example Hilborn 1990), this would be difficult in our case because of the frequent sightings of animals in multiple regions within the same season and these models typically only allow an animal to be sighted in one strata per period. This could be dealt with by assigning animals to only a single region per season but this would be forcing the data into a somewhat inaccurate construct.

Several studies have considered the question of gray whale population structure. There is widespread agreement that at least two populations of gray whales in the North Pacific exist, a western North Pacific population (also called the Korean population) and an eastern North Pacific (ENP) population (sometimes called the California population) (Swartz et al. 2006; Angliss and Outlaw 2008; Rugh et al. 1999). The population structure of the gray whales feeding in the Pacific Northwest has remained in question and only a few studies have examined this. Steeves et al. (2001) did not find mtDNA differences in a preliminary comparison of gray whales from the summer off Vancouver Island and those from the larger ENP population. Ramakrishnan et al. (2001) did not find evidence that the Pacific Northwest whales represented a maternal genetic isolate, although even very low levels of recruitment from the larger overall population would prevent genetic drift. More recently, Frasier et al. (2011) generated mtDNA sequences from a larger sample of gray whales from Vancouver Island than tested by Steeves et al. (2001). They found significant differences in the haplotype frequencies between that sample and mtDNA sequence data reported for ENP gray whales, most of which were animals that stranded along the migratory route. The Frasier et al. (2011) samples were from a relatively small area; however, Lang et al. (2011) evaluated biopsy samples from California to southern Vancouver Island in the PCFG and ENP samples from whales sampled north of the Aleutians and also found significant mtDNA halpotype frequency differences. These two studies provide the strongest evidence to date that the Pacific Northwest whales might be sufficiently isolated to allow maternally inherited mtDNA to differ from the overall ENP population.

Population structure in other large whales has been the subject of recent inquiry and has revealed diverse results for different species. Clapham et al. (2008) examined 11 subpopulations of whales subjected to whaling that were extirpated possibly due to the loss of the cultural memory of that habitat and concluded subpopulations often exist on a smaller spatial scale than had been recognized. Studies of other baleen whales, particularly humpback whales, have shown evidence of maternally directed site fidelity to specific feeding grounds based on photographic identification studies (Calambokidis et al. 1996, 2001, 2008). This high degree of fidelity to specific feeding areas is often discernible genetically. In the North Pacific strong mtDNA differences were found among feeding areas even when there was evidence of low level of interchange from photo-ID (Baker et al. 2008). Similar findings were documented for humpback whales in the North Atlantic which feed in different areas but interbreed primarily on a single breeding ground (Palsboll et al. 1995) like ENP gray whales. In the North Pacific the differences for humpback whales were often dramatic. For example, humpback whales that feed off California have almost no overlap in mtDNA haplotypes with humpback whales feeding in Southeast Alaska (Baker et al. 1990, 1998, 2008). One difference between humpback and gray whales is the coastal migration route of gray whales which means gray whales going to arctic waters to feed would migrate right through the feeding areas to the south. Other species of large whales have not shown as strong site fidelity to specific feeding grounds. Blue whales have undergone an apparent shift in their feeding distribution in the North Pacific apparently due to shifting oceanographic conditions (Calambokidis et al. 2009a). Fin whales in the North Pacific have long migrations and while there do not appear to be multiple distinct feeding areas as was the case for humpback whales, there were some distinct and isolated apparently nonmigratory populations (Mizroch et al. 2009; Berube et al. 2004).

Even though the population structure of gray whales off the Pacific Northwest remains unresolved, there is a consistent group of animals that use this area and we provide several estimates of their abundance. Different abundance methods and geographic scopes yield varied results but all suggest the annual abundance of animals using the Pacific Northwest for feeding through the summer is at most a couple hundred animals depending on the estimating method and how broadly the region is defined geographically.

The rapid increase in the abundance estimates at the start of this study is in part due to the smaller area of coverage during 1996 and 1997. We included those years to improve the estimate in 1998-1999 and the estimate for 1998 did increase by 7% from previous analysis. The increase from 1998-2000 occurred during a period the overall eastern North Pacific gray whale population was experiencing a high mortality event that included unusually high numbers of gray whales showing up in areas they were not common. The high rate of increase in the late 1990s and early 2000s should be verified with additional data such as compiling photographic identifications for this area from multiple sources to attempt to verify if the abundance of animals prior to the start of our study was as low as suggested by these trends. Even though the rate of increase may be too high, we believe the abundance did increase and now appears to be relatively stable since 2002.

Acknowledgments

This analysis would not have been possible without the collaborating organizations and individuals contributing identification photographs (the primary contributors are listed in Methods and Tables 1 and 2). Support for the photographic identification reported here, the comparison of gray whale photographs and preparation of this report came primarily from the National Marine Mammal Laboratory. Permission to conduct some portions of this research in U.S. waters was provided by the U.S. National Marine Fisheries Service and the Makah Tribe. Portions of the research in British Columbia were conducted collaboratively with Fisheries and Oceans Canada (thanks to John Ford and Graeme Ellis). Volker Deecke assisted in analysis and matching of identifications from S. Vancouver Island. William Megill coordinated providing sightings and identifications from CERF, Dawn Goley and Jeff Jacobsen coordinated effort for HSU, Christina Tombach and Dave Duffus coordinated early efforts for UVIC, Carrie Newell provided identification photographs from Oregon, Merrill Gosho, Pat Gearin, Nate Pamplin and Jonathan Scordino provided photos form Washington. Brian Gisborne's diligence and hard work provided an immense amount of data and photographs from Vancouver Island. A number of people assisted in the field effort and in the printing and matching of photographs at Cascadia Research. Erin Falcone, Lisa Schlender, Jennifer Quan, and Amber Klimek helped compile the data from different contributors and conducted photographic matching. Randy Lumper conducted gray whale matching in the early years of this study. Jonathan Scordino, Steve Stone and Donna Darm provided many helpful comments, suggestions and edits.

Table 3: Survey regions and region subsets used for abundance estimation. Numbers refer to locations on the map in Figure 1.

Survey Region	Region Description	NCA-NBC	OR-SVI	MUA
(1) SCA = Southern California				
(2) CCA = Central California				
(3) NCA = Northern California	Eureka to Oregon border; mostly from Patricks Pt. and Pt. St George	x		
(4) SOR = Southern Oregon		x	x	
(5) OR = Oregon Coast	Primarily central coast near Depoe Bay and Newport, OR	x	x	
(6) GH+ = Gray's Harbor	Waters inside Grays Harbor and coastal waters along the S Washington coast	x	x	
(7) NWA = Northern Washington	Northern outer coast waters with most effort from Cape Alava (Sea Lion Rock) to Cape Flattery	x	x	x
(8) SJF = Strait of Juan de Fuca	US waters east of Cape Flattery extending to Admiralty Inlet (entrance to Puget Sound) with most effort ending at Sekiu Point	x	x	x
(9) NPS = Northern Puget Sound	Inside waters and embayments from Edmonds to the Canadian border			
(10) PS = Puget Sound	Central and southern Puget Sound (S of Edmonds), including Hood Canal, Boundary Bay, and the San Juan Islands			
(11) SVI = Southern Vancouver Island	Canadian waters of the Strait of Juan de Fuca along Vancouver Island from Victoria to Barkley Sound, along West Coast Trail	x	x	
(12) WVI = West Vancouver Island		x		
(13) NBC = Northern British Columbia	British Columbia waters north of Vancouver Island, with principal effort around Cape Caution	x		
(14) SEAK = Southeast Alaska	Waters of southeastern Alaska with the only effort in the vicinity of Sitka			
(15) KAK = Kodiak, Alaska				

Table 4: Model specifications for survival (φ) and capture probability (p) parameters in POPAN models for gray whale photo-identification data. For survival models, β_0 is the baseline intercept for non-transient survival. Fy is 1 if it is year the whale was first seen and 0 otherwise. A subscript for Fy means that it applies only for that cohort except that Fy_{99}applies to cohorts 1999 and beyond and Fy_c represents each of the cohorts from 1996 to 2015. C is 1 if identified as a calf in its first year and 0 otherwise. R is 1 for calves or any whale seen in 1998 or was already in the catalog prior to 1998 and 0 otherwise. β_r is an adjustment to post-first-year survival. MT is minimum tenure value of a whale and β_M is the estimated slope parameter for φ or p. $\beta_{M,96-97}$ applies to 1996-97, $\beta_{M,98}$ to 1998 and $\beta_{M,99}$ applies to 1999-2014. $\beta_{Fy,96-97}$, $\beta_{Fy,98}$ and $\beta_{Fy,99}$ are the first-year survival intercept adjustments for 1996-97, 1998 and cohorts 1999-2014 respectively and $\beta_{Fy,c}$ represents 19 cohort-specific first year survival parameters for 1996-2014. β_{CF} is an adjustment for calf first year survival and β_{CM} is an adjustment for calves to the slope of MT for survival. For the capture probability models, β_t has 18 levels for t=1998,...2015 and β_0 represents the 1997 value. For 1996 p=1.

Model	Parameter Logit Formula	Number of parameters
φ		
1	$\beta_0 + \beta_{Fy}Fy + \beta_r R(1 - Fy)$	3
2	$\beta_0 + \beta_{Fy}Fy + \beta_M MT\,Fy + \beta_r R(1 - Fy)$	4
3	$\beta_0 + \beta_{Fy,96-97}Fy_{96-97} + \beta_{Fy,98}Fy_{98} + \beta_{Fy,99}Fy_{99} + \beta R(1 - Fy)$	5
4	$\beta_0 + \beta_{Fy,96-97}Fy_{96-97} + \beta_{Fy,98}Fy_{98} + \beta_{Fy,99}Fy_{99} + \beta_M MT\,Fy + \beta_r R(1 - Fy)$	6
5	$\beta_0 + (\beta_{Fy,96-97} + \beta_{M,96-97}MT)Fy_{96-97} + (\beta_{Fy,98} + \beta_{M,98}MT)Fy_{98} + (\beta_{Fy,99} + \beta_{M,99}MT)Fy_{99} + \beta_r R(1 - Fy)$	8
6	$\beta_0 + \beta_{Fy,c}Fy_c + \beta_M MT\,Fy + \beta_r R(1 - Fy)$	22
7	$\beta_0 + \beta_{Fy,c}Fy_c + \beta_M MT\,Fy + \beta_{CF}C\,F_y + \beta_r R(1 - Fy)$	23
8	$\beta_0 + \beta_{Fy,c}Fy_c + \beta_M MT\,Fy + \beta_{CF}C\,F_y + \beta_{CM}C\,MT + \beta_r R(1 - Fy)$	24
9	$\beta_0 + (\beta_{Fy,96-97} + \beta_{M,96-97}MT)Fy_{96-97} + (\beta_{Fy,98} + \beta_{M,98}MT)Fy_{98} + (\beta_{Fy,99} + \beta_{M,99}MT)Fy_{99} + \beta_{CF}C\,F_y + \beta_r R(1 - Fy)$	9
10	$\beta_0 + (\beta_{Fy,96-97} + \beta_{M,96-97}MT)Fy_{96-97} + (\beta_{Fy,98} + \beta_{M,98}MT)Fy_{98} + (\beta_{Fy,99} + \beta_{M,99}MT)Fy_{99} + \beta_{CF}C\,F_y + \beta_{CM}C\,MT + \beta_r R(1 - Fy)$	10
p		
1	$\beta_0 + \beta_t$	19
2	$\beta_0 + \beta_t + \beta_M MT$	20

Table 8: Interchange of whales across regions for all years (1996-2015) for June-November. The diagonal is the number of unique whales seen in that region over the 20 year time span. Many of those whales were only seen once. Here PS includes NPS and CA represents SCA and CCA.

Table 11: Discovery of new unique whales over years 1996-2015 for PCFG,OR-SVI and MUA. Recruited only means that the whale was seen in at least one more year after the initial year it was seen. The number 'recruited' will usually be greater than the abundance estimate because some whales die and others may permanently emigrate and do not return.

Region	1996	1997	1998	1999	2000	2001	2002	2003	2004	2005	2006	2007	2008	2009	2010	2011	2012	2013	2014	2015

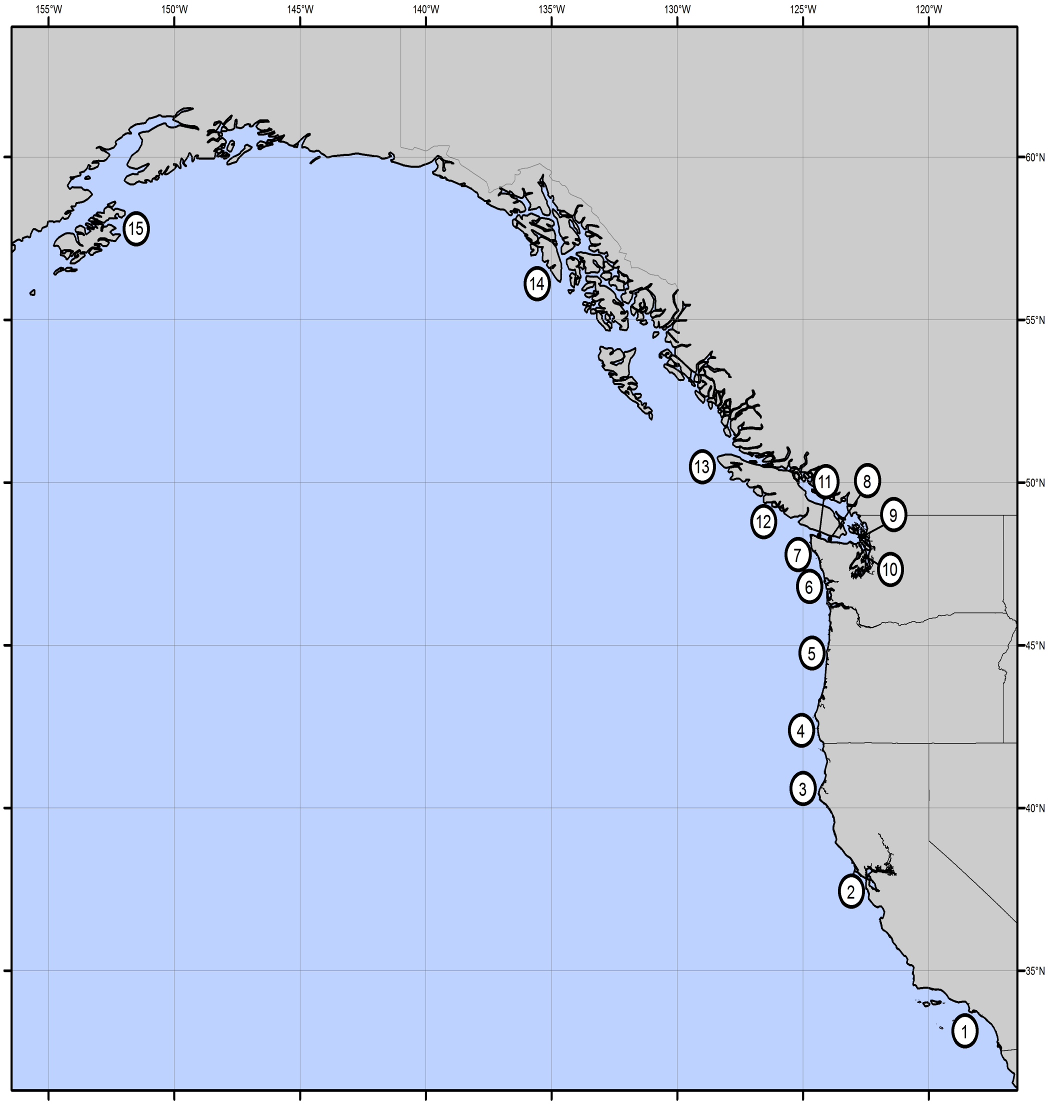

Figure 1: Locations for photo-identifications of gray whales. Numbers refer to values in Table 3.

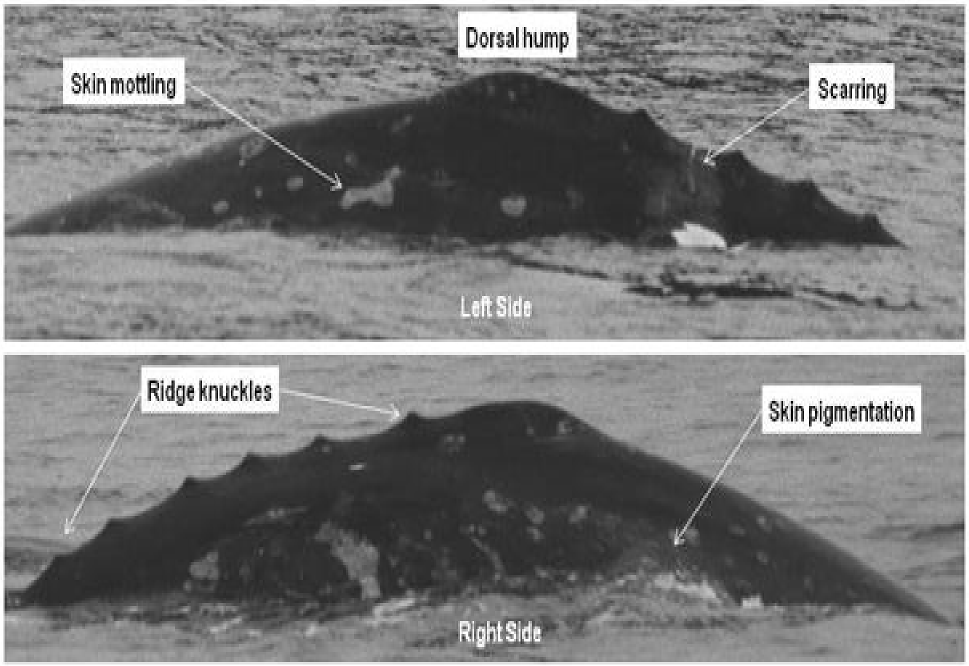

Figure 2: Characteristics used for gray whale photo-identification.

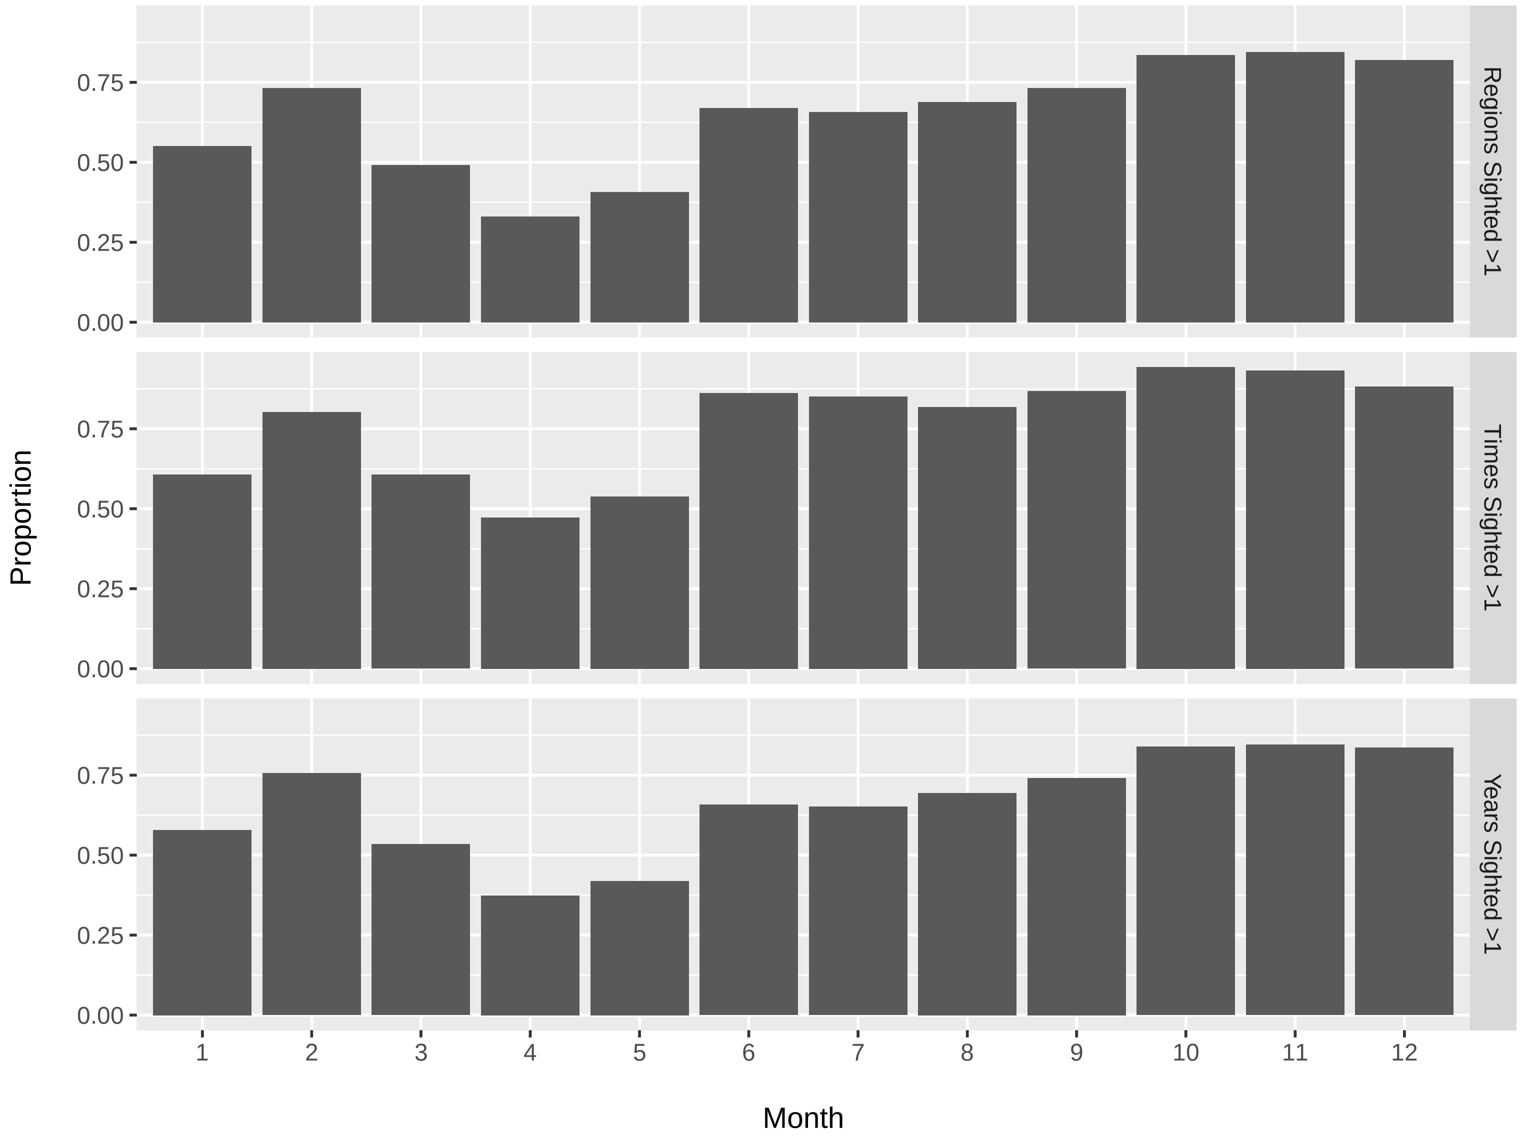

Figure 3: Monthly measures of proportion of whales that were seen in more than one region, seen on more than one day and seen in more than one year. The values include sightings from 1996-2015 in all regions from California to Alaska. Lower values imply whales were simply migrating through the area in a short time frame and were thus less likely to be seen at other times and in other regions. Values are not shown for months with fewer than 20 sightings. Whales seen more often are overrepresented because they are used in each month they were seen. For example a whale seen in June, July and August will be in each summary. Thus, these values may be larger than values computed without splitting by month (e.g., overall proportion of whales seen in more than one year).

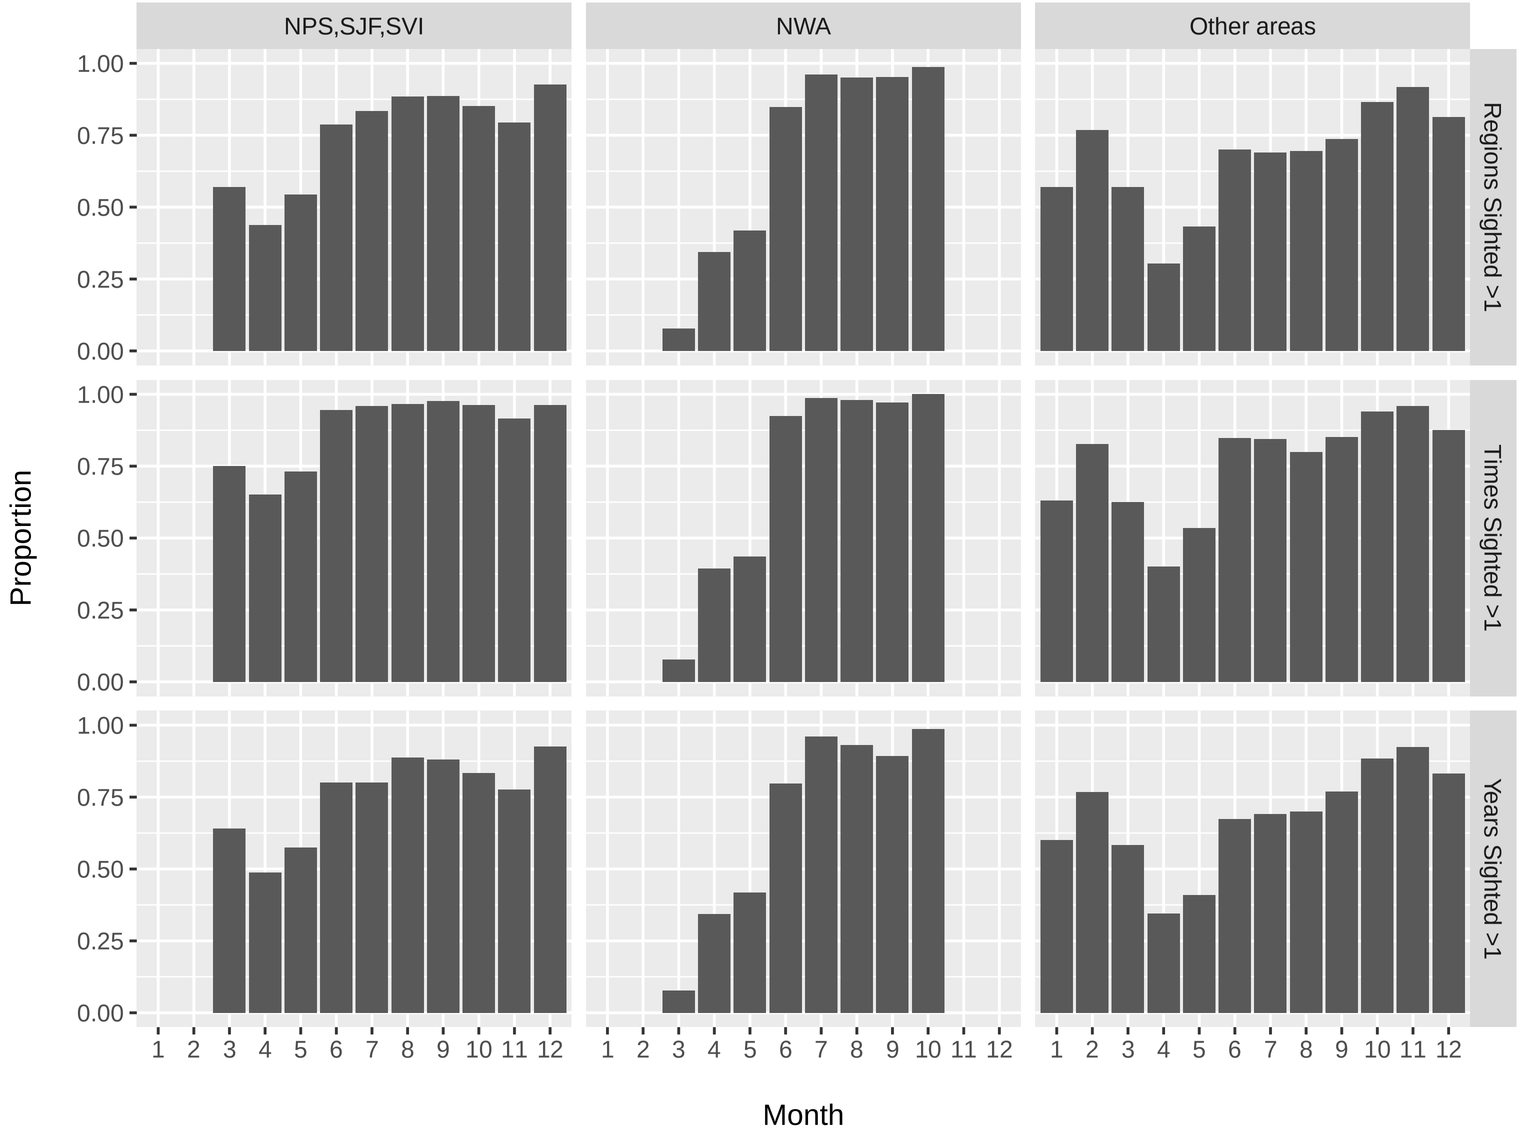

Figure 4: Region and monthly measures of proportion of whales that were seen in more than one region, seen on more than one day and seen in more than one year. The values include sightings from 1996-2015 in all regions from California to Alaska. Lower values imply whales were simply migrating through the area in a short time frame and were thus less likely to be seen at other times and in other regions. Values are not shown for months with fewer than 20 sightings. Whales seen more often are over-represented because they are used in each month they were seen. For example a whale seen in June, July and August will be in each summary. Thus, these values may be larger than values computed without splitting by month (e.g., overall proportion of whales seen in more than one year).

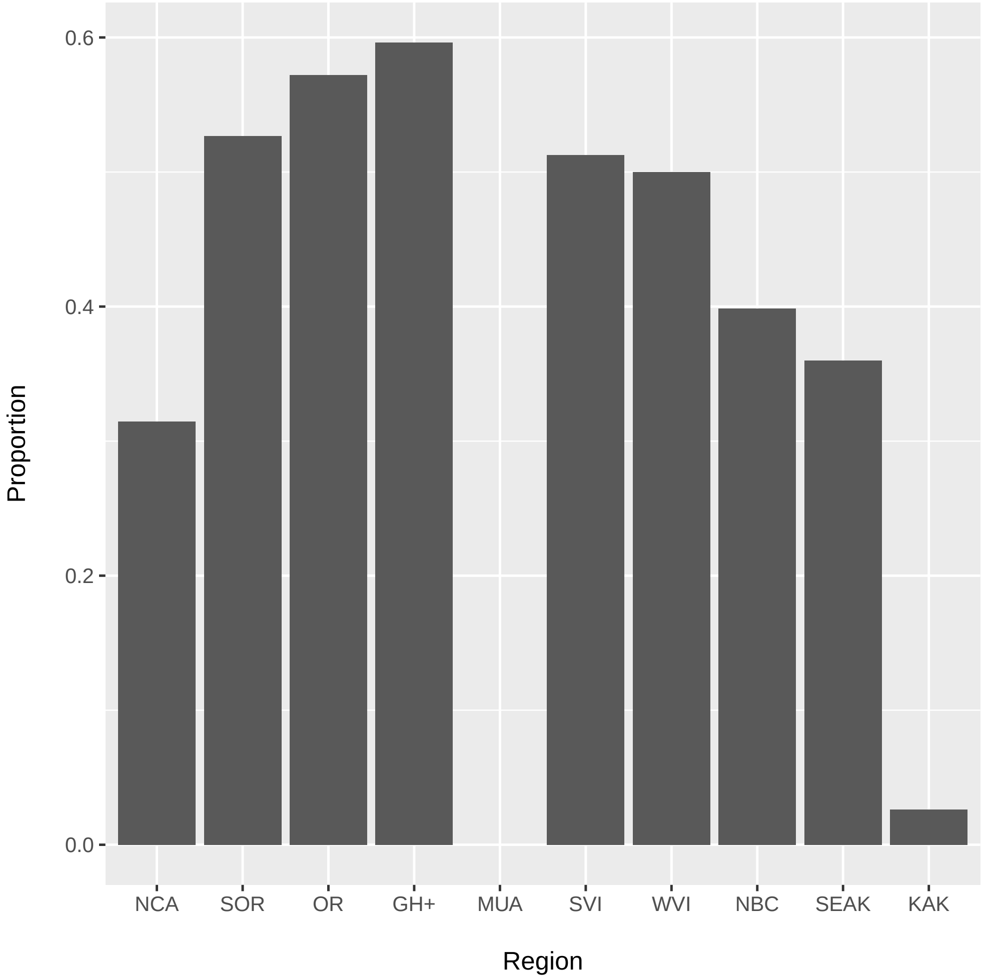

Figure 5: Proportion of whales in sub-regions from NCA to KAK that have been seen in the MUA using sightings after 1 June from 1996-2015.

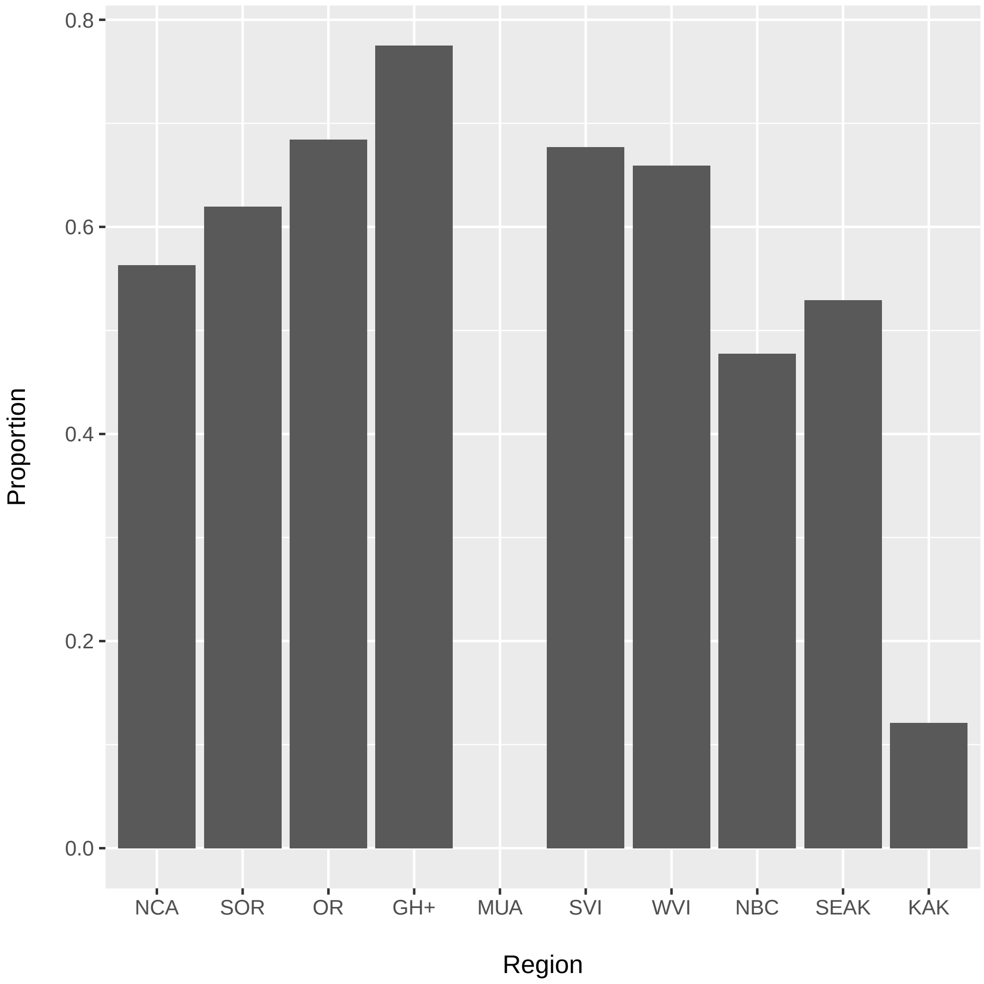

Figure 6: Proportion of whales seen in at least 2 years in sub-regions from NCA to KAK that have been seen in the MUA using sightings after 1 June from 1996-2015.

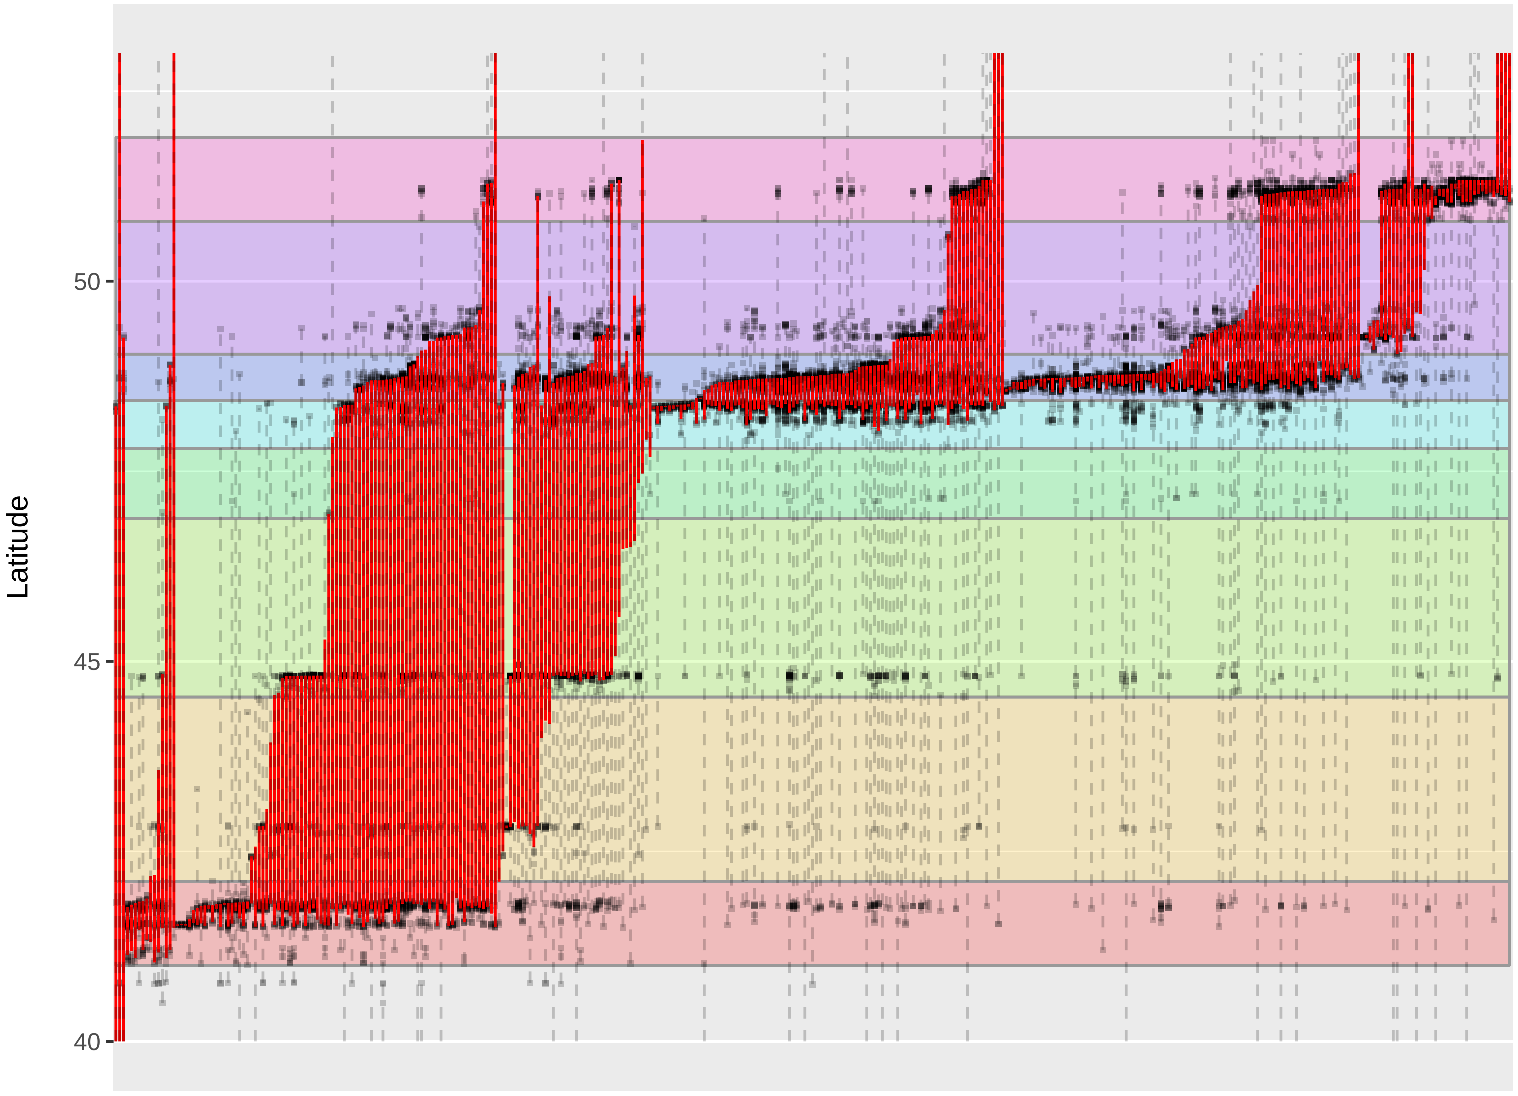

Figure 7: Distribution of latitudes of sightings (points) for whales with 6 or more sightings after 1 June from 1996-2015, the 75% inner quantile (solid thick line), and full range (light dashed line). Each position on the x axis represents an individual whale. Whales have been arranged on the plot by sorting first on the lower bound of the inner quantile (to a half-degree) and then the upper bound of the quantile. This has the effect of sorting from south to north and clusters whales with smaller quantile ranges followed by whales with larger ranges.

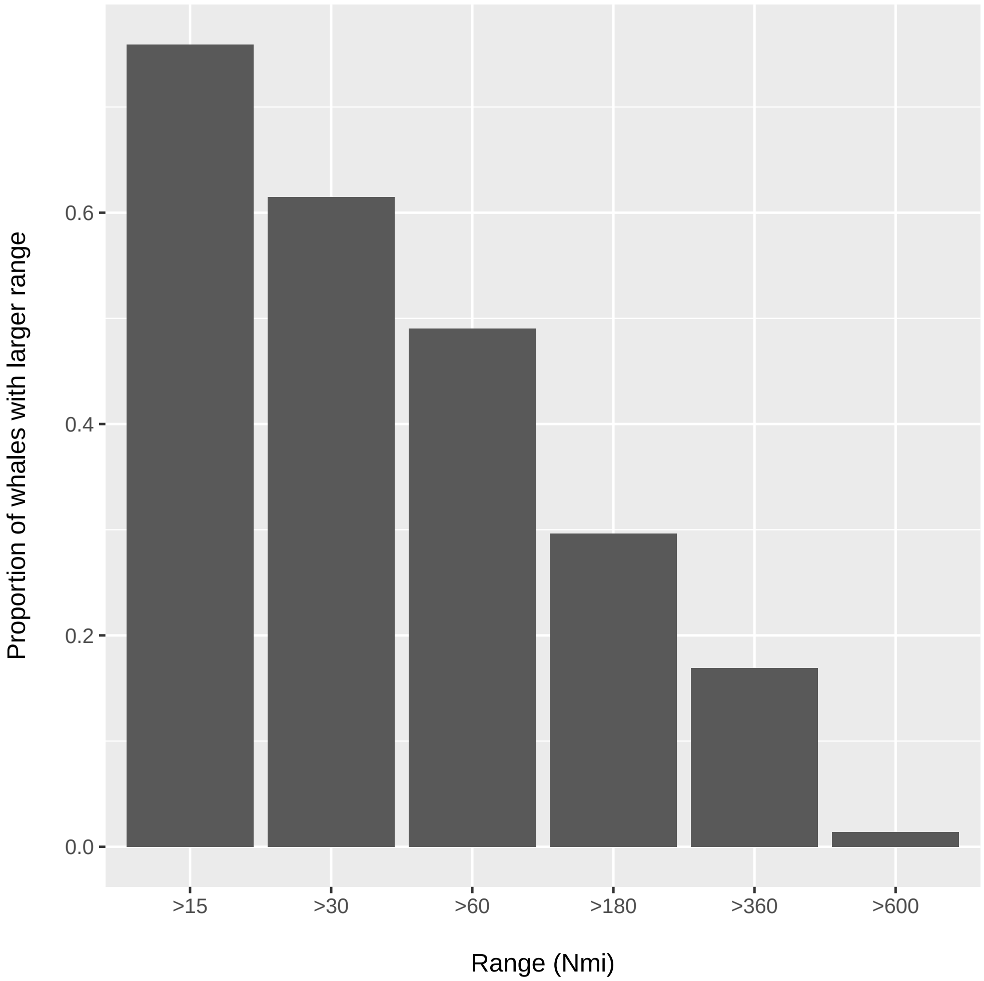

Figure 8: Distribution of ranges of 75% inner quantiles of latitudes expressed in nautical miles for whales sighted on 6 or more days during 1996-2015.

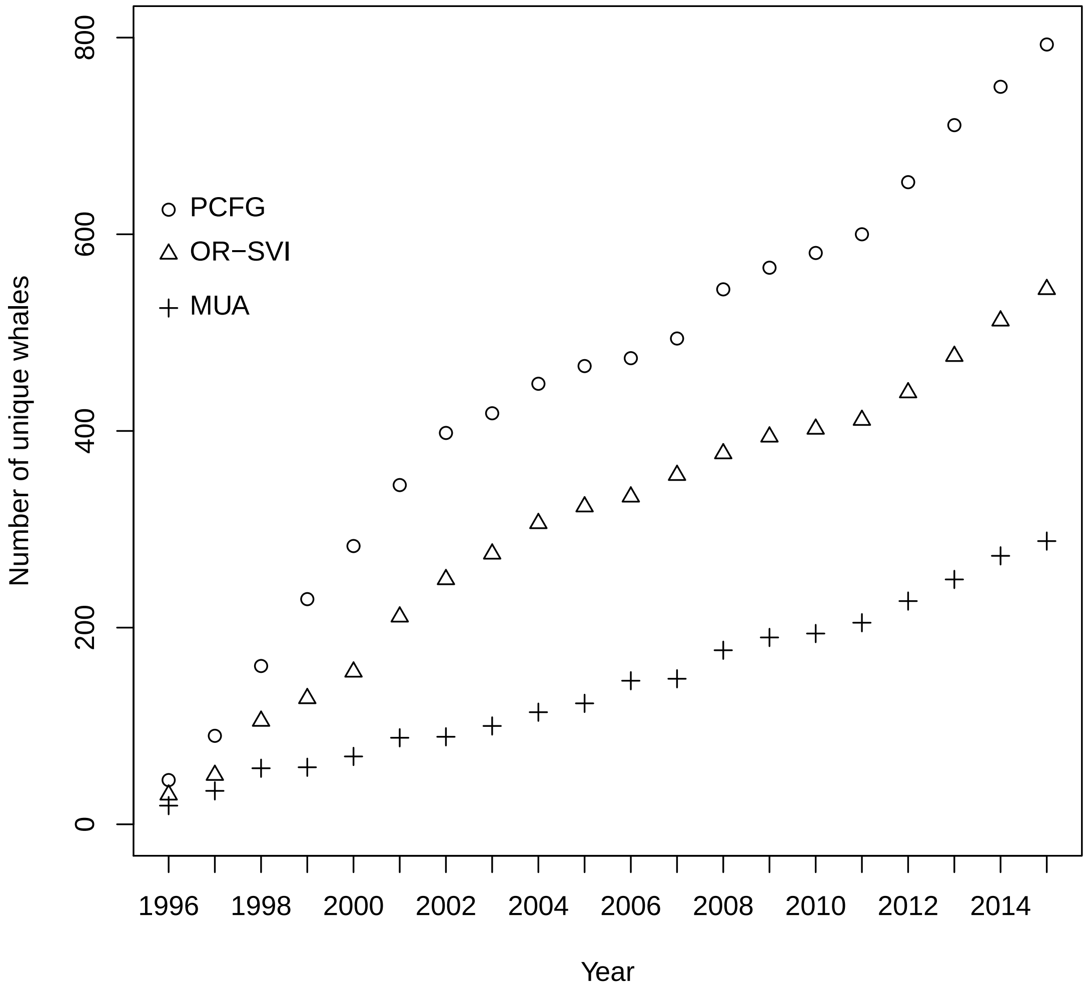

Figure 9: Discovery curves for unique whales seen in PCFG, OR-SVI and MUA for 1996-2015.

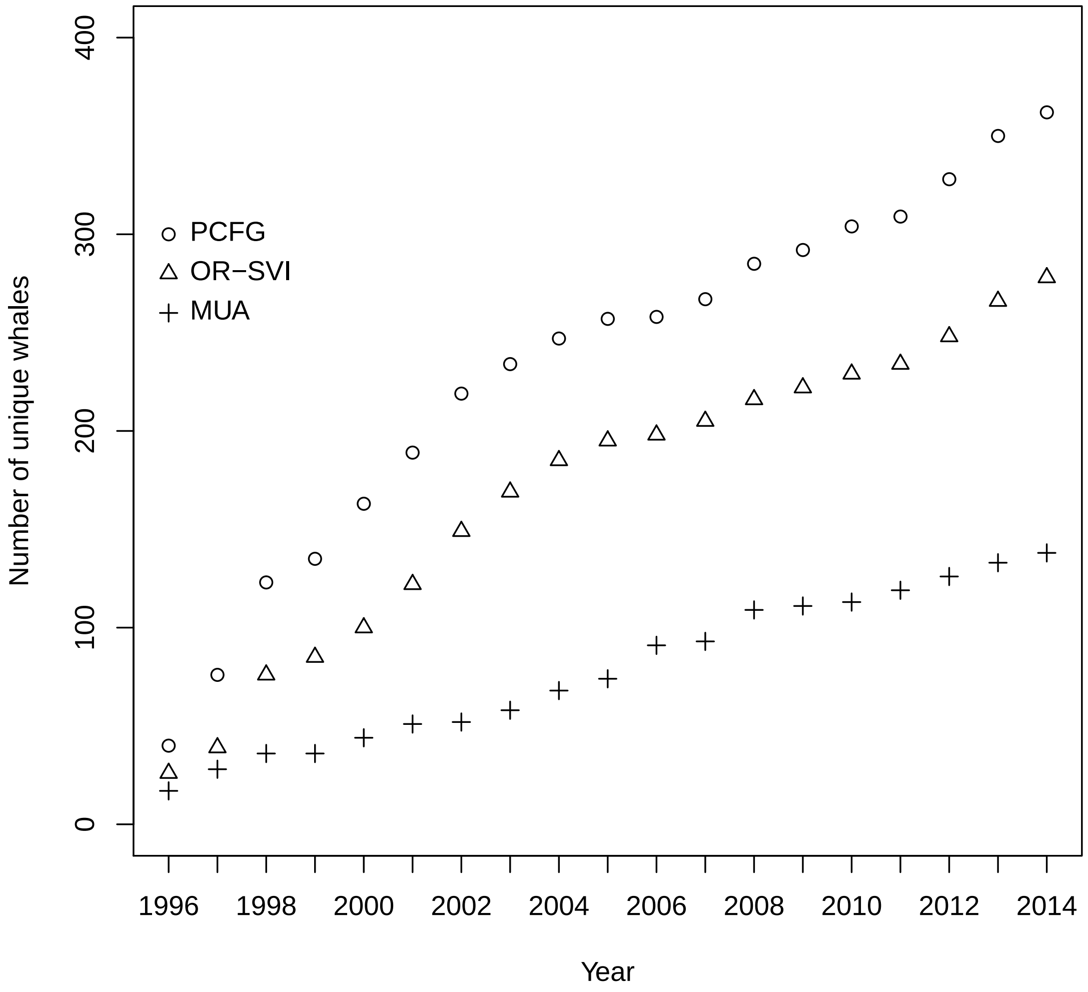

Figure 10: Discovery curves for unique recruited whales seen in PCFG, OR-SVI and MUA for 1996-2015.

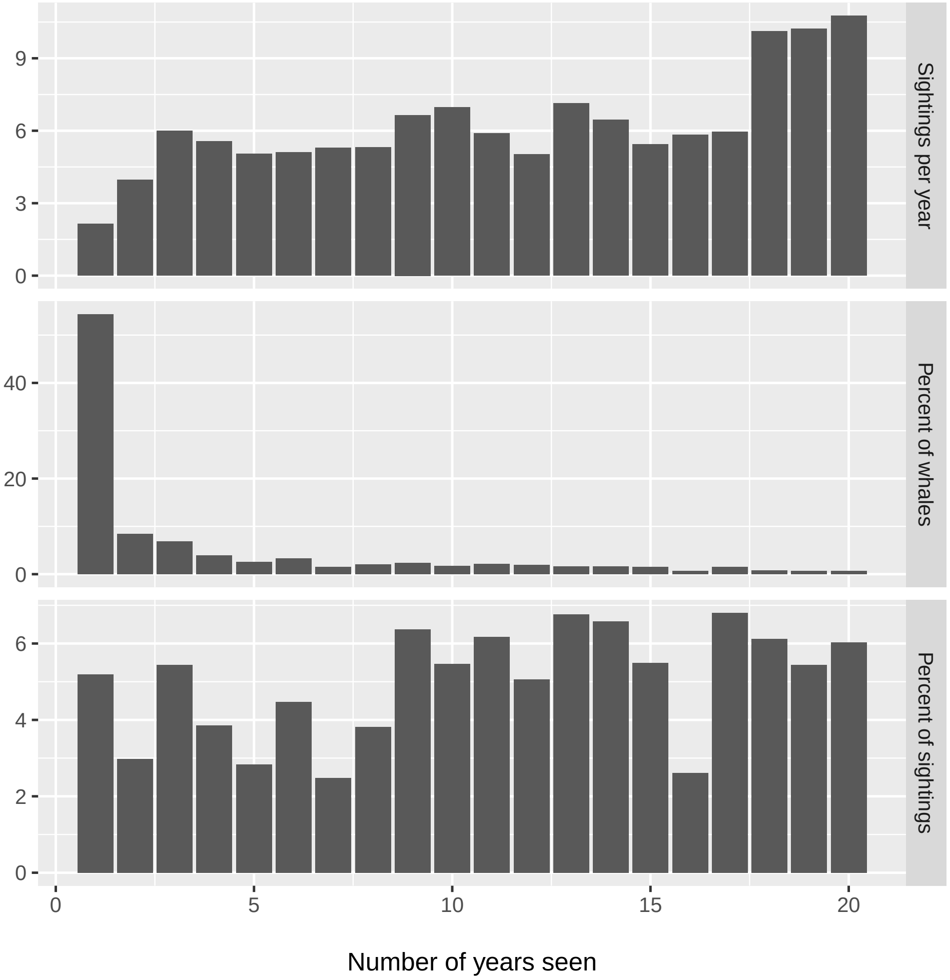

Figure 11: Average number of sightings per year and distribution of whales and numbers of sightings based on numbers of years a whale was seen in NCA-NBC between June-November during 1996-2015.

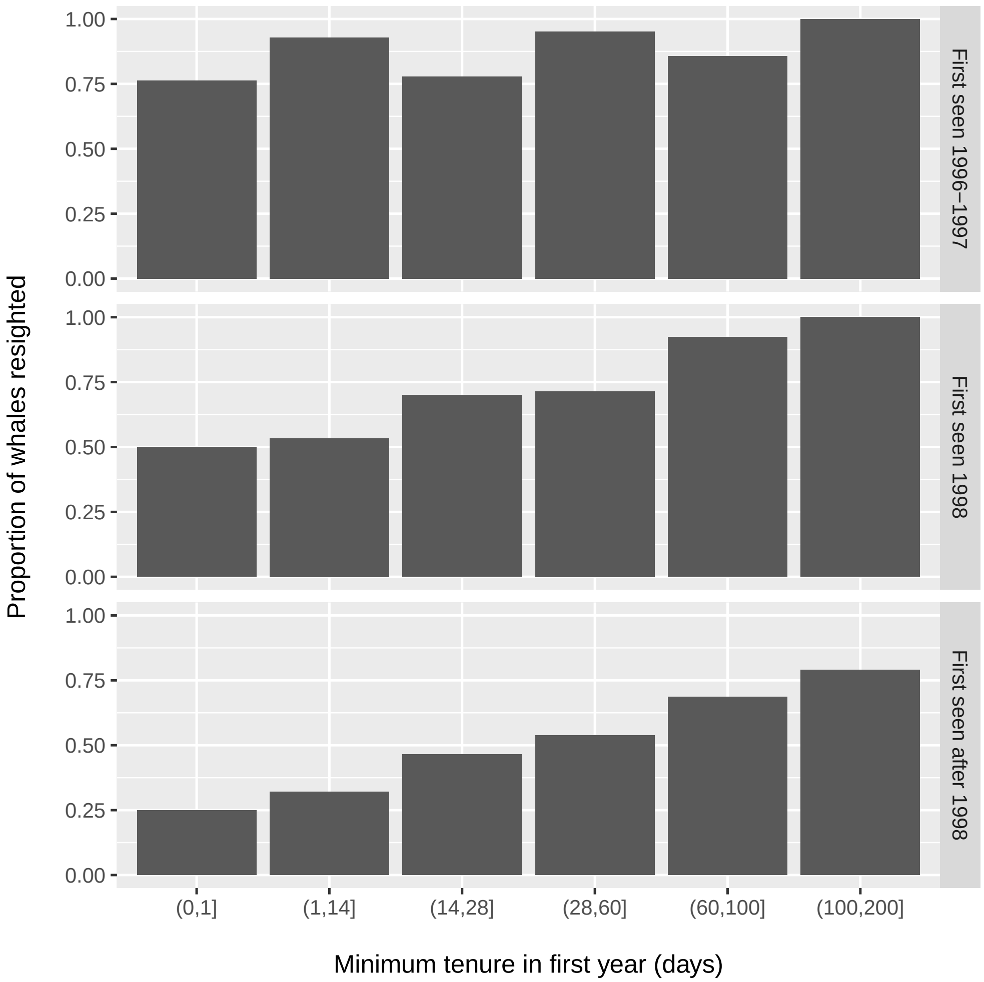

Figure 12: Influence of minimum tenure (MT) in the first year the whale was photographed on the probability it will be re-sighted in one or more following years for whales seen in NCA-NBC for June-November 1996-2015. The bar graphs are divided based on first year in 1996-1997, 1998 and after 1998. Re-sightings for 2015 are used but initial sightings for 2015 are excluded because there are no data beyond to evaluate re-sighting probability.

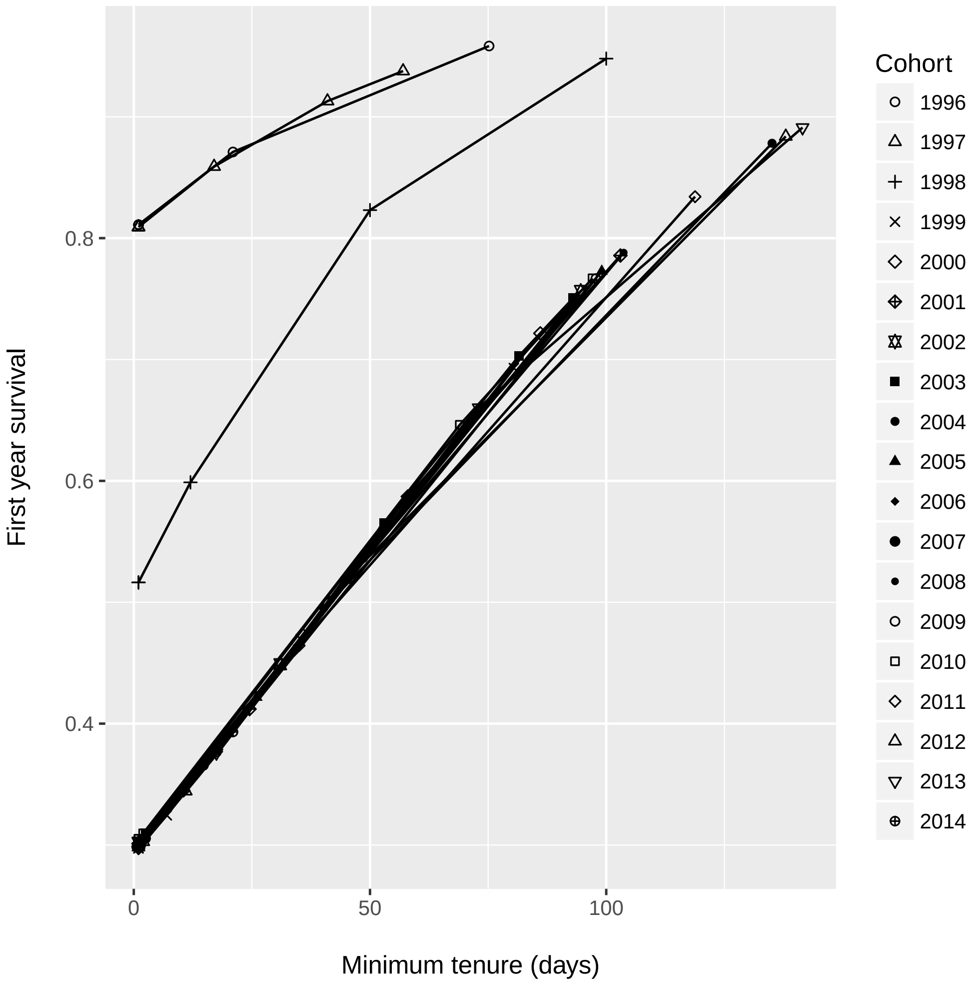

Figure 13: For NCA-NBC analysis of 1996-2015 data, model-averaged estimates of first year survival of non-calves for each cohort at 5%, 25%, 50%, 75%, and 95% quantiles of minimum tenure values for that cohort.

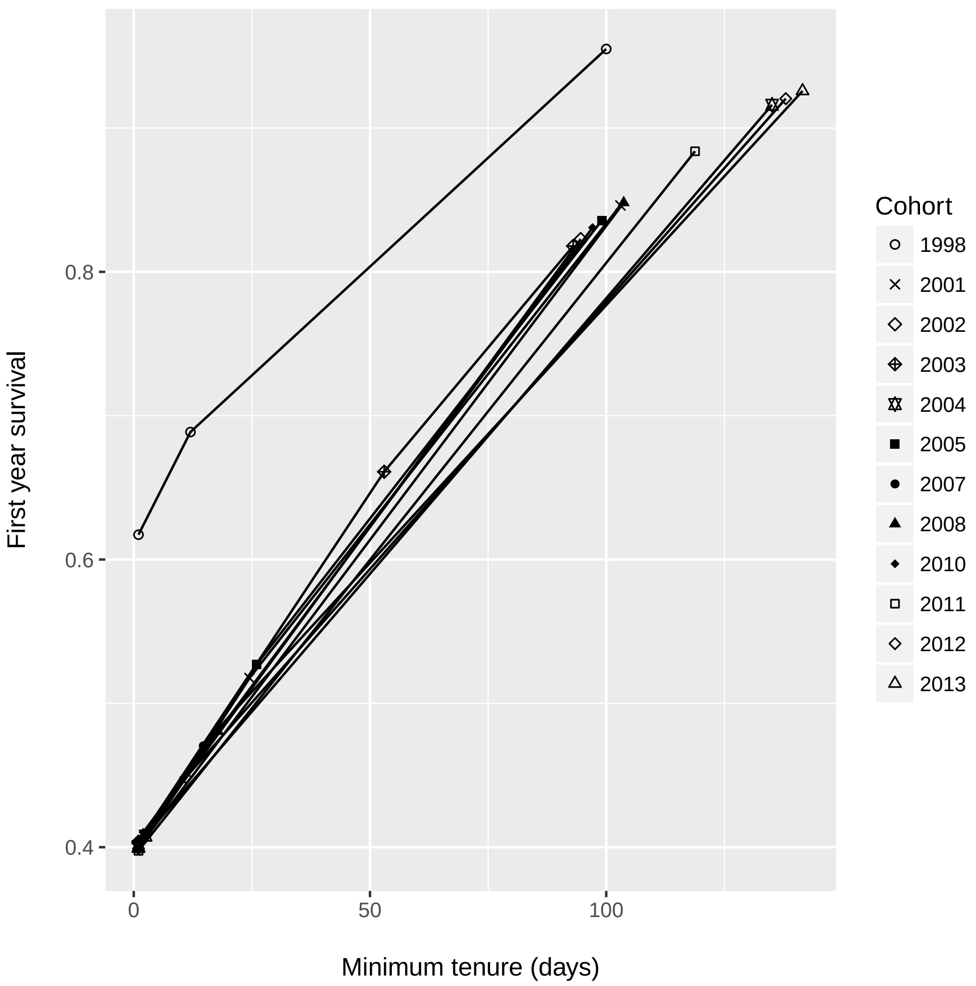

Figure 14: For NCA-NBC analysis of 1996-2015 data, model-averaged estimates of first year survival of calves for each cohort at 5%, 25%, 50%, 75%, and 95% quantiles of minimum tenure values for that cohort.

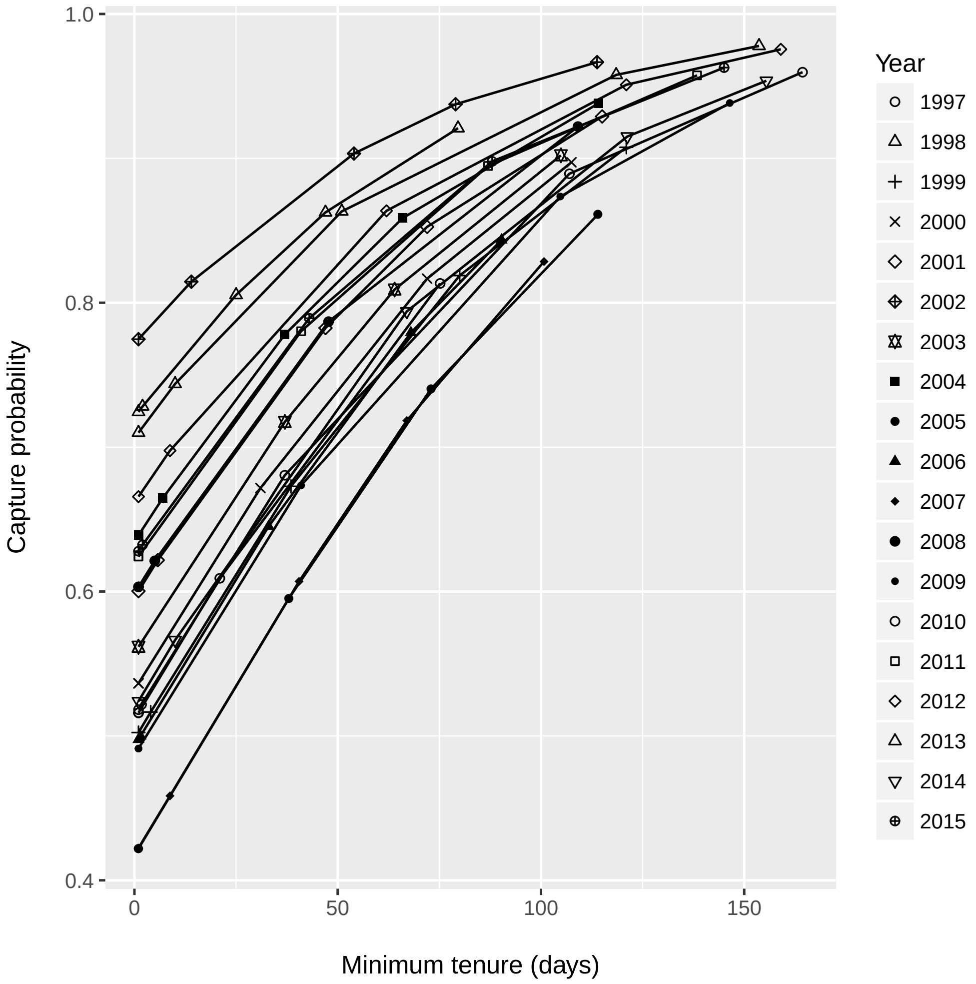

Figure 15: For NCA-NBC analysis of 1996-2015 data, model-averaged estimates of capture probability for each year at 5%, 25%, 50%, 75%, and 95% quantiles of minimum tenure values for whales in the previous year.

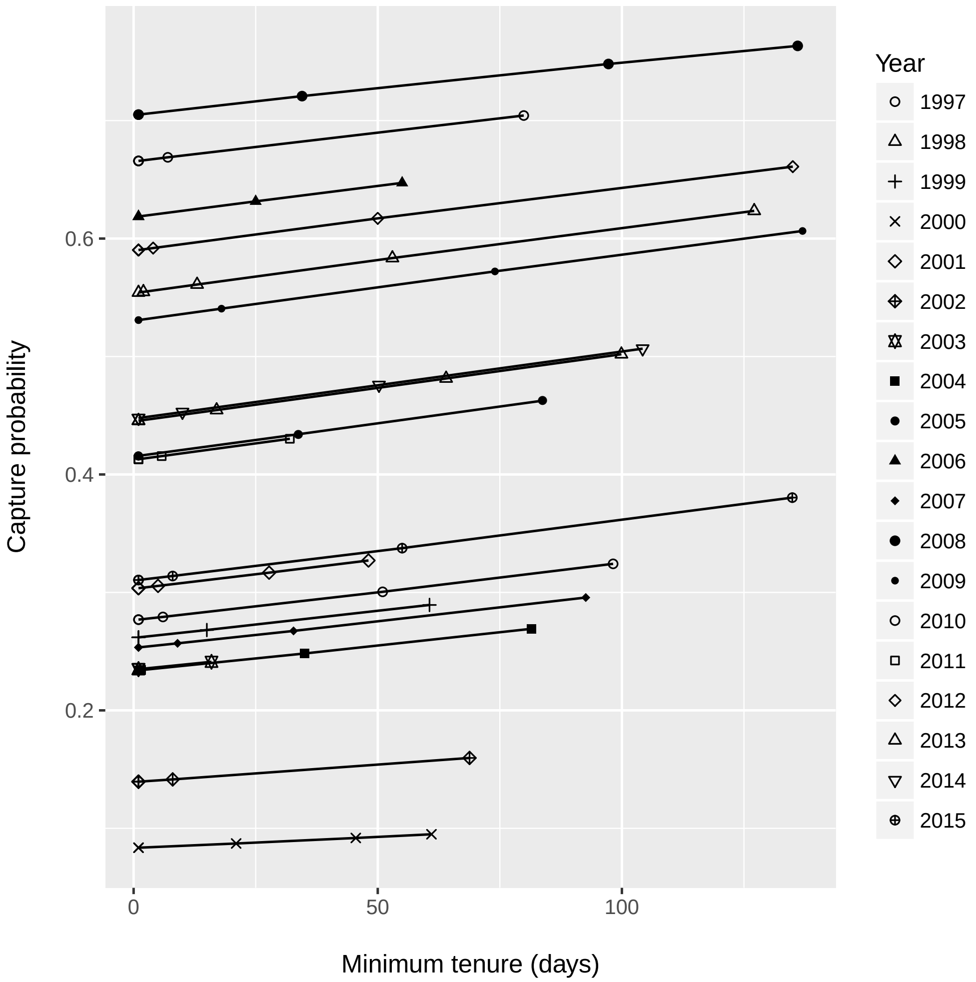

Figure 16: For MUA analysis of 1996-2015 data, model-averaged estimates of capture probability for each year at 5%, 25%, 50%, 75%, and 95% quantiles of minimum tenure values for whales in the previous year.

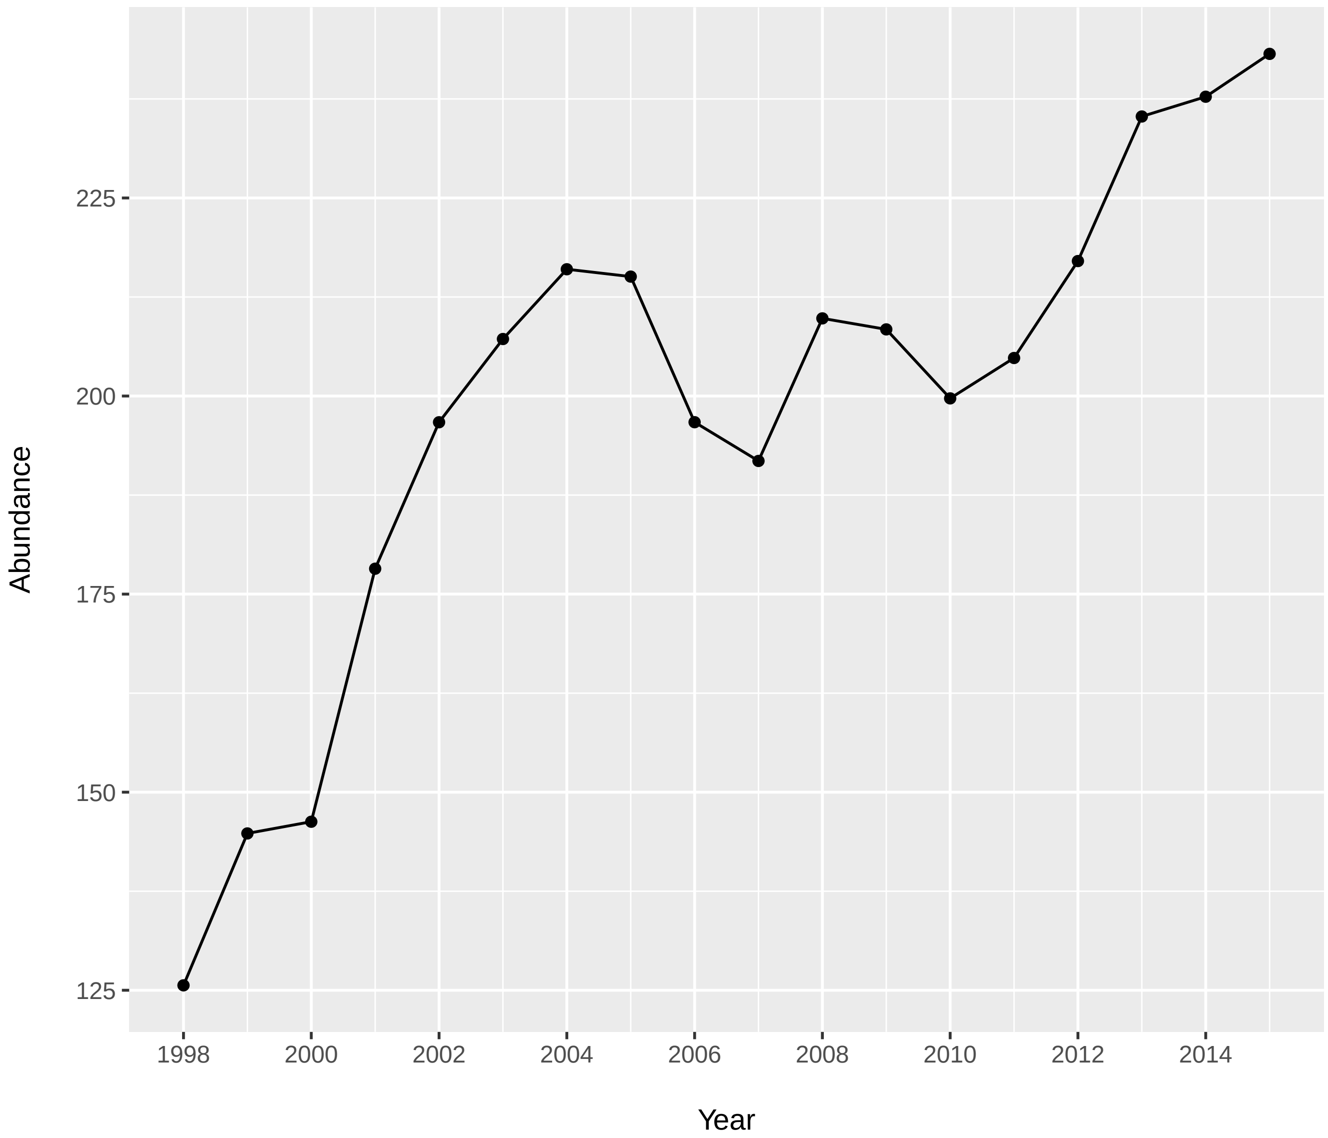

Figure 17: Annual abundance estimates for 1998-2015 in NCA-NBC using the open (Jolly-Seber; POPAN parametrization) population model approach JS1.

Appendix

Table 1 provides capture histories of whales seen in the PCFG at least once from 1 June - 30 November and displays by year, when they were seen only in spring (March-May), only from 1 June - 30 Nov and when they were seen in both time periods. Table 2 provides capture histories using data from 1 June - 30 Nov of whales seen in the MUA at least once. It shows when whales were seen only outside of the MUA but in the PCFG, only in the MUA and both inside the MUA and in the PCFG outside of the MUA

Table 1: Sighting histories of whales seen in the PCFG in at least one year. In year columns, a 1 means the whale was only sighted in the spring (March-May), 2 means it was only seen in June-Nov, and 3 means it was seen in both March-May and June-Nov. The region value is the nunber of years the whale was seen in that region.

Table 1: Sighting histories of whales seen in the PCFG in at least one year. In year columns, a 1 means the whale was only sighted in the spring (March-May), 2 means it was only seen in June-Nov, and 3 means it was seen in both March-May and June-Nov. The region value is the nunber of years the whale was seen in that region.

Report of the Scientific Committee

The meeting was held at Centre de Congrès, Les Dunes d'Or, Agadir, Morocco from 30 May-11 June 2010 and was chaired by Debra Palka. A list of participants is given as Annex A.

1. INTRODUCTORY ITEMS

1.1 Chair's welcome and opening remarks

Palka welcomed the participants to the meeting. She thanked the Government of Morocco for hosting the meeting and for providing excellent facilities along with fabulous weather. She also expressed thanks for the beautiful artwork exhibited throughout the meeting venue.

With sadness, the Committee noted that Sidney Brown had passed away since the 2009 meeting. Sidney was a long-standing member of the Committee from the early 1960s to the mid 1980s. He was particularly involved in the Discovery Whale Marking Scheme, for which he was responsible for maintaining records of marks fired and recovered, ordering supplies and ensuring their availability for relevant whaling and scientific operations, and writing up the results. His advice on all things cetacean was much sought and greatly respected. His modest English manner belied a shrewd intellect and wide range of interests in maritime history and exploration. A minute of silence was observed in his memory.

1.2 Appointment of rapporteurs

Donovan was appointed rapporteur with assistance from various members of the Committee as appropriate. The Committee gave particular thanks to Butterworth for rapporteuring Item 20. Chairs of sub-committees and Working Groups appointed rapporteurs for their individual meetings.

1.3 Meeting procedures and time schedule

Grandy summarised the meeting arrangements and information for participants. The Committee agreed to follow the work schedule prepared by the Chair.

1.4 Establishment of sub-committees and Working Groups

Two pre-meetings preceded the start of the Scientific Committee. The Working Group on the *pre-Implementation assessment* of Western North Pacific Common Minke Whales (NPM) and the correspondence Working Group on Abundance Analysis Methods for Southern Hemisphere Minke Whales met from 28-29 May, during which agenda items covered were incorporated into their main agendas and reports (Annexes D1 and G respectively).

A number of sub-committees and Working Groups were established. Their reports were either made annexes (see below) or subsumed into this report.

Annex D – Sub-Committee on the Revised Management Procedure (RMP);
Annex D1 – Working Group on the *pre-Implementation assessment* of Western North Pacific common minke whales (NPM);
Annex E – Standing Working Group on an Aboriginal Whaling Management Procedure (AWMP);
Annex F – Sub-Committee on Bowhead, Right and Gray Whales (BRG);
Annex G – Sub-Committee on In-Depth Assessments (IA);
Annex H – Sub-Committee on Other Southern Hemisphere Whale Stocks (SH);
Annex I – Working Group on Stock Definition (SD);
Annex J – Working Group on Estimation of Bycatch and other Human-Induced Mortality (BC);
Annex K – Standing Working Group on Environmental Concerns (E);
Annex K1 – Working Group to Address Multi-species and Ecosystem Modelling Approaches (EM);
Annex L – Standing Sub-Committee on Small Cetaceans (SM);
Annex M – Sub-Committee on Whalewatching (WW); and
Annex N – Working Group on DNA (DNA).

1.5 Computing arrangements

Allison outlined the computing and printing facilities available for delegate use. Requests for Secretariat computing are addressed according to the priority assigned by the Convenors.

2. ADOPTION OF AGENDA

The adopted Agenda is given as Annex B1. Statements on the Agenda are given as Annex U. The Agenda took into account the priority items agreed last year and approved by the Commission (IWC, 2010c). Annex B2 links the Committee's Agenda with that of the Commission.

3. REVIEW OF AVAILABLE DATA, DOCUMENTS AND REPORTS

3.1 Documents submitted

Donovan noted that the pre-registration procedure, coupled with the availability of electronic papers, had again been successful. With such a large number of documents, pre-specifying papers had reduced the amount of photocopying and unnecessary paper dramatically. He was pleased to note that this year, the percentage of people opting to receive their primary papers entirely electronically (27%) was almost triple that of last year (10%) and he hoped that this percentage would continue to grow in future years. The list of documents is given as Annex C.

3.2 National Progress Reports on research

National Progress Reports presented at the 2002-10 meetings are accessible on the IWC website. Reports from previous years will also become available in this format in the future.

The Committee reaffirmed its view of the importance of national Progress Reports and **recommends** that the Commission continues to urge member nations to submit them following the approved guidelines (IWC, 1993). Non-member nations wishing to submit progress reports are welcome to do so. The Secretariat is looking into the possibility of online submission of the data included in national Progress Reports; a simplified progress report template has also been developed (see Annex P).

A summary of the information included in the reports presented this year is given as Annex O; the report template,

Table 1

List of data and programs received by the IWC Secretariat since the 2009 meeting.

Date	From	IWC ref.	Details
Catch data from the previous season:			
03/05/10	Norway: N. Øien	E84 Cat09	Individual minke catch records from the Norwegian 2009 commercial catch. Access restricted (specified 14-11-00).
31/05/10	Iceland: G. Víkingsson	E87 Cat09	Individual catch records from the Icelandic commercial catch 2009.
31/05/10	Japan: H. Okada	E88 Cat09	Individual catch records from the Japanese 2009 North Pacific special permit catch (JARPN II) and 2009/10 Antarctic special permit catch (JARPA II).
31/05/10	Russia: R.G. Borodin	E89 Cat09	Individual catch records from the aboriginal harvest in the Russian Federation in 2009.
03/06/10	St.Vincent: L. Edwards	E90 Cat10	Individual catch records from St. Vincent and The Grenadines for the 2010 humpback harvest.
Sightings data/programs:			
22/02/10	K. Sekiguchi	E86 CD92a-n	2009/10 SOWER cruise photographs and data including sightings, effort, waypoint, ice edge, weather.
00/04/10	L. Burt	CD93	DESS Version 3.63 2010.
30/05/10	Japan: K. Matsuoka	CD94	ICR blue whale photo-id pictures from JARPA 1987/88-2004/05 submitted under IWC data access Procedure B.

is available on the IWC website (*http://www.iwcoffice.org/sci_com/scprogress/htm*). The importance of using the agreed template was **emphasised** by the Committee.

3.3 Data collection, storage and manipulation

3.3.1 Catch data and other statistical material

Table 1 lists data received by the Secretariat since the 2009 meeting.

3.3.2 Progress of data coding projects and computing tasks

Allison reported that work has continued on the entry of catch data into both the IWC individual and summary catch databases, including data received from the 2008 season. Work has focused on updating data for eastern North Pacific gray whales (see Item 9.2) and data from the North Atlantic in the period 1897-1930. Version 5.0 of the catch databases will be available shortly. Entry of data into the bycatch database developed by Simon Northridge has continued with data from the 2004 and 2008 seasons being added. Data from the 2008/09 SOWER sightings cruise have been validated and incorporated into the DESS database and work on encoding and validation of data from the 2009/10 cruise has begun. Burt and Hughes began an audit of the Western North Pacific Bryde's whale survey data intersessionally and this work was completed during the course of the meeting.

Programming work during the past year is discussed later under the relevant agenda items.

4. COOPERATION WITH OTHER ORGANISATIONS

4.1 Convention on the Conservation of Migratory Species (CMS)

4.1.1 Scientific Council

There were no meetings of the Scientific Council during the intersessional period. Perrin will represent the IWC at its next meeting.

4.1.2 Conference of Parties (COP)

There were no meetings of the Conference of Parties during the intersessional period. The Secretariat will represent the IWC at the next COP.

4.1.3 Agreement on Small Cetaceans of the Baltic and North Seas (ASCOBANS)

The report of the IWC observer at the 6th Meeting of the Parties to ASCOBANS held in Bonn, Germany from 16-18 September 2009 is given as IWC/62/4D. The main topics of relevance to the IWC are summarised as follows:

(1) a new version of the Recovery Plan for Baltic Harbour Porpoises was adopted;
(2) a new Conservation Plan for the Harbour Porpoise in the North Sea was adopted; and
(3) the meeting agreed on guidelines to address the adverse affects of underwater noise on marine mammals during offshore construction activities for renewable energy production.

The 17th meeting of the Advisory Committee to ASCOBANS had been scheduled to take place from 21-23 April 2010 in Cornwall. This was postponed due to flight restrictions caused by volcanic eruptions in Iceland. It has been rescheduled for 4-6 October 2010 in Bonn, Germany.

The Committee thanked Scheidat for her report and **agrees** that she should represent the Committee as an observer at the next ASCOBANS Advisory Committee meeting and Meeting of Parties. Further information can be found at *http://www.ascobans.org*.

4.1.4 Agreement on the Conservation of Cetaceans of the Black Sea, Mediterranean Sea and Contiguous Atlantic Area (ACCOBAMS)

The ACCOBAMS Scientific Committee met in Casablanca from the 11-13 January 2010, primarily to prepare information for the forthcoming Meeting of Parties that will be held from 9-12 November 2010 in Monaco. It was attended by members of the Scientific Committee, representatives from the Sub-Regional Coordination Units, representatives from International Organisations and observers including partners of ACCOBAMS. The report of the IWC observer is given as IWC/62/4M.

Nine recommendations and a Declaration expressing the Committee's concern about the slow and/or limited level of implementation of the Agreement to effectively address the conservation problems affecting cetaceans in the Agreement area were adopted by the Committee during the meeting:

Recommendation	Topic
6.1	ACCOBAMS Survey Initiative
6.2	Programme of work on population structure
6.3	Conservation of Mediterranean common dolphins
6.4	Ship strikes
6.5	Marine Protected Areas
6.6	Anthropogenic noise
6.7	Monitoring, assessment and reducing cetacean bycatch in the Black Sea
6.8	Climate change
6.9	Minimum funding for the Scientific Committee

The next meeting of the Scientific Committee is planned for early 2011. The full report of the Scientific Committee can be found on the ACCOBAMS website *http://www.accobams.org.* The Committee thanked Donovan for his report and **agrees** that he should represent the IWC at the forthcoming Meeting of the Parties and Scientific Committee meetings.

4.1.5 Memorandum of Understanding (MoU) on the Conservation of the Manatee and Small Cetaceans of Western Africa and Macaronesia

There was no report related to the MoU on the Conservation of the Manatee and Small Cetaceans of Western Africa and Macaronesia. Perrin will represent the Committee at future activities.

4.1.6 Memorandum of Understanding (MoU) for the Conservation of Cetaceans and Their Habitats in the Pacific Islands Region (MoU for Pacific Islands Cetaceans)

The report of the IWC observer at the 2nd meeting of the MoU for Pacific Islands Cetaceans held 28-29 July 2009 in Auckland, New Zealand is given as IWC/62/4E. The meeting was attended by most of the signatories (Australia, Cook Islands, Fiji, French Polynesia, New Caledonia, New Zealand, Niue, Papua New Guinea, Samoa and the Solomon Islands). Federated States of Micronesia was unable to attend, and Tonga attended as an observer. The UK, on behalf of the Pitcairn Islands, signed the MoU at the meeting, bringing the total number of signatories to twelve.

The meeting, *inter alia*, reviewed progress in cetacean conservation in the region, endorsed a proposal to develop an Oceania Humpback Whale Recovery Plan and adopted an Action Plan for the MoU. An offer by the Whale and Dolphin Conservation Society (WDCS) to convene a Pacific Cetaceans MoU Technical Advisory Group was gratefully accepted. The meeting also noted with appreciation the continued support by WDCS for the development of the CMS Pacific MoU website: *http://www.pacificcetaceans.org.* The Committee thanked Donohue for his report and **agrees** that he should represent the Committee at the next meeting of the MoU for Pacific Islands. Further information can be found at *http://www.cms.int/species/pacific_cet/pacific_cet_bkrd.htm.*

4.2 International Council for the Exploration of the Sea (ICES)

The report of the IWC observer documenting the 2009 activities of ICES is given as IWC/62/4B. The ICES Working Group on Marine Mammal Ecology (WGMME) met in February 2009. Issues considered included management procedures for estimating bycatch limits for small cetaceans, assessing population and stock structure in small cetaceans, improvements in the procedure for reporting on favourable Conservation Status (FSC) under the EU habitats Directive, and developing a framework for monitoring and surveillance of European marine mammal populations.

A review of the ASCOBANS/HELCOM Working Group (WG) on common dolphin population structure in the Northeast Atlantic was conducted. The WGMME concurred with the recommendation that only one common dolphin population inhabits the Northeast Atlantic, although the distributional range of the population is unknown. A separate Iberian harbour porpoise population has recently been identified using genetic analysis and the WGMME strongly recommended that this population be given a high priority for conservation. The WGMME also strongly recommended immediate action by the Spanish and Portuguese governments in monitoring and conserving the Iberian harbour porpoise population.

New data from the SCANS II and CODA projects were reviewed and the WGMME concurred with the recommendation to use the *Catch Limit Algorithm* approach for estimating bycatch limits for small cetaceans.

The WG noted that the continuation and establishment of national observer bycatch programmes is extremely important in order to obtain current estimates of incidental capture for all marine mammal species. The WG also noted the need for the continuation of surveys such as SCANS II and CODA at least every 5-10 years in order to estimate absolute abundance.

Initial development of a European framework for surveillance and monitoring of marine mammals was undertaken. While it is clear that monitoring of abundance, bycatch and health status may reasonably form the core of surveillance for cetaceans, the importance of other types of information (e.g. life history data) and monitoring of specific threats (e.g. offshore construction) should also be recognised when designing a surveillance strategy. Further, monitoring programme design should take account of new findings on the target stock's structure.

The 2009 ICES Annual Science Conference (ASC) was held in Berlin, Germany, 21-25 September 2009. Some sessions were designed with marine mammals included as an integral part. A number of sessions were of relevance to the Committee, including those describing:

(1) advances in marine ecosystem research;
(2) comparative study of climate impact on coastal and continental shelf ecosystems in the ICES area;
(3) habitat science to support stock assessment;
(4) avoidance of bycatch and discards; and
(5) ecological foodweb and network analysis.

The Committee thanked Haug for the report and **agrees** that he should represent the Committee as an observer at the next ICES meeting.

4.3 Inter-American Tropical Tuna Commission (IATTC)

No observer for the IWC attended the 2009 meeting of IATTC.

4.4 International Commission for the Conservation of Atlantic Tunas (ICCAT)

The report of the IWC observer to the 21st meeting of ICCAT is given as IWC/62/4J. The critical status of some stocks was highlighted, including the bluefin tuna, and measures adopted to allow the rebuilding of stocks as well as measures to improve the management frameworks and status for swordfish and albacore. The Committee thanked Corrêa for attaneding the meeting on its behalf.

4.5 Convention for the Conservation of Antarctic Marine Living Resources (CCAMLR)

The report of the IWC observer at the 28th Meeting of the CCAMLR Scientific Committee (CCAMLR-SC), held in Hobart, Australia from 23-27 October 2009 is given as IWC/61/4A. The main items considered at the CCAMLR meeting of relevance to the IWC included: (1) fishery status and trends of Antarctic fish stocks, krill, squid and stone crabs; (2) incidental mortality of seabirds and marine mammals in fisheries in the CCAMLR Convention Area; (3) harvested species (krill, fish, and stone crabs and their assessment); (4) ecosystem monitoring and management; (5) management under conditions of uncertainty about stock size and sustainable yield; (6) scientific research exemption; (7) CCAMLR Scheme of International Scientific Observation; (8) new and exploratory fisheries; (9) joint CCAMLR-IWC workshop with respect to ecosystem modelling in the Southern Ocean; and (10) the CCAMLR performance review.

Marine Protected Areas were discussed in detail. The area of the southern South Orkney shelf and the Seasonal Pack-ice Zone and part of the Fast Ice Zone south of the Shelf was the first MPA designated by CCAMLR. The following milestones were previously agreed: (1) by 2010, collate relevant data for as many of the 11 priority regions as possible; (2) by 2010, submit proposals on a representative system of MPAs to the CCAMLR Commission; (3) by early 2011, convene a workshop to review progress, share experience and determine a work programme for the identification of MPAs; and (4) by 2011, submit proposals for areas for protection to the CCAMLR-SC.

Two reports of cetacean-fisheries interactions in the Southern Ocean were received by CCAMLR in 2009: (1) a killer whale hooked on a line was dead when brought to the surface; and (2) a sperm whale hauled up dead after being caught in discarded fishing gear on the seabed.

The Committee thanked Kock for attending on its behalf and **agrees** that he should represent the Committee as an observer at the next CCAMLR-SC meeting.

4.6 Southern Ocean GLOBEC (SO-GLOBEC)

The synthesis and analysis process under SO-GLOBEC has continued and has produced a number of papers relating cetacean distribution to prey and other environmental variables. There is no active work with respect to SO-GLOBEC at this time.

4.7 North Atlantic Marine Mammal Commission (NAMMCO)

Scientific Committee

The report of the IWC observer at the 16th meeting of the NAMMCO Scientific Committee held in Reykjavik, Iceland 19-22 April 2009 is given as IWC/62/4L.

The Working Group on Marine Mammals-Fisheries (MMFI WG) considered: (1) new developments in the quantitative description of marine mammal diet by species; (2) new developments in the estimation of energy consumption; and (3) recent developments in multi-species modelling. In light of the report of the WG, the NAMMCO SC agreed that multi-species modelling is a valid approach for understanding ecological relations between species. However, it was noted that ecosystem models have significant data requirements, many of which are currently unavailable. In order to improve the understanding of such modelling, an exercise is planned in which four different modelling approaches are used to describe the same ecosystem.

A successful survey of narwhals was conducted in East Greenland during August 2008. The abundance estimates developed from this are the first for the Scoresby Sound fjord system south to Ammassalik. The abundance estimate for narwhals in Melville Bay, developed from the 2007 survey is the first estimate from this locality. The NAMMCO SC recommended catches be set so that there is at least a 70% probability that management objectives be met for West and East Greenland narwhals, i.e. maximum total removals of 310 and 85 narwhals in West and East Greenland respectively.

At the last NAMMCO SC meeting it was recognised that the preliminary data on abundance of narwhals and white whales show higher estimates and encouraged Greenland to submit fully corrected estimates. These were submitted to and endorsed by the NAMMCO/JCNB Joint Working Group in February 2009.

The Committee thanked Walløe for attending on its behalf and **agrees** that he should represent the Committee as an observer at the next NAMMCO SC meeting.

Council

The report of the IWC observer at the 17th Annual Meeting of NAMMCO held in Tromso, Norway in September 2009 is given as IWC/61/4F. The whaling and sealing nations in the North Atlantic confirmed their commitment to ensuring the sustainable utilisation of marine mammals through science-bases management decisions, stressing the vital importance marine mammals have as renewable resources for economies and cultures across the region.

Key conclusions from the meeting relevant to IWC included:

(1) welcoming Greenland's multi-annual catch quotas for white whales and narwhal stocks;
(2) a recommendation from the NAMMCO SC that a quota of 10 humpback whales in West Greenland, including struck and lost animals, would be sustainable;
(3) initiation of an ecosystem modelling programme; and
(4) agreement to convene an expert working group to undertake a review and evaluate the whale killing data submitted to NAMMCO by Japan and to look at data and information on recent and ongoing research on improvements and technical innovations in hunting methods and gears used for the hunting of large whales in NAMMCO countries.

The Committee thanked Goodman for attending on its behalf and **agrees** that he should represent the Committee as an observer at the next NAMMCO Council meeting. Further information on NAMMCO can be found at *http://www.nammco.no.*

4.8 International Union for the Conservation of Nature (IUCN)

Cooke and Larsen, the IWC observers, reported on the considerable cooperation with IUCN that had occurred during the past year and this is given as IWC/62/4K.

Western gray whales (see also Item 10.4)

The IUCN Western Gray Whale Advisory Panel has continued its work (*http://www.iucn.org/wgwap*). The Panel had earlier advised that a seismic survey commissioned by Sakhalin Energy and scheduled for 2009 in the Astokh area be postponed, in view of the anomalous (and possibly disturbance-related) distribution of gray whales off Sakhalin in 2008. Given the apparent return to normal gray whale distribution in the area in 2009, the Panel agreed that carrying out of the survey in 2010 was acceptable, particularly in the light of the jointly developed, improved monitoring and mitigation measures and completion of the survey early in the season before large numbers of whales arrive in the Piltun feeding area.

The Panel was extremely concerned to learn that a further seismic survey is planned for July-September 2010 by the company Rosneft Shelf - Far East, to cover the Lebedenskoie field which underlies the northern part of the prime near-shore feeding ground of western gray whales The IUCN Director General has written to Prime Minister Putin urging the Russian government to order the postponement of the survey at least until 2011 to enable satisfactory mitigation measures to be put in place to minimise the disturbance to whales[1]. A draft Western Gray Whale Conservation Plan has been developed with the help of the IUCN Marine Programme as part of its Range-Wide Conservation Initiative for western Gray Whales (SC/62/BRG24).

Red List updates
Following the comprehensive updating of the Red List entries for cetaceans in 2008, the Cetacean Specialist Group has completed separate assessments of the two species of *Sotalia*, the freshwater tucuxi and the coastal marine and estuarine Guiana dolphin. Draft assessments of a number of Mediterranean subpopulations (fin whale, sperm whale, long-finned pilot whale, Risso's dolphin, striped dolphin, common bottlenose dolphin and Cuvier's beaked whale) are in review.

Asian freshwater cetaceans (see also Item 14.3)
The Cetacean Specialist Group has undertaken several initiatives in Asia over the past year. These have included, most notably a workshop in Samarinda, East Kalimantan, Indonesia in October 2009 on freshwater protected areas for dolphins; a special meeting in Phnom Penh, Cambodia in November 2009 on the conservation of Irrawaddy dolphins in the Mekong River; and a meeting in Patna, India in February 2010 to assist in the development of a national action plan for the conservation of Ganges river dolphins (*Susus*).

The Committee thanked Cooke and Larsen for their report and **agrees** that they should continue to act as observers to IUCN for the IWC. Further information on IUCN can be found at *http://www.iucn.org.*

4.9 Food and Agriculture Organisation (FAO) related meetings – Committee on Fisheries (COFI)
There was no meeting of COFI in 2010. Further information on FAO can be found at *http://www.fao.org*.

4.10 Convention on International Trade in Endangered Species of Wild Flora and Fauna (CITES)
The report of the IWC observer at the 15th meeting of the CITES Conference of the Parties held 13-25 March 2010 in, Doha, Qatar is given as IWC/62/4H. There were no proposals for changing the listing of whale stocks from Appendix I to Appendix II (downlisting). There were also no proposals for changing the listing of a dolphin or whale species from Appendix II to Appendix I (uplisting).

The CITES Secretariat reviewed all of the Decisions that were in effect after the 14th meeting of the Conference of the Parties, including a recommendation to delete Decision 14.81 relating to great whales. Decision 14.81 states that 'No periodic review of any great whale, including the fin whale, should occur while the moratorium by the International Whaling Commission is in place'. The CITES Secretariat recommendation also noted that if the substance of this Decision should remain in effect, it should be considered in the context of the draft resolution on the periodic review of the Appendices.

A number of Parties opposed its deletion on the basis that the draft resolution on the periodic review had not been accepted. After a vote, the recommendation to delete the Decision was rejected.

The Committee thanked the US Government for attending on its behalf and **agrees** that it should represent the Committee as an observer at the next CITES meeting. Information on CITES can be found at *http://www.cites.org.*

4.11 North Pacific Marine Science Organisation (PICES)
The report of the IWC observer at the 18th annual meeting of PICES held 23 October-1 November 2009 in Jeju, Republic of Korea is given as IWC/62/4G. The Marine Birds and Mammals Advisory Group (AP-MBM), cosponsored by ICES held a theme session on 'integrating marine mammal populations and rates of prey consumption in models and forecasts of climate change-ecosystem change in the North Pacific and North Atlantic Oceans'. A diverse range of topics were covered, including population trends, diet, estimates of prey consumption and models of trophic impact. AP-MBM reviewed aspects of the new PICES science programme (FUTURE), specifically: (1) understanding climate change and anthropogenic impacts on marine ecosystems; (2) forecasting future ecosystem change; and (3) better communication with society. The AP reiterated its primary mission to provide advice to the PICES community about the role of marine birds and mammals in marine ecosystems. Based on its role in FUTURE the AP-MBM defined its focal points as: (1) spatial ecology of predators in marine ecosystems; (2) models of prey consumption of top predators; (3) marine birds and mammals as indicators of ecosystem change; (4) marine mammals as autonomous oceanographic sampling devices; and (5) providing advice to the PICES community.

The Committee thanked Kato for attending on its behalf and **agrees** that he should represent the Committee as an observer at the next PICES meeting. Further information on PICES can be found at *http://www.pices.int*.

4.12 Eastern Caribbean Cetacean Commission (ECCO)
No information on the activities of ECCO was provided.

4.13 Protocol on Specially Protected Areas and Wildlife (SPAW) of the Cartagena Convention for the Wider Caribbean
There were no meetings of SPAW during the intersessional period. Carlson will represent the IWC at its next meeting. Further information on SPAW can be found at *http://www.cep.unep.org/cartagena-convention*.

4.14 Indian Ocean Commission (IOC)
No information on the activities of IOC was provided. Further information on the IOC can be found at *http://www.coi-ioc.org*.

4.15 Permanent Commission for the South Pacific (CPPS)
No information on the activities of CPPS was provided. Further information on CPPS can be found at *http://www.cpps-int.org*.

4.16 International Maritime Organisation (IMO)
The report of the IWC observer at the General Assembly of the IMO held 23 November-4 December 2009 is given as IWC/62/4I. The proposed Agreement of Cooperation between IMO and IWC was approved, which means that the IWC now has definitive IMO observer status. While the impetus for closer co-operation between IMO and IWC was in relation to ship strikes on cetaceans, there are a number of other issues of potential mutual relevance including habitat degradation and noise from shipping. Discussions on

---

[1] See *http://www.iucn.org/wgwap/wgwap/public_statements/* for the text of this and other letters.

collisions with whales and underwater noise from shipping took place within the Marine Environment Protection Committee (MEPC) at its 59th session held in July 2009 and 60th session held in March 2010.

The MEPC has had 'noise from commercial shipping and its adverse impact on marine life' on its work programme since 2008. A correspondence group was established to identify and address ways to minimise the introduction of incidental noise into the marine environment from commercial shipping to reduce the potential adverse impact on marine life and in particular develop voluntary technical guidelines for ship-quieting technologies as well as potential navigation and operational practices. The IWC Secretariat is a member of this group.

The Committee thanked the IWC Secretariat for its report and **agrees** that it should represent the Committee at the next IMO meeting. Further information on IMO can be found at *http://www.imo.org.*

4.17 Other

An update was received on conservation in the Southeast Pacific under the framework of the Lima Convention and is given as IWC/62/4C. In January 2010 the 16th Meeting to the Parties to the Lima Convention was held in Guayaquil, Ecuador. The five member countries (Chile, Colombia, Ecuador, Panama and Chile) reviewed the activities regarding implementation of a Plan of Action for the Conservation of Marine Mammals in the Southeast Pacific (PAMM). The PAMM was formed to help countries to improve their policies on marine mammals' conservation and to develop activities that require regional cooperation.

In 2009 five pilot projects to mitigate the impacts of fishing activities were conducted: (1) implementation of actions for the conservation of the Chilean dolphin in the zone of Constitucion; (2) study to mitigate impact of the incidental entanglement of coastal cetaceans in the Columbia Pacific; (3) preliminary assessment of the interaction of cetaceans with artisanal fisheries in the Machalilla National Park, Ecuador; (4) reduction of the impact of gillnets on cetaceans in coastal waters within the Gulf of Chiriqui; and (5) study to test the use of pingers to reduce the incidental bycatch of small cetaceans in Peru.

As a result of these projects, a document entitled 'Efforts to mitigate the impact of fishing activities on cetaceans in the Southeast Pacific countries' will be published.

The first phase of a biodiversity and MCPA information system (SIBIMAP-PSE) was finalised. This is an online tool for searching and downloading information crucial for management and conservation of cetaceans, sea turtles and MCPA in the Southeast Pacific. The module on cetaceans is now complete.

A workshop on legal aspects of whalewatching was planned for March 2010, but was postponed until late 2010 due to an earthquake in Chile.

The Committee thanked Felix for his report and **agrees** that he should represent the Committee at future activities related to cetacean conservation in the Southeast Pacific under the framework of the Lima Convention.

5. REVISED MANAGEMENT PROCEDURE (RMP) – GENERAL ISSUES

5.1 Review MSY rates

5.1.1 Report of the intersessional workshop

The Committee has been discussing maximum sustainable yield rates (MSYR) for some time in the context of a general reconsideration of the plausible range to be used in population models used for testing the *Catch Limit Algorithm* (*CLA*) of the RMP (and see Item 5.1.2 below). At present, this range is 1% to 7% when expressed in terms of the mature component of the population. As part of the review process, information on observed population growth rates at low population sizes is being considered because Cooke (2007) noted that in circumstances where variability and/or temporal autocorrelation in the effects of environmental variability on population growth rates is high, simple use of such observed population growth rates could lead to incorrect inferences being drawn concerning the lower end of the range of plausible values for MSYR.

A Third Workshop was held intersessionally to examine whether the observed levels of variation in baleen whale reproduction and annual survival rate parameters were sufficiently large that biases of the nature identified from population models incorporating environmentally-induced variability might be of concern (SC/62/Rep2; Annex D, item 2.1.1).

At the Workshop, an analytical approach was developed and followed to estimate the coefficient of variation (CV) and temporal autocorrelation for the selected time series of calving proportion indices and calving interval data. This information, modified appropriately, provides input for a method developed to relate variability in calving proportion to variability in the annual growth rate of a population using a population dynamics model (see SC/62/Rep2). The model can take into account environmentally-induced variability in population abundance arising from variation in annual survival rate.

The Workshop identified two further steps needed before results from this model can be used to draw inferences about the plausible ranges for the CV and temporal autocorrelation parameters describing the effects of environmental variability on population dynamics in the model of Cooke (2007). The Committee incorporated these into its work plan under this item (see Annex D, item 2.1.2).

The Workshop received a revised approach for a meta-analysis of population growth rates previously discussed (IWC, 2010b) and suggested some additional work to be completed before the 2010 Annual Meeting. Item 5.1.2 and Annex D, item 2.1.1 describe progress made on three other issues listed in the work plan for completion of the MSYR review at last year's meeting.

5.1.2 Issues arising

The Committee received SC/62/RMP3 in response to the Workshop recommendations to: (1) apply the age-structured model of SC/62/Rep2, Annex D to all of the datasets assembled during the Workshop to estimate the resultant CV and temporal auto-correlation in growth rate; and (2) to conduct further tests of the Bayesian meta-analysis approach. More details are given in Annex D, item 2.1.2.

The Committee **agrees** that this Bayesian approach was an acceptable basis to compute a posterior distribution for r_0, once the inputs needed to apply it become available. It also **agrees** that account will need to be taken that the estimates of lower posterior percentiles from this method are positively biased, before making recommendations regarding appropriate values for MSYR for use in trials.

SC/62/RMP2 and SC/62/RMP4 responded to recommendations to use the environmental variability model of Cooke (2007) to provide CVs and temporal autocorrelation estimates for the growth of the population from one year to the next for the standard set of scenarios and to use this model to determine the predicted relationship between the length of series and the estimated level of variability in the population rate of increase. More details are given in Annex D, item 2.1.2. The Committee **agrees** that it now has a basis to link variability in demographic processes with the inputs of the Cooke (2007) model.

Efforts to fit models that account for both process and observation error to the data on calving rates and calving intervals had encountered numerical problems intersessionally The Committee **endorses** a work plan to address this (Annex D, Appendix 2) and looks forward to seeing the results of this work next year.

The Committee discussed how to relate variation in net recruitment rate, which depends on variation in both survival and reproduction, to variation in reproductive rates alone. Details are given in Annex D, item 2.1.2. The Committee considered the question of correlations between survival and reproductive rates to be potentially important for the question of estimating typical levels of variation in net recruitment rate for baleen whales, but **agrees** that more analysis is required before any general inference can be drawn. It **requests** in particular:

(1) a literature review with regard to the question of the circumstances under which correlations between survival and reproductive rates would be negative or positive;
(2) more extensive modelling to cover the full range of parameter values deemed to be plausible for baleen whales in order to determine whether general inferences can be drawn, or at least to identify the circumstances where substantial correlations of a specific sign would be expected;
(3) direct estimation of variability in survival rates to the extent that this is possible.

The Committee **agrees** that if results from this work are available at its next meeting, then they should be taken into account in its deliberations with respect to the level of variability in baleen whale demography. However, that lack of results will not preclude the Committee from completing its review of MSY rates next year.

The Committee considered the extent to which genetic data could place bounds on fluctuations in population size for some examples of trajectories arising for the environmental variation model of Cooke (2007). It recognised the potential of genetic methods to inform its deliberations on the plausible range of MSYR values, but **agrees** that these methods could not be used during the current review. However, it **recommends** that the number of haplotypes in whale populations, along with other population and demographic measures should be assembled since this might inform the current review. The Committee **encourages** completion of a compilation already initiated by Brownell.
